3. The argument does not apply to free fermions which have not suffered topological condensation and are therefore represented by  $CP_2$  type vacuum extremal with single wormhole throat. If one accepts the weak form of electric-magnetic duality, one can circumvent this difficulty. The free fermions carry Kähler magnetic charge whereas physical fermions are accompanied by a bosonic wormhole throat carrying opposite Kähler magnetic charge and opposite electroweak isospin so that a ground state of string like object with size of order electroweak length scale is in question. In the case of quarks the Kähler magnetic charges need not be opposite since color confinement could involve Kähler magnetic confinement: electro-weak confinement holds however true also now. The above argument generalizes as such to the pairs formed by wormhole throats at the ends of string like object. One can of course imagine also more complex hybrids of these basic options but the general idea remains the same.

Note that the argument involves in an essential manner non-locality, which is indeed the defining property of the Yangian algebra and also the fact that physical particles are bound states. The massivation of the physical particles brings in the IR cutoff.

### 7.4.3 Number theoretical constraints on the pseudo-momenta

One can consider also further assumptions motivated by the recent view about the generalized eigenvalues of Chern-Simons Dirac operator having interpretation as pseudo-momentum. The details of this view need not of course be final.

1. Assume that the pseudo-momentum assigned to fermion lines by the modified Dirac equation [28] is the counterpart of region momentum as already explained and therefore does not directly correspond to the actual light-like four-momentum associated with partonic line of the generalized Feynman diagram. This assumption conforms with the assumption that incoming particles are built out of massless partonic fermions. It also implies that the propagators are massless propagators as required by twistorialization and Yangian generalization of super-conformal invariance.
2. Since (pseudo)-mass squared is number theoretically quantized as the length of a hyper-complex prime in preferred plane  $M^2$  of pseudo-momentum space fermionic propagators are massless propagators with pseudo-masses restricted on discrete mass shells. Lorentz invariance suggests that  $M^2$  cannot be common to all particles but corresponds to preferred reference frame for the virtual particle having interpretation as plane spanned by the quantization axes of energy and spin.
3. Hyper-complex primeness means also the quantization of pseudo-momentum components so that one has hyper-complex primes of form  $\pm((p+1)/2, \pm(p-1)/1)$  corresponding to pseudo-mass squared  $M^2 = p$  and hypercomplex primes  $\pm(p, 0)$  with pseudo-mass squared  $M^2 = p^2$ . Space-like fermionic momenta are not needed since for opposite signs of energy wormhole throats can have space-like net momenta. If space-like pseudo-momenta are allowed/needed for some reason, they could correspond to space-like hyper-complex primes  $\pm((p-1)/2, \pm(p+1)/1)$  and  $\pm(0, p)$  so that one would obtain also discretization of space-like mass shells also. The number theoretical mass squared is proportional to  $p$ , whereas p-adic mass squared is proportional to  $1/p$ . For p-adic mass calculations canonical identification  $\sum x_n p^n$  maps p-adic mass squared to its real counterpart. The simplest mapping consistent with this would be  $(p_0, p_1) \rightarrow (p_0, p_1)/p$ . This could be assumed from the beginning in real context and would mean that the mass squared scale is proportional to  $1/p$ .
4. Lorentz invariance requires that the preferred coordinate system in which this holds must be analogous to the rest system of the virtual fermion and thus depends on the virtual particle. In accordance with the general vision discussed in [28] Lorentz invariance could correspond to a discrete algebraic subgroup of Lorentz group spanned by transformation matrices expressible in terms of roots of unity. This would give a discrete version of mass shell and the preferred coordinate system would have a precise meaning also in the real context. Unless one allows algebraic extension of p-adic numbers p-adic mass shell reduces to the set of above number-theoretic momenta. For algebraic extensions of p-adic numbers the same algebraic mass shell is obtained as in real correspondence and is essential for the number theoretic universality. The interpretation for the algebraic discretization would be in terms of a finite measurement resolution. In real context this would mean discretization inducing a decomposition of the mass shell to cells. In the p-adic context each discrete point would be replaced with a p-adic continuum. As far as loop integrals are considered, this vision means that they make sense in both real and p-adic context and reduce to summations in p-adic context. This picture is discussed in detail in [28].
5. Concerning p-adicization the beautiful aspect of residue integral is that it makes sense also in p-adic context provided one can circumvent the problems related to the identification of p-adic counterpart of  $\pi$  requiring infinite-dimensional transcendental extension coming in powers of  $\pi$ . Together with the discretization of both real and virtual four-momenta this would allow to define also p-adic variants of the scattering amplitudes.

#### 7.4.4 Could recursion formula allow interpretation in terms of zero energy ontology?

The identification of pseudo-momentum as a counterpart of region momentum suggests that generalized Feynman diagrams could be seen as a generalization of momentum twistor diagrams. Of course, the generalization from  $\mathcal{N} = 4$  SYM to TGD is an enormous step in complexity and one must take all proposals in the following with a big grain of salt. For instance, the replacement of point-like particles with wormhole throats and the decomposition of gauge bosons to pairs of wormhole throats means that naive generalizations are dangerous.

With this in firmly in mind one can ask whether the recursion formula could allow interpretation in terms of zero energy states assigned to causal diamonds (*CDs*) containing *CDs* containing  $\dots$ . In this framework loops could be assigned with sub-*CDs*.

The interpretation of the leading order singularities forming the basic building blocks of the twistor approach in zero ontology is the basic source of questions. Before posing these questions recall the basic proposal that partonic fermions are massless but opposite signs of energy are possible for the opposite throats of wormhole contacts. Partons would be on mass shell but besides physical states identified as bound states formed from partons also more general intermediate states would be possible but restricted by momentum conservation and mass shell conditions for partons at vertices. Consider now the questions.

1. Suppose that the massivation of virtual fermions and their super partners allows only ladder diagrams in which the intermediate states contain on mass shell massless states. Should one allow this kind of ladder diagrams? Can one identify them in terms of leading order singularities? Could one construct the generalized Feynman diagrams from Yangian invariant tree diagrams associated with the hierarchy of sub-*CDs* and using BCFW bridges and entangled pairs of massless states having interpretation as box diagrams with on mass shell momenta at microscopic level? Could it make sense to say that scattering amplitudes are represented by tree diagrams inside *CDs* in various scales and that the fermionic momenta associated with throats and emerging from sub-*CDs* are always massless?
2. Could BCFW bridge generalizes as such and could the interpretation of BCFW bridge be in terms of a scattering in which the four on mass shell massless partonic states (partonic throats have arbitrary fermion number) are exchanged between four sub-*CDs*. This admittedly looks somewhat artificial.
3. Could the addition of 2-particle zero energy state responsible for addition of loop in the recursion relations and having interpretation in terms of the cutting of line carrying loop momentum correspond to an addition of sub-*CD* such that the 2-particle zero energy state has its positive and negative energy part on its past and future boundaries? Could this mean that one cuts a propagator line by adding *CD* and leaves only the portion of the line within *CD*. Could the reverse operation mean to the addition of zero energy "thermally entangled" states in shorter time and length scales and assignable as a zero energy state to a sub-*CD*. Could one interpret the Cutkosky rule for propagator line in terms of this cutting or its reversal. Why only pairs would be needed in the recursion formula? Why not more general states? Does the recursion formula imply that they are included? Does this relate to the fact that these zero energy states have interpretation as single particle states in the positive energy ontology and that the basic building block of Feynman diagrams is single particle state? Could one regard the unitarity as an identity which states that the discontinuity of T-matrix characterizing zero energy state over cut is expressible in terms of  $TT^\dagger$  and  $T$  matrix is the relevant quantity?

Maybe it is again dangerous to try to draw too detailed correspondences: after all, point like particles are replaced by partonic two-surfaces in TGD framework.

4. If I have understood correctly the genuine  $l$ -loop term results from  $l - 1$ -loop term by the addition of the zero energy pair and integration over  $GL(2)$  as a representative of loop integral reducing  $n + 2$  to  $n$  and calculating the added loop at the same time [33]. The integrations over the two momentum twistor variables associated with a line in twistor space defining off mass shell four-momentum and integration over the lines represent the integration over loop momentum. The reduction to  $GL(2)$  integration should result from the delta functions relating the additional momenta to  $GL(2)$  variables (note that  $GL(2)$  performs linear transformations in the space spanned by the twistors  $Z_A$  and  $Z_B$  and means integral over the positions of  $Z_A$  and  $Z_B$ ). The resulting object is formally Yangian invariant but IR divergences along some contours of integration breaks Yangian symmetry.

The question is what happens in TGD framework. The previous arguments suggests that the reduction of the the loop momentum integral to integrals over discrete mass shells and possibly to a sum over their discrete subsets does not spoil the reduction to contour integrals for loop integrals in the example considered in [33]. Furthermore, the replacement of mass continuum

with a discrete set of mass shells should eliminate IR divergences and might allow to preserve Yangian symmetry. One can however wonder whether the loop corrections with on mass shell massless fermions are needed. If so, one would have at most finite number of loop diagrams with on mass shell fermionic momenta and one of the TGD inspired dreams already forgotten would be realized.

### 7.4.5 What about unitarity?

The approach of Arkani-Hamed and collaborators means that loop integral over four-momenta are replaced with residue integrals around a small sphere  $p^2 = \epsilon$ . This is very much reminiscent of my own proposal for a few years ago based on the idea that the condition of twistorialization forces to accept only massless virtual states [82, 56]. I of course soon gave up this proposal as too childish.

This idea seems to however make a comeback in a modified form. At this time one would have only massive and quantized pseudo-momenta located at discrete mass shells. Can this picture be consistent with unitarity?

Before trying to answer this question one must make clear what one could assume in TGD framework.

1. Physical particles are in the general case massive and consist of collinear fermions at wormhole throats. External partons at wormhole throats must be massless to allow twistorial interpretation. Therefore massive states emerge. This applies also to stringy states.
2. The simplest assumption generalizing the childish idea is that on mass shell massless states for partons appear as both virtual particles and external particles. Space-like virtual momentum exchanges are possible if the virtual particles can consist of pairs of positive and negative energy fermions at opposite wormhole throats. Hence also partons at internal lines should be massless and this raises the question about the identification of propagators.
3. Generalized eigenvalue equation for Chern-Simons Dirac operator implies that virtual elementary fermions have massive and quantized pseudo-momenta whereas external elementary fermions are massless. The massive pseudo-momentum assigned with the Dirac propagator of a parton line cannot be identified with the massless real momentum assigned with the fermionic propagator line. The region momenta introduced in Grassmannian approach are something analogous.

As already explained, this brings in mind is the identification of this pseudo momentum as the counterpart of the region momentum of momentum twistor diagrams so that the external massless fermionic momenta would be differences of the pseudo-momenta. Indeed, since region momenta are determined apart from a common shift, they need not correspond to real momenta. Same applies to pseudo-momenta and one could assume that both internal and external fermion lines carry light-like pseudo-momenta and that external pseudo-momenta are equal to real momenta.

4. This picture has natural correspondence with twistor diagrams. For instance, the region momentum appearing in BCFW bridge defining effective propagator is in general massive although the underlying Feynman diagram would contain on-line massless momenta. In TGD framework massless lines of Feynman graphs associated with singularities would correspond to real momenta of massless fermions at wormhole throats. Also other canonical operations for Yangian invariants involve light-like momenta at the level of Feynman diagrams and would in TGD framework have a natural identification in terms of partonic momenta. Hence partonic picture would provide a microscopic description for the lines of twistor diagrams.

Let us assume being virtual particle means only that the discretized pseudo-momentum is on shell but massive whereas all real momenta of partons are light-like, and that negative partonic energies are possible. Can one formulate Cutkosky rules for unitarity in this framework? What could the unitarity condition

$$iDisc(T - T^\dagger) = -TT^\dagger$$

mean now? In particular, are the cuts associated with mass shells of physical particles or with mass shells of pseudo-momenta? Could these two assignments be equivalent?

1. The restriction of the partons to be massless but having both signs of energy means that the spectrum of intermediate states contains more states than the external states identified as bound states of partons with the same sign of energy. Therefore the summation over intermediate states does not reduce to a mere summation over physical states but involves a summation over states formed from massless partons with both signs of energy so that also space-like momentum exchanges become possible.
2. The understanding of the unitarity conditions in terms of Cutkosky rules would require that the cuts of the loop integrands correspond to mass shells for the virtual states which are also physical states. Therefore real momenta have a definite sign and should be massless. Besides this bound state conditions guaranteeing that the mass spectrum for physical states is discrete must be assumed. With these assumptions the unitary cuts would not be assigned with the partonic light-cones but with the mass shells associated of physical particles.
3. There is however a problem. The pseudo-momenta of partons associated with the external partons are assumed to be light-like and equal to the physical momenta.
  - (a) If this holds true also for the intermediate physical states appearing in the unitarity conditions, the pseudo-momenta at the cuts are light-like and cuts must be assigned with pseudo-momentum light-cones. This could bring in IR singularities and spoil Yangian symmetry. The formation of bound states could eliminate them and the size scale of the largest  $CD$  involved would bring in a natural IR cutoff as the mass scale of the lightest particle. This assumption would however force to give up the assumption that only massive pseudo-momenta appear at the lines of the generalized Feynman diagrams.
  - (b) On the other hand, if pseudo-momenta are not regarded as a property of physical state and are thus allowed to be massive for the real intermediate states in Cutkosky rules, the cuts at parton level correspond to on mass shell hyperboloids and IR divergences are absent.

## 7.5 Could TGD allow formulation in terms of twistors

There are many questions to be asked. There would be in-numerable questions upwelling from my very incomplete understanding of the technical issues. In the following I restrict only to the questions which relate to the relationship of TGD approach to Witten's twistor string approach [70] and M-theory like frameworks. The arguments lead to an explicit proposal how the preferred extremals of Kähler action could correspond to holomorphic 4-surfaces in  $CP_3 \times CP_3$ . The basic motivation for this proposal comes from the observation that Kähler action is Maxwell action for the induced Kähler form and metric. Hence Penrose's original twistorial representation for the solutions of linear Maxwell's equations could have a generalization to TGD framework.

### 7.5.1 $M^4 \times CP_2$ from twistor approach

The first question which comes to mind relates to the origin of the Grassmannians. Do they have some deeper interpretation in TGD context. In twistor string theory Grassmannians relate to the moduli spaces of holomorphic surfaces defined by string world sheets in twistor space. Could partonic 2-surfaces have analogous interpretation and could one assign Grassmannians to their moduli spaces? If so, one could have rather direct connection with topological QFT defining twistor strings [70] and the almost topological QFT defining TGD. There are some hints to this direction which could be of course seen as figments of a too wild imagination.

1. The geometry of  $CD$  brings strongly in mind Penrose diagram for the conformally compactified Minkowski space [25], which indeed becomes  $CD$  when its points are replaced with spheres. This would suggest the information theoretic idea about interaction between observer and externals as a map in which  $M^4$  is mapped to its conformal compactification represented by  $CD$ . Compactification means that the light-like points at the light-like boundaries of  $CD$  are identified and the physical counterpart for this in TGD framework is conformal invariance along light-rays along the boundaries of  $CD$ . The world of conscious observer for which  $CD$  is identified as a geometric correlate would be conformally compactified  $M^4$  (plus  $CP_2$  or course).

2. Since the points of the conformally compactified  $M^4$  correspond to twistor pairs [56], which are unique only apart from opposite complex scalings, it would be natural to assign twistor space to  $CD$  and represent its points as pairs of twistors. This suggests an interpretation for the basic formulas of Grassmannian approach involving integration over twistors. The incoming and outgoing massless particles could be assigned at point-like limit light-like points at the lower and upper boundaries of  $CD$  and the lifting of the points of the light-cone boundary at partonic surfaces would give rise to the description in terms of ordinary twistors. The assumption that massless collinear fermions at partonic 2-surfaces are the basic building blocks of physical particles at partonic 2-surfaces defined as many particles states involving several partonic 2-surfaces would lead naturally to momentum twistor description in which massless momenta and described by twistors and virtual momenta in terms of twistor pairs. It is important to notice that in TGD framework string like objects would emerge from these massless fermions.
3. Partonic 2-surfaces are located at the upper and lower light-like boundaries of the causal diamond ( $CD$ ) and carry energies of opposite sign in zero energy ontology. Quite generally, one can assign to the point of the conformally compactified Minkowski space a twistor pair using the standard description. The pair of twistors is determined apart from  $Gl(2)$  rotation. At the light-cone boundary  $M^4$  points are light-like so that the two spinors of the two twistors differ from each other only by a complex scaling and single twistor is enough to characterize the space-time point this degenerate situation. The components of the twistor are related by the well known twistor equation  $\mu^{a'} = -ix^{aa'}\lambda_a$ . One can therefore lift each point of the partonic 2-surface to single twistor determined apart from opposite complex scalings of  $\mu$  and  $\lambda$  so that the lift of the point would be 2-sphere. In the general case one must lift the point of  $CD$  to a twistor pair. The degeneracy of the points is given by  $Gl(2)$  and each point corresponds to a 2-sphere in projective twistor space.
4. The new observation is that one can understand also  $CP_2$  factor in twistor framework. The basic observation about which I learned in [56] (giving also a nice description of basics of twistor geometry) is that a pair  $(X, Y)$  of twistors defines a point of  $CD$  on one hand and complex 2-planes of the dual twistor space -which is nothing but  $CP_2$ - by the equations

$$X_\alpha W^\alpha = 0 \quad , \quad Y_\alpha W^\alpha = 0 \quad .$$

The intersection of these planes is the complex line  $CP_1 = S^2$ . The action of  $G(2)$  on the twistor pair affects the pair of surfaces  $CP_2$  determined by these equations since it transforms the equations to their linear combination but not the the point of conformal  $CD$  resulting as projection of the sphere. Therefore twistor pair defines both a point of  $M^4$  and assigns with it pair of  $CP_2$ :s represented as holomorphic surfaces of the projective dual twistor space. Hence the union over twistor pairs defines  $M^4 \times CP_2$  via this assignment if it is possible to choose "the other"  $CP_2$  in a unique manner for all points of  $M^4$ . The situation is similar to the assignment of a twistor to a point in the Grassmannian diagrams forming closed polygons with light-like edges. In this case one assigns to the the "region momenta" associated with the edge the twistor at the either end of the edge. One possible interpretation is that the two  $CP_2$ :s correspond to the opposite ends of the  $CD$ . My humble hunch is that this observation might be something very deep.

Recall that the assignment of  $CP_2$  to  $M^4$  point works also in another direction.  $M^8 - H$  duality associates with so called hyper-quaternionic 4-surface of  $M^8$  allowing preferred hyper-complex plane at each point 4-surfaces of  $M^4 \times CP_2$ . The basic observation behind this duality is that the hyper-quaternionic planes (copies of  $M^4$ ) with preferred choices of hyper-complex plane  $M^2$  are parameterized by points of  $CP_2$ . One can therefore assign to a point of  $CP_2$  a copy of  $M^4$ . Maybe these both assignments indeed belong to the core of quantum TGD. There is also an interesting analogy with Uncertainty Principle: complete localization in  $M^4$  implies maximal uncertainty of the point in  $CP_2$  and vice versa.

### 7.5.2 Does twistor string theory generalize to TGD?

With this background the key speculative questions seem to be the following ones.

1. Could one relate twistor string theory to TGD framework? Partonic 2-surfaces at the boundaries of  $CD$  are lifted to 4-D sphere bundles in twistor space. Could they serve as a 4-D counterpart for Witten's holomorphic twistor strings assigned to point like particles? Could these surfaces be actually lifts of the holomorphic curves of twistor space replaced with the product  $CP_3 \times CP_2$  to 4-D sphere bundles? If I have understood correctly, the Grassmannians  $G(n, k)$  can be assigned to the moduli spaces of these holomorphic curves characterized by the degree of the polynomial expressible in terms of genus, number of negative helicity gluons, and the number of loops for twistor diagram.

Could one interpret  $G(n, k)$  as a moduli space for the  $\delta CD$  projections of  $n$  partonic 2-surfaces to which  $k$  negative helicity gluons and  $n - k$  positive helicity gluons are assigned (or something more complex when one considers more general particle states)? Could quantum numbers be mapped to integer valued algebraic invariants? IF so, there would be a correlation between the geometry of the partonic 2-surface and quantum numbers in accordance with quantum classical correspondence.

2. Could one understand light-like orbits of partonic 2-surfaces and space-time surfaces in terms of twistors? To each point of the 2-surface one can assign a 2-sphere in twistor space  $CP_3$  and  $CP_2$  in its dual. These  $CP_2$ s can be identified. One should be able to assign to each sphere  $S^2$  at least one point of corresponding  $CP_2$ s associated with its points in the dual twistor space and identified as single  $CP_2$  union of  $CP_2$ :s in the dual twistor space a point of  $CP_2$  or even several of them. One should be also able to continue this correspondence so that it applies to the light-like orbit of the partonic 2-surface and to the space-time surface defining a preferred extremal of Kähler action. For space-time sheets representable as graph of a map  $M^4 \rightarrow CP_2$  locally one should select from a  $CP_2$  assigned with a particular point of the space-time sheet a unique point of corresponding  $CP_2$  in a manner consistent with field equations. For surfaces with lower dimensional  $M^4$  projection one must assign a continuum of points of  $CP_2$  to a given point of  $M^4$ . What kind equations-could allow to realize this assignment? Holomorphy is strongly favored also by the number theoretic considerations since in this case one has hopes of performing integrals using residue calculus.

- (a) Could two holomorphic equations in  $CP_3 \times CP_2$  defining 6-D surfaces as sphere bundles over  $M^4 \times CP_2$  characterize the preferred extremals of Kähler action? Could partonic 2-surfaces be obtained by posing an additional holomorphic equation reducing twistors to null twistors and thus projecting to the boundaries of  $CD$ ? A philosophical justification for this conjecture comes from effective 2-dimensionality stating that partonic 2-surfaces plus their 4-D tangent space data code for physics. That the dynamics would reduce to holomorphy would be an extremely beautiful result. Of course this is only an additional item in the list of general conjectures about the classical dynamics for the preferred extremals of Kähler action.
- (b) One could also work in  $CP_3 \times CP_3$ . The first  $CP_3$  would represent twistors endowed with a metric conformally equivalent to that of  $M^{2,4}$  and having the covering of  $SU(2, 2)$  of  $SO(2, 4)$  as isometries. The second  $CP_3$  defining its dual would have a metric consistent with the Calabi-Yau structure (having holonomy group  $SU(3)$ ). Also the induced metric for canonically imbedded  $CP_2$ s should be the standard metric of  $CP_2$  having  $SU(3)$  as its isometries. In this situation the linear equations assigning to  $M^4$  points twistor pairs and  $CP_2 \subset CP_3$  as a complex plane would hold always true. Besides this two holomorphic equations coding for the dynamics would be needed.
- (c) The issues related to the induced metric are important. The conformal equivalence class of  $M^4$  metric emerges from the 5-D light-cone of  $M^{2,4}$  under projective identification. The choice of a proper projective gauge would select  $M^4$  metric locally. Twistors inherit the conformal metric with signature  $(2, 4)$  from the metric of 4+4 component spinors with metric having  $(4, 4)$  signature. One should be able to assign a conformal equivalence class of Minkowski metric with the orbits of pairs of twistors modulo  $GL(2)$ . The metric of conformally compactified  $M^4$  would be obtained from this metric by dropping from the line element the contribution to the  $S^2$  fiber associated with  $M^4$  point.

- (d) Witten related [70] the degree  $d$  of the algebraic curve describing twistor string, its genus  $g$ , the number  $k$  of negative helicity gluons, and the number  $l$  of loops by the following formula

$$d = k - 1 + l \quad , \quad g \leq l \quad . \quad (7.5.1)$$

One should generalize the definition of the genus so that it applies to 6-D surfaces. For projective complex varieties of complex dimension  $n$  this definition indeed makes sense. Algebraic genus [2] is expressible in terms of the dimensions of the spaces of closed holomorphic forms known as Hodge numbers  $h^{p,q}$  as

$$g = \sum (-1)^{n-k} h^{k,0} \quad . \quad (7.5.2)$$

The first guess is that the formula of Witten generalizes by replacing genus with its algebraic counterpart . This requires that the allowed holomorphic surfaces are projective curves of twistor space, that is described in terms of homogenous polynomials of the 4+4 projective coordinates of  $CP_3 \times CP_3$ .

### 7.5.3 What is the relationship of TGD to M-theory and F-theory?

There are also questions relating to the possible relationship to M-theory and F-theory.

1. Calabi-Yau-manifolds [6, 52] are central for the compactification in super string theory and emerge from the condition that the super-symmetry breaks down to  $\mathcal{N} = 1$  SUSY. The dual twistor space  $CP_3$  with Euclidian signature of metric is a Calabi-Yau manifold [70] . Could one have in some sense two Calabi-Yaus! Twistorial  $CP_3$  can be interpreted as a four-fold covering and conformal compactification of  $M^{2,4}$ . I do not know whether Calabi-Yau property has a generalization to the situation when Euclidian metric is replaced with a conformal equivalence class of flat metrics with Minkowskian signature and thus having a vanishing Ricci tensor. As far as differential forms (no dependence on metric) are considered there should be no problems. Whether the replacement of the maximal holonomy group  $SU(3)$  with its non-compact version  $SU(1,2)$  makes sense is not clear to me.
2. The lift of the  $CD$  to projective twistor space would replace  $CD \times CP_2$  with 10-dimensional space which inspires the familiar questions about connection between TGD and M-theory. If Calabi-Yau with a Minkowskian signature of metric makes sense then the Calabi-Yau of the standard M-theory would be replaced with its Minkowskian counterpart! Could it really be that M-theory like theory based on  $CP_3 \times CP_2$  reduces to TGD in  $CD \times CP_2$  if an additional symmetry mapping 2-spheres of  $CP_3$  to points of  $CD$  is assumed? Could the formulation based on 12-D  $CP_3 \times CP_3$  correspond to F-theory which also has two time-like dimensions. Of course, the additional conditions defined by the maps to  $M^4$  and  $CP_2$  would remove the second time-like dimension which is very difficult to justify on purely physical grounds.
3. One can actually challenge the assumption that the first  $CP_3$  should have a conformal metric with signature (2,4). Metric appears nowhere in the definition holomorphic functions and once the projections to  $M^4$  and  $CP_2$  are known, the metric of the space-time surface is obtained from the metric of  $M^4 \times CP_2$ . The previous argument for the necessity of the presence of the information about metric in the second order differential equation however suggests that the metric is needed.
4. The beginner might ask whether the 6-D 2-sphere bundles representing space-time sheets could have interpretation as Calabi-Yau manifolds. In fact, the Calabi-Yau manifolds defined as complete intersections in  $CP_3 \times CP_3$  discovered by Tian and Yau are defined by three polynomials [52] . Two of them have degree 3 and depend on the coordinates of single  $CP_3$  only whereas the third is bilinear in the coordinates of the  $CP_3$ :s. Obviously the number of these manifolds is quite too small (taking into account scaling the space defined by the coefficients is 6-dimensional). All these manifolds are deformation equivalent. These manifolds have Euler characteristic  $\chi = \pm 18$

and a non-trivial fundamental group. By dividing this manifold by  $Z_3$  one obtains  $\chi = \pm 6$ , which guarantees that the number of fermion generations is three in heterotic string theory. This manifold was the first one proposed to give rise to three generations and  $\mathcal{N} = 1$  SUSY.

#### 7.5.4 What could the field equations be in twistorial formulation?

The fascinating question is whether one can identify the equations determining the 3-D complex surfaces of  $CP_3 \times CP_3$  in turn determining the space-time surfaces.

The first thing is to clarify in detail how space-time  $M^4 \times CP_2$  results from  $CP_3 \times CP_3$ . Each point  $CP_3 \times CP_3$  define a line in third  $CP_3$  having interpretation as a point of conformally compactified  $M^4$  obtained by sphere bundle projection. Each point of either  $CP_3$  in turn defines  $CP_2$  in in fourth  $CP_3$  as a 2-plane. Therefore one has  $(CP_3 \times CP_3) \times (CP_3 \times CP_3)$  but one can reduce the consideration to  $CP_3 \times CP_3$  fixing  $M^4 \times CP_2$ . In the generic situation 6-D surface in 12-D  $CP_3 \times CP_3$  defines 4-D surface in the dual  $CP_3 \times CP_3$  and its sphere bundle projection defines a 4-D surface in  $M^4 \times CP_2$ .

1. The vanishing of three holomorphic functions  $f^i$  would characterize 3-D holomorphic surfaces of 6-D  $CP_3 \times CP_3$ . These are determined by three real functions of three real arguments just like a holomorphic function of single variable is dictated by its values on a one-dimensional curve of complex plane. This conforms with the idea that initial data are given at 3-D surface. Note that either the first or second  $CP_3$  can determine the  $CP_2$  image of the holomorphic 3-surface unless one assumes that the holomorphic functions are symmetric under the exchange of the coordinates of the two  $CP_3$ s. If symmetry is not assumed one has some kind of duality.
2. Effective 2-dimensionality means that 2-D partonic surfaces plus 4-D tangent space data are enough. This suggests that the 2 holomorphic functions determining the dynamics satisfy some second order differential equation with respect to their three complex arguments: the value of the function and its derivative would correspond to the initial values of the imbedding space coordinates and their normal derivatives at partonic 2-surface. Since the effective 2-dimensionality brings in dependence on the induced metric of the space-time surface, this equation should contain information about the induced metric.
3. The no-where vanishing holomorphic 3-form  $\Omega$ , which can be regarded as a "complex square root" of volume form characterizes 6-D Calabi-Yau manifold [6, 52], indeed contains this information albeit in a rather implicit manner but in spirit with TGD as almost topological QFT philosophy. Both  $CP_3$ s are characterized by this kind of 3-form if Calabi-Yau with (2, 4) signature makes sense.
4. The simplest second order- and one might hope holomorphic- differential equation that one can imagine with these ingredients is of the form

$$\Omega_1^{i_1 j_1 k_1} \Omega_2^{i_2 j_2 k_2} \partial_{i_1 i_2} f^1 \partial_{j_1 j_2} f^2 \partial_{k_1 k_2} f^3 = 0, \quad \partial_{ij} \equiv \partial_i \partial_j. \quad (7.5.3)$$

Since  $\Omega_i$  is by its antisymmetry equal to  $\Omega_i^{123} \epsilon^{ijk}$ , one can divide  $\Omega^{123}$ s away from the equation so that one indeed obtains holomorphic solutions. Note also that one can replace ordinary derivatives in the equation with covariant derivatives without any effect so that the equations are general coordinate invariant.

One can consider more complex equations obtained by taking instead of  $(f^1, f^2, f^3)$  arbitrary combinations  $(f^i, f^j, f^k)$  which results uniquely if one assumes anti-symmetrization in the labels (1, 2, 3). In the sequel only this equation is considered.

5. The metric disappears completely from the equations and skeptic could argue that this is inconsistent with the fact that it appears in the equations defining the weak form of electric-magnetic duality as a Lagrange multiplier term in Chern-Simons action. Optimist would respond that the representation of the 6-surfaces as intersections of three hyper-surfaces is different from the representation as imbedding maps  $X^4 \rightarrow H$  used in the usual formulation so that the argument does not bite, and continue by saying that the metric emerges in any case when one endows space-time with the induced metric given by projection to  $M^4$ .

6. These equations allow infinite families of obvious solutions. For instance, when some  $f^i$  depends on the coordinates of either  $CP_3$  only, the equations are identically satisfied. As a special case one obtains solutions for which  $f^1 = Z \cdot W$  and  $(f^2, f^3) = (f^2(Z), f^3(W))$ . This family contains also the Calabi-Yau manifold found by Yau and Tian, whose factor space was proposed as the first candidate for a compactification consistent with three fermion families.
7. One might hope that an infinite non-obvious solution family could be obtained from the ansatz expressible as products of exponential functions of  $Z$  and  $W$ . Exponentials are not consistent with the assumption that the functions  $f_i$  are homogenous polynomials of finite degree in projective coordinates so that the following argument is only for the purpose for learning something about the basic character of the equations.

$$\begin{aligned}
f^1 &= E_{a_1, a_2, a_3}(Z) E_{\hat{a}_1, \hat{a}_2, \hat{a}_3}(W) \ , & f^2 &= E_{b_1, b_2, b_3}(Z) E_{\hat{b}_1, \hat{b}_2, \hat{b}_3}(W) \ , \\
f^3 &= E_{c_1, c_2, c_3}(Z) E_{\hat{c}_1, \hat{c}_2, \hat{c}_3}(W) \ , & & (7.5.4) \\
E_{a,b,c}(Z) &= \exp(az_1) \exp(bz_2) \exp(cz_3) \ .
\end{aligned}$$

The parameters  $a, b, c$ , and  $\hat{a}, \hat{b}, \hat{c}$  can be arbitrary real numbers in real context. By the basic properties of exponential functions the field equations are algebraic. The conditions reduce to the vanishing of the products of determinants  $\det(a, b, c)$  and  $\det(\hat{a}, \hat{b}, \hat{c})$  so that the vanishing of either determinant is enough. Therefore the dependence can be arbitrary either in  $Z$  coordinates or in  $W$  coordinates. Linear superposition holds for the modes for which determinant vanishes which means that the vectors  $(a, b, c)$  or  $(\hat{a}, \hat{b}, \hat{c})$  are in the same plane.

Unfortunately, the vanishing conditions reduce to the conditions  $f^i(W) = 0$  for case a) and to  $f^i(Z) = 0$  for case b) so that the conditions are equivalent with those obtained by putting the "wave vector" to zero and the solutions reduce to obvious ones. The lesson is that the equations do not commute with the multiplication of the functions  $f^i$  with nowhere vanishing functions of  $W$  and  $Z$ . The equation selects a particular representation of the surfaces and one might argue that this should not be the case unless the hyper-surfaces defined by  $f^i$  contain some physically relevant information. One could consider the possibility that the vanishing conditions are replaced with conditions  $f^i = c_i$  with  $f^i(0) = 0$  in which case the information would be coded by a family of space-time surfaces obtained by varying  $c_i$ .

One might criticize the above equations since they are formulated directly in the product  $CP_3 \times CP_3$  of projective twistor by choosing a specific projective gauge by putting  $z^4 = 1, w^4 = 1$ . The manifestly projectively invariant formulation for the equations is in full twistor space so that 12-D space would be replaced with 16-D space. In this case one would have 4-D complex permutation symbol giving for these spaces Calabi-Yau structure with flat metric. The product of functions  $f = z^4 = \text{constant}$  and  $g = w^4 = \text{constant}$  would define the fourth function  $f_4 = fg$  fixing the projective gauge

$$\epsilon^{i_1 j_1 k_1 l_1} \epsilon^{i_2 j_2 k_2 l_2} \partial_{i_1 i_2} f^1 \partial_{j_1 j_2} f^2 \partial_{k_1 k_2} f^3 \partial_{l_1 l_2} f^4 = 0 \ , \ \partial_{ij} \equiv \partial_i \partial_j \ . \quad (7.5.5)$$

The functions  $f^i$  are homogenous polynomials of their twistor arguments to guarantee projective invariance. These equations are projectively invariant and reduce to the above form which means also loss of homogenous polynomial property. The undesirable feature is the loss of manifest projective invariance by the fixing of the projective gauge.

A more attractive ansatz is based on the idea that one must have one equation for each  $f^i$  to minimize the non-determinism of the equations obvious from the fact that there is single equation in 3-D lattice for three dynamical variables. The quartets  $(f^1, f^2, f^3, f^i)$ ,  $i = 1, 2, 3$  would define a possible minimally non-linear generalization of the equation

$$\epsilon^{i_1 j_1 k_1 l_1} \epsilon^{i_2 j_2 k_2 l_2} \partial_{i_1 i_2} f^1 \partial_{j_1 j_2} f^2 \partial_{k_1 k_2} f^m \partial_{l_1 l_2} f^4 = 0 \ , \ \partial_{ij} \equiv \partial_i \partial_j \ , \ m = 1, 2, 3 \ . \quad (7.5.6)$$

Note that the functions are homogenous polynomials of their arguments and analogous to spherical harmonics suggesting that they can allow a nice interpretation in terms of quantum classical correspondence.

The minimal non-linearity of the equations also conforms with the non-linearity of the field equations associated with Kähler action. Note that also in this case one can solve the equations by diagonalizing the dynamical coefficient matrix associated with the quadratic term and by identifying the eigen-vectors of zero eigen values. One could consider also more complicated strongly non-linear ansätze such as  $(f^i, f^i, f^i, f^i)$ ,  $i = 1, 2, 3$ , but these do not seem plausible.

### The explicit form of the equations using Taylor series expansion for multi-linear case

In this section the equations associated with  $(f_1, f_2, f_3)$  ansatz are discussed in order to obtain a perspective about the general structure of the equations by using simpler (multilinearity) albeit probably non-realistic case as starting point. This experience can be applied directly to the  $(f^1, f^2, f^3, f^i)$  ansatz, which is quadratic in  $f^i$ .

The explicit form of the equations is obtained as infinite number of conditions relating the coefficients of the Taylor series of  $f^1$  and  $f^2$ . The treatment of the two variants for the equations is essentially identical and in the following only the manifestly projectively invariant form will be considered.

1. One can express the Taylor series as

$$\begin{aligned} f^1(Z, W) &= \sum_{m,n} C_{m,n} M_m(Z) M_n(W) , \\ f^2(Z, W) &= \sum_{m,n} D_{m,n} M_m(Z) M_n(W) , \\ f^3(Z, W) &= \sum_{m,n} E_{m,n} M_m(Z) M_n(W) , \\ M_{m \equiv (m_1, m_2, m_3)}(Z) &= z_1^{m_1} z_2^{m_2} z_3^{m_3} . \end{aligned} \quad (7.5.7)$$

2. The application of derivatives to the functions reduces to a simple algebraic operation

$$\partial_{ij}(M_m(Z) M_n(W)) = m_i n_j M_{m_1 - e_i}(Z) M_{n - e_j}(W) . \quad (7.5.8)$$

Here  $e_i$  denotes  $i$ :th unit vector.

3. Using the product rule  $M_m M_n = M_{m+n}$  one obtains

$$\begin{aligned} &\partial_{ij}(M_m(Z) M_n(W)) \partial_{rs}(M_k(Z) M_l(W)) \\ &= m_i n_j k_r l_s \times M_{m - e_i}(Z) M_{n - e_j}(W) \times M_{k - e_r}(Z) M_{l - e_s}(W) \\ &= m_i n_j k_r l_s \times M_{m+k - e_i - e_r}(Z) \times M_{n+l - e_j - e_l}(W) . \end{aligned} \quad (7.5.9)$$

4. The equations reduce to the trilinear form

$$\begin{aligned} &\sum_{m,n,k,l,r,s} C_{m,n} D_{k,l} E_{r,s}(m, k, r)(n, l, s) M_{m+k+r-E}(Z) M_{n+l+s-E}(W) = 0 , \\ E &= e_1 + e_2 + e_3 , \quad (a, b, c) = \epsilon^{ijk} a_i b_j c_c . \end{aligned} \quad (7.5.10)$$

Here  $(a, b, c)$  denotes the determinant defined by the three index vectors involved. By introducing the summation indices

$$(M = m + k + r - E, k, r) , \quad (N = n + l + s - E, l, s)$$

one obtains an infinite number of conditions, one for each pair  $(M, N)$ . The condition for a given pair  $(M, N)$  reads as

$$\sum_{k,l,r,s} C_{M-k-r+E, N-l-s+E} D_{k,l} E_{r,s} \times (M - k - r + E, k, r)(N - l - s + E, l, s) = 0 . \quad (7.5.11)$$

These equations can be regarded as linear equations by regarding any matrix selected from  $\{C, D, E\}$  as a vector of linear space. The existence solutions requires that the determinant associated with the tensor product of other two matrices vanishes. This matrix is dynamical. Same applies to the tensor product of any of the matrices.

5. Hyper-determinant [6] is the generalization of the notion of determinant whose vanishing tells that multilinear equations have solutions. Now the vanishing of the hyper-determinant defined for the tensor product of the three-fold tensor power of the vector space defined by the coefficients of the Taylor expansion should provide the appropriate manner to characterize the conditions for the existence of the solutions. As already seen, solutions indeed exist so that the hyper-determinant must vanish. The elements of the hyper matrix are now products of determinants for the exponents of the monomials involved. The non-locality of the Kähler function as a functional of the partonic surface leads to the argument that the field equations of TGD for vanishing  $n$ :th variations of Kähler action are multilinear and that a vanishing of a generalized hyper-determinant characterizes this [28] .
6. Since the differential operators are homogenous polynomials of partial derivatives, the total degrees of  $M_m(Z)$  and  $M_m(W)$  defined as a sum  $D = \sum m_i$  is reduced by one unit by the action of both operators  $\partial_{ij}$ . For given value of  $M$  and  $N$  only the products

$$M_m(Z)M_n(W)M_k(Z)M_r(W)M_s(Z)M_l(W)$$

for which the vector valued degrees  $D_1 = m + k + r$  and  $D_2 = n + l + s$  have the same value are coupled. Since the degree is reduced by the operators appearing in the equation, polynomial solutions for which  $f^i$  contain monomials labelled by vectors  $m_i, n_i, r_i$  for which the components vary in a finite range  $(0, n_{max})$  look like a natural solution ansatz. All the degrees  $D_i \leq D_{i,max}$  appear in the solution ansatz so that quite a large number of conditions is obtained.

What is nice is that the equation can be interpreted as a difference equation in 3-D lattice with "time direction" defined by the direction of the diagonal.

1. The counterparts of time=constant slices are the planes  $n_1 + n_2 + n_3 = n$  defining outer surfaces of simplices having  $E$  as a normal vector. The difference equation does not seem to say nothing about the behavior in the transversal directions.  $M$  and  $N$  vary in the simplex planes satisfying  $\sum M_i = T_1, \sum N_i = T_2$ . It seems natural to choose  $T_1 = T_2 = T$  so that  $Z$  and  $W$  dynamics corresponds to the same "time". The number of points in the  $T = constant$  simplex plane increases with  $T$  which is analogous to cosmic expansion.
2. The "time evolution" with respect to  $T$  can be solved iteratively by increasing the value of  $\sum M_i = N_i = T$  by one unit at each step. Suppose that the values of coefficients are known and satisfy the conditions for  $(m, k, r)$  and  $(n, l, s)$  up to the maximum value  $T$  for the sum of the components of each of these six vectors. The region of known coefficients -"past"- obviously corresponds to the interior of the simplex bounded by the plane  $\sum M_i = \sum N_i = T$  having  $E$  as a normal. Let  $(m_{min}, n_{min}), (k_{min}, l_{min})$  and  $(r_{min}, s_{min})$  correspond to the smallest values of 3-indices for which the coefficients are non-vanishing- this could be called the moment of "Big Bang". The simplest but not necessary assumption is that these indices correspond zero vectors  $(0, 0, 0)$  analogous to the tip of light-cone.

- For given values of  $M$  and  $N$  corresponding to same value of "cosmic time"  $T$  one can separate from the formula the terms which correspond to the un-known coefficients as the sum  $C_{M+E,N+E}D_{0,0}E_{0,0} + D_{M+E,N+E}D_{0,0}C_{0,0} + E_{M+E,N+E}C_{0,0}D_{0,0}$ . The remaining terms are by assumption already known. One can fix the normalization by choosing  $C_{0,0} = D_{0,0} = E_{0,0} = 1$ . With these assumptions the equation reduces at each point of the outer boundary of the simplex to the form

$$C_{M+E,N+E} + D_{M+E,N+E} + E_{M+E,N+E} = X$$

where  $X$  is something already known and contain only data about points in the plane  $m+k+r = M$  and  $n+r+s = N$ . Note that these planes have one "time like direction" unlike the simplex plane so that one could speak about a discrete analog of string world sheet in 3+3+3-D lattice space defined by a 2-plane with one time-like direction.

- For each point of the simplex plane one has equation of the above form. The equation is non-deterministic since only constrain only the sum  $C_{M+E,N+E} + D_{M+E,N+E} + E_{M+E,N+E}$  at each point of the simplex plane to a plane in the complex 3-D space defined by them. Hence the number of solutions is very large. The condition that the solutions reduce to polynomials poses conditions on the coefficients since the quantities  $X$  associated with the plane  $T = T_{max}$  must vanish for each point of the simplex plane in this case. In fact, projective invariance means that the functions involved are homogenous functions in projective coordinates and thus polynomials and therefore reduce to polynomials of finite degree in 3-D treatment. This obviously gives additional condition to the equations.

**The minimally non-linear option**

The simple equation just discussed should be taken with a caution since the non-determinism seems to be too large if one takes seriously the analogy with classical dynamics. By the vacuum degeneracy also the time evolution associated with Kähler action breaks determinism in the standard sense of the word. The non-determinism is however not so strong and removed completely in local sense for non-vacuum extremals. One could also try to see the non-determinism as the analog for non-deterministic time evolution by quantum jumps.

One can however consider the already mentioned possibility of increasing the number of equations so that one would have three equations corresponding to the three unknown functions  $f^i$  so that the determinism associated with each step would be reduced. The equations in question would be of the same general form but with  $(f^1, f^2, f^3)$  replaced with some other combination.

- In the genuinely projective situation where one can consider the  $(f^1, f^2, f^3, f^i)$ ,  $i = 1, 2, 3$  as a unique generalization of the equation. This would make the equations quadratic in  $f_i$  and reduce the non-determinism at given step of the time evolution. The new element is that now only monomials  $M_m(z)$  associated with the  $f^i$  with same degree of homogeneity defined by  $d = \sum m_i$  are consistent with projective invariance. Therefore the solutions are characterized by six integers  $(d_{i,1}, d_{i,2})$  having interpretation as analogs of conformal weights since they correspond to eigenvalues of scaling operators. That homogenous polynomials are in question gives hopes that a generalization of Witten's approach might make sense. The indices  $m$  vary at the outer surfaces of the six 3-simplices defined by  $(d_{i,1}, d_{i,2})$  and looking like tetrahedrons in 3-D space. The functions  $f^i$  are highly analogous to the homogenous functions appearing in group representations and quantum classical correspondence could be realized through the representation of the space-time surfaces in this manner.
- The 3-determinants  $(a, b, c)$  appearing in the equations would be replaced by 4-determinants and the equations would have the same general form. One has

$$\sum_{k,l,r,s,t,u} C_{M-k-r-t+E,N-l-s-u+E} D_{k,l} E_{r,s} C_{t,u} \times \\ \times (M - k - r - t + E, k, r, t)(N - l - s - u + E, l, s, u) = 0 \ , \\ E = e_1 + e_2 + e_3 + e_4 \ , \ (a, b, c, d) = \epsilon^{ijkl} a_i b_j c_k d_l \ . \tag{7.5.12}$$

and its variants in which  $D$  and  $E$  appear quadratically. The values of  $M$  and  $N$  are restricted to the tetrahedrons  $\sum M_i = \sum d_{k,1} + d_{1,i}$  and  $\sum N_i = \sum d_{i,2} + d_{i,2}$ ,  $i = 1, 2, 3$ . Therefore the dynamics in the index space is 3-dimensional. Since the index space is in a well-defined sense dual to  $CP_3$  as is also the  $CP_3$  in which the solutions are represented as counterparts of 3-surfaces, one could say that the 3-dimensionality of the dynamics corresponds to the dynamics of Chern-Simons action at space-like at the ends of  $CD$  and at light-like 3-surfaces.

3. The view based on 4-D time evolution is not useful since the solutions are restricted to time=constant plane in 4-D sense. The elimination of one of the projective coordinates would lead however to the analog of the above describe time evolution. In four-D context a more appropriate form of the equations is

$$\sum_{m,n,k,l,r,s} C_{m,n} D_{k,l} E_{r,s} C_{t,u}(m, k, r, t)(n, l, s, u) M_{m+k+r-E}(Z) M_{n+l+s-E}(W) = 0 \quad (7.5.13)$$

with similar equations for  $f^2$  and  $f^3$ . If one assumes that the  $CP_2$  image of the holomorphic 3-surface is unique (it can correspond to either  $CP_3$ ) the homogenous polynomials  $f^i$  must be symmetric under the exchange of  $Z$  and  $W$  so that the matrices  $C, D$ , and  $E$  are symmetric. This is equivalent to a replacement of the product of determinants with a sum of 16 products of determinants obtained by permuting the indices of each index pair  $(m, n)$ ,  $(k, l)$ ,  $(r, s)$  and  $(t, u)$ .

4. The number  $N_{cond}$  of conditions is given by the product  $N_{cond} = N(d_M)N(d_N)$  of numbers of points in the two tetrahedrons defined by the total conformal weights

$$\sum M_r = d_M = \sum_k d_{k,1} + d_{1,i} \quad \text{and} \quad \sum N_r = d_N = \sum_k d_{k,2} + d_{i,2} \quad , \quad i = 1, 2, 3.$$

The number  $N_{coeff}$  of coefficients is

$$N_{coeff} = \sum_k n(d_{k,1}) + \sum_k n(d_{k,2}) \quad ,$$

where  $n(d_{k,i})$  is the number points associated with the tetrahedron with conformal weight  $d_{k,i}$ . Since one has  $n(d) \propto d^3$ ,  $N_{cond}$  scales as

$$N_{cond} \propto d_M^3 d_N^3 = \left( \sum_k d_{k,1} + d_{1,i} \right)^3 \times \left( \sum_k d_{k,2} + d_{i,2} \right)^3$$

whereas the number  $N_{coeff}$  of coefficients scales as

$$N_{coeff} \propto \sum_k (d_{k,1}^3 + d_{k,2}^3) \quad .$$

$N_{cond}$  is clearly much larger than  $N_{coeff}$  so the solutions are analogous to partial waves and that the reduction of the rank for the matrices involved is an essential aspect of being a solution. The reduction of the rank for the coefficient matrices should reduce the effective number of coefficients so that solutions can be found. An interesting question is whether the coefficients are rationals with a suitable normalization allowed by independent conformal scalings. An analogy for the dynamics is quantum entanglement for 3+3 systems respecting the conservation of conformal weights and quantum classical correspondence taken to extreme suggests something like this.

5. One can interpret these equations as linear equations for the coefficients of the either linear term or as quadratic equations for the non-linear term. Also in the case of quadratic term one can apply general linear methods to identify the vanishing eigen values of the matrix of the quadratic form involved and to find the zero modes as solutions. The rank of the dynamically determined multiplier matrix must be non-maximal for the solutions to exist. One can imagine that the

rank changes at critical surfaces in the space of Taylor coefficients meaning a multi-furcation in the space determined by the coefficients of the polynomials. Also the degree of the polynomial can change at the critical point.

Solutions for which either determinant vanishes for all terms present in the solution exist. This is achieved if either the index vectors  $(m, l, r, t)$  or  $(n, l, s, u)$  in their respective parallel 3-planes are also in a 3-plane going through the origin. These solutions might be seen as the analogs of vacuum extremals of Chern-Simons action for which the  $CP_2$  projection is at most 2-D Lagrangian manifold.

Quantum classical correspondence requires that the space-time surface carries also information about the momenta of partons. This information is quasi-continuous. Also information about zero modes should have representation in terms of the coefficients of the polynomials. Is this really possible if only products of polynomials of fixed conformal weights with strong restrictions on coefficients can be used? The counterpart for the vacuum degeneracy of Kähler action might resolve the problem. The analog for the construction of space-time surfaces as deformations of vacuum extremals would be starting from a trivial solution and adding to the building blocks of  $f^i$  some terms of same degree for which the wave vectors are not in the intersection of a 3-plane and simplex planes. The still existing "vacuum part" of the solution could carry the needed information.

6. One can take "obvious solutions" characterized by different common 3-planes for the "wave vectors" characterizing the 8 monomials  $M_a(Z)$  and  $M_b(W)$ ,  $a \in \{m, k, r, t\}$  and  $b \in \{n, l, s, u\}$ . The coefficient matrices  $C, D, E, F$  are completely free. For the sum of these solutions the equations contain interaction terms for which at least two "wave vectors" belong to different 3-planes so that the corresponding 4-determinants are non-vanishing. The coefficients are not anymore free. Could the "obvious solutions" have interpretation in terms of different space-time sheets interacting via wormhole contacts? Or can one equate "obvious" with "vacuum" so that interaction between different vacuum space-time sheets via wormhole contact with 3-D  $CP_2$  projection would deform vacuum extremals to non-vacuum extremals? Quantum classical correspondence inspires the question whether the products for functions  $f_i$  associated with an obvious solution associated with a particular plane correspond to a tensor products for quantum states associated with a particular partonic 2-surface or space-time sheet.
7. Effective 2-dimensionality realized in terms of the extremals of Chern-Simons actions with Lagrange multiplier term coming from the weak form of electric magnetic duality should also have a concrete counterpart if one takes the analogy with the extremals of Kähler action seriously. The equations can be transformed to 3-D ones by the elimination of the fourth coordinate but the interpretation in terms of discrete time evolution seems to be impossible since all points are coupled. The total conformal weights of the monomials vary in the range  $[0, d_{1,i}]$  and  $[0, d_{2,i}]$  so that the non-vanishing coefficients are in the interior of 3-simplex. The information about the fourth coordinate is preserved being visible via the four-determinants.
8. It should be possible to relate the hierarchy with respect to conformal weights would to the geometrization of loop integrals if a generalization of twistor strings is in question. One could hope that there exists a hierarchy of solutions with levels characterized by the rank of the matrices appearing in the linear representation. There is a temptation to associate this hierarchy with the hierarchy of deformations of vacuum extremals of Kähler action forming also a hierarchy. If this is the case the obvious solutions would correspond to vacuum extremals. At each step when the rank of the matrices involved decreases the solution becomes nearer to vacuum extremal and there should exist vanishing second variation of Kähler action. This structural similarity gives hopes that the proposed ansatz might work. Also the fact that a generalization of the Penrose's twistorial description for the solutions of Maxwell's equations to the situation when Maxwell field is induced from the Kähler form of  $CP_2$  raises hopes. One must however remember that the consistency with other proposed solution ansätze and with what is believed to be known about the preferred extremals is an enormously powerful constraint and a mathematical miracle would be required.

## 7.6 Comparing twistor revolution with TGD revolution

Lubos Motl saved my Sunday by giving a link to an excellent talk by Nima Arkani-Hamed about the latest twistorial breakthroughs. Lubos Motl talks about "minirevolution" but David Gross uses a more appropriate expression "uprising". I would prefer to speak about revolution inducing at the sociological level a revolt. One must give up QFT in fixed space-time and string theory, and replace them with a theory whose name Nima guesses to be just "T".

For some time ago Lubos Motl told about the latest articles from Nima and collaborators: A Note on Polytopes for Scattering Amplitudes and Local Integrals for Planar Scattering Amplitudes.

Soon after this Lubos Motl gave a link to a video in which Witten talked about knot invariants. This talk was very inspiring and led to TGD based vision about how to calculate invariants of braids, braid cobordisms, and 2-knots in TGD framework and the idea that TGD could be seen as symplectic QFT for calculating these invariances among other things. Much of work was just translation of the basic ideas involved to TGD framework.

One crucial observation was that one can assign to the symplectic group of  $\delta M_+^4 \times CP_2$  gerbe gauge potentials generalizing ordinary gauge potentials in terms of which one can define infinite number of classical 2-fluxes allowing to generalize Wilson loop to a Wilson surface. Most importantly, a unique identification for the decomposition of space-time surface to string world sheets identified as singularities of induce gauge fields and partonic 2-surfaces emerged and one can see the two decompositions as dual descriptions. TGD as almost topological QFT concretized to a symplectic QFT for knots, braids, braid cobordisms, and 2-knots. These ideas are documented in the chapter Knots and TGD of "TGD: Physics as Infinite-Dimensional Geometry" [36]. I did not realize the obvious connection with twistor approach as I wrote the new chapter.

In his rather energetic lecture Nima emphasized how the Yangian symmetry originally discovered in 2-D QFTs, algebraic geometry, twistor theory, and string theory fuse to something bigger called "T". I realized that the twistorial picture developed in the earlier postings integrates nicely with the braided vision inspired by Witten's talk and that one could understand in TGD framework why twistor description, Yangian symmetry of 2-D integrable systems, and algebraic geometry picture are so closely related. In particular, the dual conformal symmetries of twistor approach could be understood in terms of duality between partonic 2-surfaces and string world sheets expressing the strong form of holography. Also a generalization for the dual descriptions provided by super Wilson loop and ordinary scattering amplitude in  $\mathcal{N} = 4$  SUSY in terms of Wilson sheets suggests itself among many other things. Also a rather obvious solution to the problem posed by non-planar diagrams to twistor approach suggests itself. Planar diagrams are simply not present and parton-string duality and huge symmetries of TGD give good reasons for why this should be the case.

### 7.6.1 The declaration of revolution by Nima from TGD point of view

At first look Nima's program is a declaration of revolution against all sacred principles. Nima dooms space-time, wants to get rid of QFT, does not even explicitly care about unitarity, and wants to throw Feynman diagrams to paper basket. Nima does not even respect string theory and sees it only as one particular- possibly not the best- manner to describe the underlying simplicity.

#### Give up space-time

In many respects I agree with Nima about the fate of space-time of QFT. I however see Nima's view a little bit exaggerated: one can perhaps compute scattering amplitudes without Minkowski space but one cannot translate the results of computations to the language of experiments without bringing in frequencies and wavelengths, classical fields, and therefore also space-time. Quantum classical correspondence: this is needed and this brings space-time unavoidably into the picture. Space-time surface serves as a dynamical correlate for quantum dynamics- generalized Bohr orbit required by General Coordinate Invariance and strong form of holography. The enormously important implication is absence of Feynman graphs in ordinary sense since there is no path integral over space-time surface but just single surface: the preferred extremal of Kähler action is enough (forgetting the delicacies caused by the failure of classical determinism in standard sense for Kähler action allowing to realize also the space-time correlates of quantum jump sequences).

Nima uses black hole based arguments to demonstrate that local observables are not operationally defined in neither gravitational theories nor quantum field theories and concludes that space-time is doomed. What would remain would be 4-D space-time regarded as a boundary of higher dimensional space-time (AdS/CFT correspondence). I think that this is quite too complex and that the reduction in degrees of freedom is much more radical: the landscape misery is after all basically due to the exponential inflation in the number of degrees of freedom due to the fatal mistake of making 10-D or 11-D target space dynamical.

What remains in TGD are boundaries of space-time surfaces at the upper and lower ends of causal diamonds  $CD \times CP_2$  (briefly  $CD$ ) and wormhole throats at which the signature of induced metric changes from Euclidian to Minkowskian (recall that Euclidian regions represent generalized Feynman diagrams).  $CD$  is essentially a representation of Penrose diagram which fits nicely with twistor approach. Strong form of holography implies that partonic 2-surfaces (or dual string world sheets) and 4-D tangent space data are enough as basic particle physics objects. The rest of space-time is needed to realize quantum classical correspondence essential for quantum measurement theory.

The basic message of TGD is that quantum superpositions of space-time surfaces are relevant for physics in all scales. Particles are the dynamical space-time quanta. There is however higher-dimensional space-time which is fixed and rigid  $H = M^4 \times CP_2$  and is needed for the symmetries of the theory and guarantees the Kähler geometric existence of the world of classical worlds (WCW). This simplifies the situation enormously: instead of 10- or 11-D dynamical space-time one has just 4-D space-time and 2-D surfaces plus 4-D tangent space data. Holography is what we experience it to be: we see only 2-D surfaces. And physics is experimental science although some super string theorists might argue something else!

### Give up fields

Nima argues also that fields are doomed too. I must say that I do not like this Planck length mysticism: it assumes quite too much and in TGD framework something new emerges already in  $CP_2$  scale about  $10^4$  longer than Planck scale. According to Nima all this pain with Feynman diagrams would be due to the need to realize unitary representations of Poincaré group in terms of fields. For massless particles one is forced to assume gauge invariance to eliminate the unphysical polarizations. Nima sees gauge invariance as the source of all troubles. Here I do not completely agree with Nima. The unitary time evolution in fixed space-time translated to the path integral over classical fields is what leads to the combinatorial nightmare of summing over Feynman diagrams and plagues also  $\phi^4$  theory. Amusingly, as Nima emphasizes all this has been known for 60 years. It is easy to understand that the possibility to realize unitarity elegantly using Feynman diagrams led to the acceptance of this approach as the only possible one.

In TGD framework the geometry of sub-manifolds replaces fields: the dynamics of partonic 2-surfaces identified as throats of light-like wormhole contacts containing fermions at them gives rise to bosons as bound states of fermions and antifermions. There is no path integral over space-time surfaces, just functional integral over partonic 2-surfaces so that path integral disappears. In zero energy ontology this means that incoming states are bound states of massless fermions and antifermions at wormhole throats and virtual states consist also of massless fermions but without the bound state constraint. This means horribly strong kinematic constraints on vertices defined by partonic 2-surfaces and UV finiteness and IR finiteness are automatic outcome of the theory. Massivation guaranteeing IR finiteness is consistent with masslessness of fundamental particles since massive states are bound states of massless particles.

Nima talks also about emergence as something fundamental and claims that also space-time emerges. In TGD framework emergence has very concrete meaning. All particles are bound states of massless fermions and the additional purely bosonic degrees of freedom correspond to vibrational degrees of freedom for partonic 2-surfaces.

What is lacking from the program of Nima is the vision about physics as a geometry of worlds of classical worlds [60] and physics as generalized number theory [69]. This is what makes the higher-D imbedding space unique and allows the geometrization of quantum physics and identification of standard model symmetries as number theoretical symmetries. Infinite-dimensional geometry is unique just from the requirement that it exists!

### 7.6.2 Basic results of twistor approach from TGD point of view

The basic ideas of twistor approach are remarkably consistent with the basic picture of TGD.

#### Only on mass-shell amplitudes appear in the recursion formula

What is striking that the recursion formula of Nima and collaborators for the integrands of the planar amplitudes of  $\mathcal{N} = 4$  SUSY involve only on mass shell massless particles in the role of intermediate states. This is in sharp conflict with not only Feynman diagrammatic intuition but also with the very path integral ideology motivated by the need to realize unitary time development.

As already mentioned, in ZEO (zero energy ontology) all states- both on mass shell and off mass shell are composites of massless states assigned to 2-D partonic surfaces. Path integral is indeed replaced with generalized Bohr orbits and one obtains only very few generalized Feynman diagrams. What remains is functional integral over 3-surfaces, or even less over partonic 2-surfaces with varying tangent space data.

A further simplification is that as a result of the dynamics of preferred extremals many particle states correspond to discrete sets of points at partonic 2-surfaces serving as the ends of orbits of braid strands and possibly also 2-knots and functional integral involves integral over different configurations of these points [28]. The physical interpretation is as a realization of finite measurement resolution as a property of dynamics itself. The string world sheets are uniquely identified as inverse images under imbedding map of space-time surface to  $H = M^4 \times CP_2$  of homologically non-trivial geodesic sphere of  $CP_2$  defining homological magnetic monopole. Holography in its strongest sense states that all information about non-trivial 2-homology of space-time surface and knottedness of the string world sheets is coded to the data at partonic 2-surfaces. For details see the chapter Knots and TGD of "TGD: Physics as Infinite-Dimensional Geometry [36].

#### Twistors and algebraic geometry connection emerge naturally in TGD framework

$H = M^4 \times CP_2$  and the reduction of all on mass shell states to bound states of massless states imply that twistor approach is the natural description of scattering amplitudes in TGD framework.

What is new that one must convolute massless theories in the sense that opposite throats of  $CP_2$  sized wormhole contacts carry massless states. This allows to get rid of IR divergencies and realized exact Yangian symmetry by a purely physical mechanism making particle states massive.

An important implication is that even photon, gluons, and graviton have small masses and that in TGD framework all components of Higgs field are eaten by electroweak gauge bosons. Also gluons have colored scalar and pseudo-scalar counterparts and already now there are some hints at LHC for pseudo-scalar gluons. The discovery of Higgs can of course kill this idea anytime.

The connection with twistors allows to understand how algebraic geometry of projective spaces emerges in TGD framework and one indeed ends up to an alternative formulation of quantum TGD with space-time surfaces in  $H$  replaced with holomorphic 6-surfaces of  $CP_3 \times CP_3$ , which are sphere bundles and there effectively 4-D. The equations determining the 6-surfaces are dictated by rather general constraints.

#### Dual descriptions in terms of QFT and strings

The connections of  $\mathcal{N} = 4$  SUSY with 2-D integrable systems and the possibly of both stringy and QFT descriptions characterized by dual conformal symmetries giving rise to Yangian invariance reduce in TGD framework to the duality between descriptions based on string world sheets and partonic 2-surfaces.

1. The connection with string description emerges from the basic TGD in the sense that one can localize the solutions of the modified Dirac equation [28] at braid strands located at the light-like 3-D wormhole throats. Similar localization to string world sheets defined in the above described manner holds true in space-time interior. The solutions of the modified Dirac equation localized to braid strands (and to string world sheets in space-time interior) are characterized by what I called pseudo momenta not directly identifiable as momenta. The natural identification is as region momenta of the twistor approach. Recall that the twistorialization of region momenta leads to the momentum twistor approach making dual conformal invariance manifest.

2. The strange looking localization of fermions at braid strands makes mathematically sense only because the classical dynamics of preferred extremals reduces to hydrodynamics such that the flow parameters for flow lines integrate to global coordinates. So called Beltrami flows are in question and mean that preferred extremals have interpretation as perfect fluid flows for which dissipation is minimal [28]. This property implies also the almost topological QFT property of TGD meaning that Kähler action reduces to Chern-Simons action localized at light-like wormhole throats and space-like 3-surfaces at the ends of CDs.
3. The mathematical motivation on braid strands comes from the fact that this allows to avoid delta functions in the anticommutators of fermionic oscillator operators at partonic 2-surfaces and therefore also the basic quadratic divergences of quantum field theories. Oscillator algebra has countable -perhaps even finite number- of generators and the loss of complete locality is in terms of finite measurement resolution. The larger the number of braid points selected at partonic 2-surface, the larger the number string world sheets and the higher the complexity of space-time surface. This obviously means a concrete realization of holography. The oscillator algebra has interpretation as SUSY algebra with arbitrarily large  $N$  fixed by the number of braid points. This SUSY symmetry is dynamical and badly broken. For right handed neutrino the breaking is smallest but also in this case the mixing of left- and right handed  $M^4$  chiralities in modified Dirac equation implies non-conservation of R-parity as well as particle massivation and also the absence of lightest stable SUSY partner, which means that one particular dark matter candidate is out of game.
4. The big difference between TGD and string models is that super generators do not correspond to Majorana spinors: this is indeed impossible for  $M^4 \times CP_2$  since it would mean non-conservation of baryon and lepton numbers. I believed for a long time that stringy propagators emerge from TGD and the long standing painful question was what about stringy propagator defined by the inverse  $1/G$  of the hermitian super generator in string models. In TGD  $1/G$  cannot define stringy propagator since  $G$  carries fermion number. The reduction of strings to pairs of massless particles saves the situation and ordinary massless propagator for the counterparts of region momenta gives well defined propagators for on mass shell massless states! Stringy states reduce to bound states of massless particles in accordance with emergence philosophy. Nothing is scared these days!

### Connection with integrable 2-D discrete systems

Twistor approach has revealed a striking connection between 2-D integrable systems and  $\mathcal{N} = 4$  SUSY. For instance, one can calculate the anomalous dimensions of  $\mathcal{N} = 4$  SUSY from an integrable model for spin chain in 2 dimensions without ever mentioning Feynman diagrams.

The description in terms of partonic 2-surfaces mean a direct connection with braids appearing in 2-D integrable thermodynamical systems and the description in terms of string world sheets means connection with integrable theories in 2-D Minkowski space. Both theories involve Yangian symmetry [41] for which there exists a hierarchy of non-local conserved charges. Super-conformal invariance and its dual crucial for Yangian symmetry correspond to partonic 2-surfaces and string world sheets. The symmetry algebra is extended dramatically. In  $\mathcal{N} = 4$  SUSY one has Yangian of conformal algebra of  $M^4$ . In TGD this algebra is generalized to include the super Kac-Moody algebra associated with isometries of the imbedding space, the super-conformal variant of the symplectic algebra of  $\delta M^4 \times CP_2$ , and also conformal transformations of  $M^4$  mapping given boundary of  $CD$  to itself.

This allows also to understand and generalize the duality stating that QFT amplitudes for  $\mathcal{N} = 4$  SUSY have interpretation as supersymmetric Wilson loops in dual Minkowski space. The ends of braid strands indeed define Wilson loops. In TGD framework work one must however generalize Wilson loops to Wilson sheets [36] and the circulations of gauge potentials are replaced with fluxes of gerbe gauge potentials associated with the symplectic group of  $\delta M^4_+ \times CP_2$ . As noticed, dual conformal symmetries correspond to duality of partonic 2-surfaces and string world sheets implied by the 2-D holography for string world sheets.

### 7.6.3 Could planar diagrams be enough in the theory transcending $\mathcal{N} = 4$ SUSY?

Twistor approach as it appears in  $\mathcal{N} = 4$  SYM is of course not the final solution.

1.  $\mathcal{N} = 4$  SUSY is not enough for the purposes of LHC.
2. The extremely beautiful Yangian symmetry fails as one performs integration to obtain the scattering amplitudes and generates IR singularities. ZEO provides an elegant solution to this problem by replacing physical on mass shell particles with bound states of massless particles. Also string like objects emerge as this kind of states.
3. Only planar diagrams allow to assign to the sum of Feynman diagrams a single integrand defining the twistor diagram. Something definitely goes wrong unless one is able to treat the non-planar diagrams. The basic problem is that one cannot assign common loop momentum variables to all diagrams simultaneously and this is due to the tricky character of Feynman diagrams. It is difficult to integrate without integrand!

The easy-to-guess question is whether the sum over the non-planar diagrams vanishes or whether they are just absent in a theory transcending  $\mathcal{N} = 4$  SUSY and QFTs. Let  $N$  denote the number of colors of the SUSY. For  $N \rightarrow \infty$  limit with  $g^2 N$  fixed only planar diagrams survive in this kind of theory and one obtains a string model like description as conjectured long time ago by 't Hooft [68]. This argument led later to AdS/CFT duality.

The stringy diagrams in TGD framework could correspond to planar diagrams of  $\mathcal{N} = 4$  QFT. Besides this one would have a functional integral over partonic 2-surfaces.

1. The description would be either in terms of partonic 2-surfaces or string world sheets with both determined uniquely in terms of a slicing of space-time surface with physical states characterized in terms of string world sheets in finite measurement resolution.
2.  $N \rightarrow \infty$  limit could in TGD framework be equivalent with two replacements. The color group with the infinite-D symplectic group of  $\delta M_{\pm}^4 \times CP_2$  and symplectic group and isometry group of  $H$  are replaced with their conformal variants.
3. Could  $g^2 N = \text{constant}$  be equivalent with the use of hyper-finite factors of type  $II_1$  [83] for which the trace of the unit matrix equals to 1 instead of  $\mathcal{N} = \infty$ . These factors characterize the spinor structure of WCW identifiable in terms of Clifford algebra defined by infinite-D fermionic oscillator algebra defined by second quantized fermions at partonic 2-surfaces.

### 7.6.4 Motives and twistors

Nima mentions at the end of his talk motives [11]. I know about this abstract branch of algebraic geometry only that it is an attempt to build a universal cohomology theory, which in turn is an algebraic approach to topology allowing to linearize highly non-linear situations encountered typically in algebraic geometry where topology is replaced with holomorphy which is much more stringent property and allows richer structures.

1. Physics as generalized number theory vision involving also fusion of real and p-adic number fields to a larger super structure brings algebraic geometry to the core of TGD. The partonic 2-surfaces allowing interpretation as inhabitants of the intersection of real and p-adic worlds serve as correlates for living matter in TGD Universe. They are algebraic surfaces allowing in preferred coordinates a representation in terms of polynomials with rational coefficients. Motives would be needed to understand the cohomology of these surfaces. One encounters all kinds of problems such as counting the number of rational points in the intersection of p-adic and real variants of the surface and for algebraic surfaces this reduces to the counting of rational points for real 2-surface about which algebraic geometers know a lot of. For instance, surfaces of form  $x^n + y^n + z^n = 0$  for  $n \geq 3$  appearing in Fermat's theorem are child's play since they allow only origin as a common point.

2. As cautiously concluded in "Knots and TGD" [36], the intersection form for string world sheets defines a representation of the second relative homology of space-time surface and by Poincare duality also second cohomology. "Relative" is with respect to ends of space-time at the boundaries of CDs and light-like wormhole throats. The intersection form characterizing the collection of self-intersection points at which the braid strands are forced to go through each other is almost enough to characterize connected 4-manifolds topologically by Donaldson theorem [10].
3. String world sheets define a violent unknotting procedure based on reconnections for braid strands- basic stringy vertex for closed strings- and in this manner knot invariant in the same manner as the recursion allowing to calculate the value of Jones polynomial for a given knot. Quantum TGD gives as a by-product rise to a symplectic QFT describing braids, their cobordisms, and 2-knots. It would not be surprising if the  $M$ -matrix elements would have also interpretation as symplectic covariants providing information about the topology of the space-time surface. The 2-braid theory associated with space-time surface would also characterize its topology just as ordinary knots can characterize topology of 3-manifolds.

To sum up, TGD suggests a surprisingly stringy but at the same time incredibly simple generalization of string model in which the discoveries made possible by the twistor approach to  $\mathcal{N} = 4$  SUSY find a natural generalization. Nima has realized that much more than a mere discovery of computational recipes is involved and indeed talks about T-theory. I feel that the lonely "T" is desperately yearning for the company of "G" and "D"!

### 7.6.5 Reducing non-planar diagrams to planar ones by a generalization of algorithm for calculating knot invariants?

I have been listening some lectures in Strings 2001. The lectures related to progress in the calculation of gauge theory and super-gravity amplitudes are really electrifying: one really feels the sparking enthusiasm of the speakers. Besides twistor revolution there is also other amazing progress taking place in QFT side.

At this morning I started to listen the talk of Henrik Johansson about Lie algebra structures in YM and gravitational amplitudes. I have already earlier written about the finding that there is a symmetry between kinematical numerators of the amplitudes involving polarizations and momenta on one hand and color factors on the other hand, and that one can in well defined sense express gravitational scattering amplitudes in terms of squares of YM amplitudes. This holds true for on mass shell amplitudes. The reduction of the gravitational amplitudes to squares of YM amplitudes would be incredible simplification: even 3-graviton off mass shell vertex contains about 100 terms! As a matter fact, gravitation is a gauge theory too with gauge group replaced with Poincare group so that it would not be totally surprising that this kind of duality between kinematics would hold true.

This duality is not however the topic of this posting. As Johansson was explaining the Jacobi identity for the kinematical Lie algebra I got Eureka experience. What the kinematic Jacobi identity states is following:

*The numerator for four-point amplitude with twisted legs in s-channel is expressible as a **difference of planar s- and t-channel amplitudes.***

If you did not get the association to twistor program already from this sentence, recall that the basic problem of twistor approach are non-planar diagrams. For them one cannot order the loop momenta in such a manner that the ordering would be universal and depend only on the number of loops as it is for planar diagrams without crossings. Hence one is not able to combine all diagrams to single integrand and this is related to the tricks one is forced to apply to make the loop integrals finite: same identification of loop momenta for all diagrams is not possible if one wants finiteness.

What one needs for a generalization of twistor approach to apply to non-planar diagrams is a universal identification of the loop momenta by cancelling all crossings: the amplitude itself need not be equal to the difference of the amplitudes obtained by reconnecting in two manners but could be something more general. This operation would be performed for internal lines only. For external lines it tells that the amplitudes changes possible sign when external lines are permuted. For braid statistics a more phase factor would result.

The duality of old-fashioned string models says that the difference of s- and t-channel amplitudes vanishes so that one can say that amplitudes with twisted legs vanish. Also at large  $N$  (number of

colors) limit of  $\mathcal{N} = 4$  SUSY these differences vanish and YM theory behaves like string theory and planar twistor approach should give exact answers at this limit. In TGD framework the effective replacement of gauge group with infinite-dimensional symplectic group could have the same effect. But what about finite values of  $N$  in super YM theories?

*Could one generalize the twistor approach so that one could calculate all amplitudes by recursion- not only the planar ones?*

Alert reader has of course answered already but I try to explain for non-specialists (with me included). If one has worked with braids and knots, one realizes that the expression for the amplitude as difference of planar amplitudes is analogous to what you get in elementary un-knotting operation for braids annihilating one crossing in the knot diagram! In the process you form the difference of two possible reconnections at the crossing point. If you interpret the process as time evolution, it corresponds to two vertices in which interiors of strings touch each other and reconnect in a new manner. In the construction of Jones polynomial as a knot invariant the repeated application of these un-twisting operations eventually leads to un-knot and you get as an outcome the knot invariant. Also non-planar Feynman diagram is like a knot diagram and the outcome of similar procedure should consist of only planar amplitudes.

For Feynman diagrams one cannot distinguish between upper and lower crossings of the lines. This could be interpreted by saying that both crossings give the same contribution. This is the case if untwisting gives the difference of numerators in both color and momentum degrees of freedom so that the signs cancel and the integrals of both contributions are identical despite the fact that the propagator denominators are not identical. The most general outcome would be a term proportional to the sum of the four planar contributions and one could perhaps treat the situation using twistorial methods. Proportionality coefficient could depend on dimensionless Lorentz scalars constructed from the incoming momenta of the sub-diagram with crossing and dictated to high degree by conformal invariance. Professional could probably demonstrate in five minutes that the conjecture cannot hold true.

Especially, if you have written  $N$  times "Quantum TGD as almost topological QFT ..." you get at the large  $N$  limit the vibe in your spine. Because the combinatorics of an almost topological QFT must be that of a topological QFT and because braids are basic building brick of TGD amplitudes, it should be possible to reduce all non-planar amplitudes -both those of TGD and those of  $\mathcal{N} = 4$  SUSY and even other gauge theories - by a repeated un-twisting to planar amplitudes. A generalization of the basic algorithm of knot theory would become part of twistorial Feynman diagrammatics and could perhaps also be used to *define* the integrand including also the loops with crossings!

If the proposal can be realized in some sense, the rules for calculating the twistor amplitudes would be simple.

1. You - or your knot theoretical friend- must first patiently unknot the Feynman diagrams involved by eliminating all twists using the basic formula allowing to express twisted sub-amplitude with a difference of un-twisted sub-amplitudes. You might even dream that he gives you explicit formulas for the outcome to get rid of your continual requests for help.
2. At the end of the day you get just planar diagrams and you can apply the general recursive formulas of Nima and others working for all numbers of external particles and all numbers of loops to get the *integrand*, which you should be able to integrate.
3. Unfortunately you are not! But you can knock the door of Goncharov and ask whether he could kindly perform the integral using his magic Symbolic Integration Machine [80] about which Anastasia Volovich tells in her talk "Symblifying N=4 SUSY Scattering Amplitudes".

Is this idea just a passing daydream? Or morning dream- my hungry cat forced me to wake up at 3 a'clock so that I might be hallucinating in half-sleeping state. A specialist could immediately tell where this crazy idea of Europe's (if not World's) worst Feynman diagrammatician fails.

### 7.6.6 Langlands duality, electric-magnetic duality, S-duality, finite measurement resolution, and quantum Yangian symmetry

The arguments represented in the chapter "Langlands program and TGD" [37] support the view that in TGD Universe number theoretic and geometric Langlands conjectures could be understood

very naturally. The reader is warmly recommended to consult to this chapter for a more detailed representation.

What is important is that the discussion improves considerably the understanding about TGD proper. Same can be said about other attempts to apply TGD approach to the problems of modern mathematics to which topological quantum field theories have been applied [70, 85, 37]. In particular, a connection of Langlands conjectures and Yangian symmetry emerges. The group  $G$  resp. its Langlands dual  ${}^L G$  would define what might be called twisted quantum Yangian associated with  $G$  resp.  ${}^L G$ . The Lie group  $G$  resp.  ${}^L G$  corresponds to the description of TGD in terms of partonic 2-surfaces resp. string world sheets made possible by strong form of holography in turn implied by strong form of general coordinate invariance implying also electric-magnetic duality and S-duality. Another new result is the identification of the gauge group  $G$  as a group defining the measurement resolution in the approach based on hyperfinite factors of type  $\text{II}_1$  and proposal for the concrete representation of the corresponding Kac-Moody algebra. A further unexpected outcome are S-dual descriptions of TGD in terms of open string world sheets and partonic 2-surfaces in the moduli spaces of each other. Besides TGD based view about space-time, zero energy ontology and the notion of finite measurement resolution are the basic new notions as compared with the approach of Witten and Kapustin [93] to the geometric Langlands duality.

1. Zero energy ontology (ZEO) and the related notion of causal diamond  $CD$  ( $CD$  is a short hand for the cartesian product of causal diamond of  $M^4$  and of  $CP_2$ ). ZEO leads to the notion of partonic 2-surfaces at the light-like boundaries of  $CD$  and to the notion of string world sheet. These notions are central in the recent view about TGD. One can assign to the partonic 2-surfaces a conformal moduli space having as additional coordinates the positions of braid strand ends (punctures). By electric-magnetic duality this moduli space must correspond closely to the moduli space of string world sheets.
2. Electric-magnetic duality realized in terms of string world sheets and partonic 2-surfaces. The group  $G$  and its Langlands dual  ${}^L G$  would correspond to the time-like and space-like braidings. Duality predicts that the moduli space of string world sheets is very closely related to that for the partonic 2-surfaces. The strong form of 4-D general coordinate invariance implying electric-magnetic duality and S-duality as well as strong form of holography indeed predicts that the collection of string world sheets is fixed once the collection of partonic 2-surfaces at light-like boundaries of  $CD$  and its sub- $CD$ s is known.
3. The proposal is that finite measurement resolution is realized in terms of inclusions of hyperfinite factors of type  $\text{II}_1$  at quantum level and represented in terms of confining effective gauge group [83]. This effective gauge group could be some associate of  $G$ : gauge group, Kac-Moody group or its quantum counterpart, or so called twisted quantum Yangian strongly suggested by twistor considerations. At space-time level the finite measurement resolution would be represented in terms of braids at space-time level. The braids come in two varieties correspond to braids assignable to space-like surfaces at the two light-like boundaries of  $CD$  and with light-like 3-surfaces at which the signature of the induced metric changes and which are identified as orbits of partonic 2-surfaces connecting the future and past boundaries of  $CD$ s.

There are several steps leading from  $G$  to its twisted quantum Yangian. The first step replaces point like particles with partonic 2-surfaces: this brings in Kac-Moody character. The second step brings in finite measurement resolution meaning that Kac-Moody type algebra is replaced with its quantum version. The third step brings in zero energy ontology: one cannot treat single partonic surface or string world sheet as independent unit: always the collection of partonic 2-surfaces and corresponding string worlds sheets defines the geometric structure so that multi-locality and therefore quantum Yangian algebra with multilocal generators is unavoidable. Also ZEO forces multilocality since zero energy states defining orthonormal  $M$ -matrices are define multilocal Kac-Moody type algebra with integer powers of  $S$ -matrix defining the exponent of phase factor assignable with power  $z^n$  in the loop algebra generator.

4. In finite measurement resolution geometric Langlands duality and number theoretic Langlands duality are very closely related since partonic 2-surface is effectively replaced with the punctures representing the ends of braid strands and the orbit of this set under a discrete subgroup of  $G$  defines effectively a collection of "rational" 2-surfaces. The number of the "rational" surfaces

in geometric Langlands conjecture replaces the number of rational points of partonic 2-surface in its number theoretic variant. The ability to compute both these numbers is very relevant for quantum TGD.

5. The natural identification of the associate of  $G$  is quantum Yangian of Kac-Moody type group associated with Minkowskian open string model assignable to string world sheet representing a string moving in the moduli space of partonic 2-surface. The dual group corresponds to Euclidian string model with partonic 2-surface representing string orbit in the moduli space of the string world sheets. The Kac-Moody algebra assigned with simply laced  $G$  is obtained using the standard tachyonic free field representation obtained as ordered exponentials of Cartan algebra generators identified as transversal parts of  $M^4$  coordinates for the braid strands. The importance of the free field representation generalizing to the case of non-simply laced groups in the realization of finite measurement resolution in terms of Kac-Moody algebra cannot be over-emphasized (note that in string models and conformal field theories this realization of vertex operators in terms of free fields is of comparable importance).
6. Langlands duality involves besides harmonic analysis side also the number theoretic side. Galois groups (collections of them) defined by infinite primes and integers having representation as symplectic flows defining braidings. I have earlier proposed that the hierarchy of these Galois groups define what might be regarded as a non-commutative homology and cohomology. Also  $G$  has this kind of representation which explains why the representations of these two kinds of groups are so intimately related. This relationship could be seen as a generalization of the MacKay correspondence between finite subgroups of  $SU(2)$  and simply laced Lie groups.
7. Symplectic group of the light-cone boundary acting as isometries of the WCW geometry [17] allowing to represent projectively both Galois groups and symmetry groups as symplectic flows so that the non-commutative cohomology would have braided representation. This leads to braided counterparts for both Galois group and effective symmetry group.
8. The moduli space for Higgs bundle playing central role in the approach of Witten and Kapustin to geometric Landlands program is in TGD framework replaced with the conformal moduli space for partonic 2-surfaces. It is not however possible to speak about Higgs field although moduli defined the analog of Higgs vacuum expectation value. Note that in TGD Universe the most natural assumption is that all Higgs like states are "eaten" by gauge bosons so that also photon and gluons become massive. This mechanism would be very general and mean that massless representations of Poincare group organize to massive ones via the formation of bound states. It might be however possible to see the contribution of p-adic thermodynamics depending on genus as analogous to Higgs contribution since the conformal moduli are analogous to vacuum expectation of Higgs field.

### 7.6.7 About the structure of the Yangian algebra

The attempt to understand Langlands conjecture in TGD framework led to a completely unexpected progress in the understanding of the Yangian symmetry expected to be the basic symmetry of quantum TGD and the following vision suggesting how conformal field theory could be generalized to four-dimensional context is a fruit of this work.

The structure of the Yangian algebra is quite intricate and in order to minimize confusion easily caused by my own restricted mathematical skills it is best to try to build a physical interpretation for what Yangian really is and leave the details for the mathematicians.

1. The first thing to notice is that Yangian and quantum affine algebra are two different quantum deformations of a given Lie algebra. Both rely on the notion of R-matrix inducing a swap of braid strands. R-matrix represents the projective representations of the permutation group for braid strands and possible in 2-dimensional case due to the non-commutativity of the first homotopy group for 2-dimensional spaces with punctures. The R-matrix  $R_q(u, v)$  depends on complex parameter  $q$  and two complex coordinates  $u, v$ . In integrable quantum field theories in  $M^2$  the coordinates  $u, v$  are real numbers having identification as exponentials representing Lorenz boosts. In 2-D integrable conformal field theory the coordinates  $u, v$  have interpretation as

complex phases representing points of a circle. The assumption that the coordinate parameters are complex numbers is the safest one.

2. For Yangian the R-matrix is rational whereas for quantum affine algebra it is trigonometric. For the Yangian of a linear group quantum deformation parameter can be taken to be equal to one by a suitable rescaling of the generators labelled by integer by a power of the complex quantum deformation parameter  $q$ . I do not know whether this true in the general case. For the quantum affine algebra this is not possible and in TGD framework the most interesting values of the deformation parameter correspond to roots of unity.

### Slicing of space-time sheets to partonic 2-surfaces and string world sheets

The proposal is that the preferred extremals of Kähler action are involved in an essential manner the slicing of the space-time sheets by partonic 2-surfaces and string world sheets. Also an analogous slicing of Minkowski space is assumed and there are infinite number of this kind of slicings defining what I have called Hamilton-Jacobi coordinates [8]. What is really involved is far from clear. For instance, I do not really understand whether the slicings of the space-time surfaces are purely dynamical or induced by special coordinatizations of the space-time sheets using projections to special kind of sub-manifolds of the imbedding space, or are these two type of slicings equivalent by the very property of being a preferred extremal. Therefore I can represent only what I think I understand about the situation.

1. What is needed is the slicing of space-time sheets by partonic 2-surfaces and string world sheets. The existence of this slicing is assumed for the preferred extremals of Kähler action [8]. Physically the slicing corresponds to an integrable decomposition of the tangent space of space-time surface to 2-D space representing non-physical polarizations and 2-D space representing physical polarizations and has also number theoretical meaning.
2. In zero energy ontology the complex coordinate parameters appearing in the generalized conformal fields should correspond to coordinates of the imbedding space serving also as local coordinates of the space-time surface. Problems seem to be caused by the fact that for string world sheets hyper-complex coordinate is more natural than complex coordinate. Pair of hyper-complex and complex coordinate emerge naturally as Hamilton-Jacobi coordinates for Minkowski space encountered in the attempts to understand the construction of the preferred extremals of Kähler action.

Also the condition that the flow lines of conserved isometry currents define global coordinates lead to the to the analog of Hamilton-Jacobi coordinates for space-time sheets [8]. The physical interpretation is in terms of local polarization plane and momentum plane defined by local light-like direction. What is so nice that these coordinates are highly unique and determined dynamically.

3. Is it really necessary to use two complex coordinates in the definition of Yangian-affine conformal fields? Why not to use hyper-complex coordinate for string world sheets? Since the inverse of hyper-complex number does not exist when the hyper-complex number is light-like, hyper-complex coordinate should appear in the expansions for the Yangian generalization of conformal field as positive powers only. Intriguingly, the Yangian algebra is "one half" of the affine algebra so that only positive powers appear in the expansion. Maybe the hyper-complex expansion works and forces Yangian-affine instead of doubly affine structure. The appearance of only positive conformal weights in Yangian sector could also relate to the fact that also in conformal theories this restriction must be made.
4. It seems indeed essential that the space-time coordinates used can be regarded as imbedding space coordinates which can be fixed to a high degree by symmetries: otherwise problems with general coordinate invariance and with number theoretical universality would be encountered.
5. The slicing by partonic 2-surfaces could (but need not) be induced by the slicing of  $CD$  by parallel translates of either upper or lower boundary of  $CD$  in time direction in the rest frame of  $CD$  (time coordinate varying in the direction of the line connecting the tips of  $CD$ ). These slicings are not global. Upper and lower boundaries of  $CD$  would definitely define analogs of different coordinate patches.

### Physical interpretation of the Yangian of quantum affine algebra

What the Yangian of quantum affine algebra or more generally, its super counterpart could mean in TGD framework? The key idea is that this algebra would define a generalization of super conformal algebras of super conformal field theories as well as the generalization of super Virasoro algebra. Optimist could hope that the constructions associated with conformal algebras generalize: this includes the representation theory of super conformal and super Virasoro algebras, coset construction, and vertex operator construction in terms of free fields. One could also hope that the classification of extended conformal theories defined in this manner might be possible.

1. The Yangian of a quantum affine algebra is in question. The heuristic idea is that the two R-matrices - trigonometric and rational- are assignable to the swaps defined by space-like braidings associated with the braids at 3-D space-like ends of space-time sheets at light-like boundaries of  $CD$  and time like braidings associated with the braids at 3-D light-like surfaces connecting partonic 2-surfaces at opposite light-like boundaries of  $CD$ . Electric-magnetic duality and S-duality implied by the strong form of General Coordinate Invariance should be closely related to the presence of two R-matrices. The first guess is that rational R-matrix is assignable with the time-like braidings and trigonometric R-matrix with the space-like braidings. Here one must of course be very cautious.
2. The representation of the collection of Galois groups associated with infinite primes in terms of braided symplectic flows for braid of braids of .... braids implies that there is a hierarchy of swaps: swaps can also exchange braids of ...braids. This would suggest that at the lowest level of the braiding hierarchy the R-matrix associated with a Kac-Moody algebra permutes two braid strands which decompose to braids. There would be two different braided variants of Galois groups.
3. The Yangian of the affine Kac-Moody algebra could be seen as a 4-D generalization of the 2-D Kac-Moody algebra- that is a local algebra having representation as a power series of complex coordinates defined by the projections of the point of the space-time sheet to geodesic spheres of light-cone boundary and geodesic sphere of  $CP_2$ .
4. For the Yangian the generators would correspond to polynomials of the complex coordinate of string world sheet and for quantum affine algebra to Laurent series for the complex coordinate of partonic 2-surface. What the restriction to polynomials means is not quite clear. Witten sees Yangian as one half of Kac-Moody algebra containing only the generators having  $n \geq 0$ . This might mean that the positivity of conformal weight for physical states essential for the construction of the representations of Virasoro algebra would be replaced with automatic positivity of the conformal weight assignable to the Yangian coordinate.
5. Also Virasoro algebra should be replaced with the Yangian of Virasoro algebra or its quantum counterpart. This construction should generalize also to Super Virasoro algebra. A generalization of conformal field theory to a theory defined at 4-D space-time surfaces using two preferred complex coordinates made possible by surface property is highly suggestive. The generalization of conformal field theory in question would have two complex coordinates and conformal invariance associated with both of them. This would therefore reduce the situation to effectively 2-dimensional one rather than 3-dimensional: this would be nothing but the effective 2-dimensionality of quantum TGD implied by the strong form of General Coordinate Invariance.
6. This picture conforms with what the generalization of  $D = 4 \mathcal{N} = 4$  SYM by replacing point like particles with partonic 2-surfaces would suggest: Yangian is replaced with Yangian of quantum affine algebra rather than quantum group. Note that it is the finite measurement resolution alone which brings in the quantum parameters  $q_1$  and  $q_2$ . The finite measurement resolution might be relevant for the elimination of IR divergences.

### How to construct the Yangian of quantum affine algebra?

The next step is to try to understand the construction of the Yangian of quantum affine algebra.

1. One starts with a given Lie group  $G$ . It could be the group of isometries of the imbedding space or subgroup of it or even the symplectic group of the light-like boundary of  $CD \times CP_2$  and thus infinite-dimensional. It could be also the Lie group defining finite measurement resolution with the dimension of Cartan algebra determined by the number of braid strands.
2. The next step is to construct the affine algebra (Kac-Moody type algebra with central extension). For the group defining the measurement resolution the scalar fields assigned with the ends of braid strands could define the Cartan algebra of Kac-Moody type algebra of this group. The ordered exponentials of these generators would define the charged generators of the affine algebra.

For the imbedding space isometries and symplectic transformations the algebra would be obtained by localizing with respect to the internal coordinates of the partonic 2-surface. Note that also a localization with respect to the light-like coordinate of light-cone boundary or light-like orbit of partonic 2-surface is possible and is strongly suggested by the effective 2-dimensionality of light-like 3-surfaces allowing extension of conformal algebra by the dependence on second real coordinate. This second coordinate should obviously correspond to the restriction of second complex coordinate to light-like 3-surface. If the space-time sheets allow slicing by partonic 2-surfaces and string world sheets this localization is possible for all 2-D partonic slices of space-time surface.

3. The next step is quantum deformation to quantum affine algebra with trigonometric R-matrix  $R_{q_1}(u, v)$  associated with space-like braidings along space-like 3-surfaces along the ends of  $CD$ .  $u$  and  $v$  could correspond to the values of a preferred complex coordinate of the geodesic sphere of light-cone boundary defined by rotational symmetry. Its choice would fix a preferred quantization axis for spin.
4. The last step is the construction of Yangian using rational R-matrix  $R_{q_2}(u, v)$ . In this case the braiding is along the light-like orbit between ends of  $CD$ .  $u$  and  $v$  would correspond to the complex coordinates of the geodesic sphere of  $CP_2$ . Now the preferred complex coordinate would fix the quantization axis of color isospin.

These arguments are of course heuristic and do not satisfy any criteria of mathematical rigor and the details could of course change under closer scrutiny. The whole point is in the attempt to understand the situation physically in all its generality.

### How 4-D generalization of conformal invariance relates to strong form of general coordinate invariance?

The basic objections that one can rise to the extension of conformal field theory to 4-D context come from the successes of p-adic mass calculations. p-Adic thermodynamics relies heavily on the properties of partition functions for super-conformal representations. What happens when one replaces affine algebra with (quantum) Yangian of affine algebra? Ordinary Yangian involves the original algebra and its dual and from these higher multilocal generators are constructed. In the recent case the obvious interpretation for this would be that one has Kac-Moody type algebra with expansion with respect to complex coordinate  $w$  for partonic 2-surfaces and its dual algebra with expansion with respect to hyper-complex coordinate of string world sheet.

p-Adic mass calculations suggest that the use of either algebra is enough to construct single particle states. Or more precisely, local generators are enough. I have indeed proposed that the multilocal generators are relevant for the construction of bound states. Also the strong form of general coordinate invariance implying strong form of holography, effective 2-dimensionality, electric-magnetic duality and S-duality suggests the same. If one could construct the states representing elementary particles solely in terms of either algebra, there would be no danger that the results of p-adic mass calculations are lost. Note that also the necessity to restrict the conformal weights of conformal representations to be non-negative would have nice interpretation in terms of the duality.

## 7.7 Does the exponent of Chern-Simons action reduce to the exponent of the area of minimal surfaces?

As I scanned of hep-th I found an interesting article by Giordano, Peschanski, and Seki [53] based on AdS/CFT correspondence. What is studied is the high energy behavior of the gluon-gluon and quark-quark scattering amplitudes of  $\mathcal{N} = 4$  SUSY.

1. The proposal made earlier by Aldaya and Maldacena [47] is that gluon-gluon scattering amplitudes are proportional to the imaginary exponent of the area of a minimal surface in  $AdS_5$  whose boundary is identified as *momentum space*. The boundary of the minimal surface would be polygon with light-like edges: this polygon and its dual are familiar from twistor approach.
2. Giordano, Peschanski, and Seki claim that quark-quark scattering amplitude for heavy quarks corresponds to the exponent of the area for a minimal surface in the *Euclidian* version of  $AdS_5$  which is hyperbolic space (space with a constant negative curvature): it is interpreted as a counterpart of configuration space rather than momentum space and amplitudes are obtained by analytic continuation. For instance, a universal Regge behavior is obtained. For general amplitudes the exponent of the area alone is not enough since it does not depend on gluon quantum numbers and vertex operators at the edges of the boundary polygon are needed.

In the following my intention is to consider the formulation of this conjecture in quantum TGD framework. I hasten to inform that I am not a specialist in AdS/CFT and can make only general comments inspired by analogies with TGD.

### 7.7.1 Why Chern-Simons action should reduce to area for minimal surfaces?

The minimal surface conjectures are highly interesting from TGD point of view. The weak form of electric magnetic duality implies the reduction of Kähler action to 3-D Chern-Simons terms. Effective 2-dimensionality implied by the strong form of General Coordinate Invariance suggests a further reduction of Chern-Simons terms to 2-D terms and the areas of string world sheet and of partonic 2-surface are the only non-topological options that one can imagine. Skeptic could of course argue that the exponent of the minimal surface area results as a characterizer of the quantum state rather than vacuum functional. In the following I defend the minimal interpretation as Chern-Simons terms.

Let us look this conjecture in more detail.

1. In zero energy ontology twistor approach is very natural since all physical states are bound states of massless particles. Also virtual particles are composites of massless states. The possibility to have both signs of energy makes possible space-like momenta for wormhole contacts. Mass shell conditions at internal lines imply extremely strong constraints on the virtual momenta and both UV and IR finiteness are expected to hold true.
2. The weak form of electric magnetic duality [28] implies that the exponent of Kähler action reduces to the exponent of Chern-Simons term for 3-D space-like surfaces at the ends of space-time surface inside  $CD$  and for light-like 3-surfaces. The coefficient of this term is complex since the contribution of Minkowskian regions of the space-time surface is imaginary ( $\sqrt{g_4}$  is imaginary) and that of Euclidian regions (generalized Feynman diagrams) real. The Chern-Simons term from Minkowskian regions is like Morse function and that from Euclidian regions defines Kähler function and stationary phase approximation makes sense. The two contributions differ only by imaginary coefficient if Chern-Simons term contains only contributions from wormhole throats and ends of space-time at  $CD$ s. This need not be the case.
3. Electric magnetic duality [28] leads also to the conclusion that wormhole throats carrying elementary particle quantum numbers are Kähler magnetic monopoles. This forces to identify elementary particles as string like objects with ends having opposite monopole charges. Also more complex configurations are possible.

It is not quite clear what the scale of the stringyness is. The natural first guess inspired by quantum classical correspondence is that it corresponds to the p-adic length scale of the particle

characterizing its Compton length. Second possibility is that it corresponds to electroweak scale. For leptons stringyness in Compton length scale might not have any fatal implications since the second end of string contains only neutrinos neutralizing the weak isospin of the state. This kind of monopole pairs could appear even in condensed matter scales: in particular if the proposed hierarchy of Planck constants [27] is realized.

4. Strong form of General Coordinate Invariance requires effective 2-dimensionality. In given UV and IR resolutions either partonic 2-surfaces or string world sheets form a finite hierarchy of  $CD$ s inside  $CD$ s with given  $CD$  characterized by a discrete scale coming as an integer multiple of a fundamental scale (essentially  $CP_2$  size). The string world sheets have boundaries consisting of either light-like curves in induced metric at light-like wormhole throats and space-like curves at the ends of  $CD$  whose  $M^4$  projections are light-like. These braids intersect partonic 2-surfaces at discrete points carrying fermionic quantum numbers.

This implies a rather concrete analogy with  $AdS_5 \times S_5$  duality, which describes gluons as open strings. In zero energy ontology (ZEO) string world sheets are indeed a fundamental notion and the natural conjecture is that these surfaces are minimal surfaces whose area by quantum classical correspondence depends on the quantum numbers of the external particles. String tension in turn should depend on gauge couplings -perhaps only Kähler coupling strength- and geometric parameters like the size scale of  $CD$  and the p-adic length scale of the particle.

5. Are the minimal surfaces in question minimal surfaces of the imbedding space  $M^4 \times CP_2$  or of the space-time surface  $X^4$ ? All possible 2-surfaces at the boundary of  $CD$  must be allowed so that they cannot correspond to minimal surfaces in  $M^4 \times CP_2$  unless one assumes that they emerge in stationary phase approximation only. The boundary conditions at the ends of  $CD$  could however be such that *any* partonic 2-surface correspond to a minimal surfaces in  $X^4$ . Same applies to string world sheets. One might even hope that these conditions combined with the weak form of electric magnetic duality fixes completely the boundary conditions at wormhole throats and space-like ends of space-time surface.

The trace of the second fundamental form orthogonal to the string world sheet/partonic 2-surface as sub-manifold of space-time surface would vanish: this is nothing but a generalization of the geodesic motion obtained by replacing word line with a 2-D surface. It does not imply the vanishing of the trace of the second fundamental form in  $M^4 \times CP_2$  having interpretation as a generalization of particle acceleration [77]. Effective 2-dimensionality would be realized if Chern-Simons terms reduce to a sum of the areas of these minimal surfaces.

These arguments suggest that scattering amplitudes are proportional to the product of exponents of 2-dimensional actions which can be either imaginary or real. Imaginary exponent would be proportional to the total area of string world sheets and the imaginary unit would come naturally from  $\sqrt{g_2}$ . Teal exponent proportional to the total area of partonic 2-surfaces. The coefficient of these areas would not in general be same.

The equality of the Minkowskian and Euclidian Chern-Simons terms is suggestive but not necessarily true since there could be also other Chern-Simons contributions than those assignable to wormhole throats and the ends of space-time. The equality would imply that the total area of string world sheets equals to the total area of partonic 2-surfaces suggesting strongly a duality meaning that either Euclidian or Minkowskian regions carry the needed information.

### 7.7.2 IR cutoff and connection with p-adic physics

In twistor approach the IR cutoff is necessary to get rid of IR divergences. Also in the  $AdS_5$  approach the condition that the minimal surface area is finite requires an IR cutoff. The problem is that there is no natural IR cutoff. In TGD framework zero energy ontology brings in a natural IR cutoff via the finite and quantized size scale of  $CD$  guaranteeing that the minimal surfaces involved have a finite area. This implies that also particles usually regarded as massless have a small mass characterized by the size of  $CD$ . The size scale of  $CD$  would correspond to the scale parameter  $R$  assigned with the metric of  $AdS_5$ .

1. String tension relates in  $AdS_5$  approach to the gauge coupling  $g_{YM}$  and to the number  $N_c$  of colors by the formula

$$\lambda = g_{YM}^2 N_c = \frac{R^2}{\alpha'} . \quad (7.7.1)$$

$1/N_c$ -expansion is in terms of  $1/\sqrt{\lambda}$ . The formula has an alternative form as an expression for the string tension

$$\alpha' = \frac{R^2}{\sqrt{g_{YM}^2 N_c}} . \quad (7.7.2)$$

The analog this formula in TGD framework suggests an connection with p-adic length scale hypothesis.

1. As already noticed, the natural counterpart for the scale  $R$  could be the discrete value of the size scale of  $CD$ . Since the symplectic group assignable to  $\delta M_{\pm}^4 \times CP_2$  (or the upper or lower boundary of  $CD$ ) is the natural generalization of the gauge group, it would seem that  $N_c = \infty$  holds true in the absence of cutoff. At the limit  $N_c = \infty$  only planar diagrams would contribute to YM scattering amplitudes. Finite measurement resolution must make the effective value of  $N_c$  finite so that also  $\lambda$  would be finite. String tension would depend on both the size of  $CD$  and the effective number of symplectic colors.
2. If  $\alpha'$  is characterized by the square of the Compton length of the particle,  $\lambda$  would be essentially the square of the ratio of  $CD$  size scale given by secondary p-adic lengths and of the primary p-adic length scale associated with the particle:  $\lambda = g_{YM}^2 \sqrt{p}$ , where  $p$  is the p-adic prime characterizing the particle. Favored values of the p-adic prime correspond to primes near powers of two. The effective number of symplectic colors would be  $N_c = \sqrt{p}/g_{YM}^2$  and the expansion would come in powers of  $g_{YM}^2/\sqrt{p}$ . For electron one would have  $p = M_{127} = 2^{127-1}$  so that the expansion would converge extremely fast. Together with the amazing success of the p-adic mass calculations based on p-adic thermodynamics for the scaling generator  $L_0$  [48] this suggests a deep connection with p-adic physics and number theoretic universality.

### 7.7.3 Could Kähler action reduce to Kähler magnetic flux over string world sheets and partonic 2-surfaces?

Can one consider alternative identifications of Kähler action for preferred extremals? The only alternative identification of Kähler function that I can imagine is that Kähler action proportional to the Kähler magnetic flux  $\int_{Y^2} J$  or Kähler electric flux  $\int_{Y^2} *J$  for string world sheets and possibly also partonic 2-surfaces. These fluxes are dimensionless numbers. If the weak form of electric-magnetic duality holds true also at string world sheets, the two options are equivalent apart from a proportionality constant.

1. For Kähler magnetic flux there would be no explicit dependence on the induced metric. This is in accordance with the almost topological QFT property.
2. Unless the weak form of electric-magnetic duality holds true, the Kähler electric flux has an explicit dependence on the induced metric but in a scaling invariant manner. The most obvious objection relates to the sign factor of the dual flux which depends on the orientation of the string world sheet and thus changes sign when the orientation of space-time sheet is changed by changing that of the string world sheet. This is in conflict with the independence of Kähler action on orientation. One can however argue that the orientation makes itself actually physically visible via the weak form of electric-magnetic duality and that the change of the orientation as a symmetry is dynamically broken. This breaking would be analogous to parity breaking at the level of imbedding space.

3. In [36] it is proposed that braids defined by the boundaries of string world sheets could correspond to Legendrian sub-manifolds, whereas partonic 2-surfaces could be the duals of Legendrian manifolds, so that braiding would take place dynamically. The identification of the Kähler action as Kähler magnetic flux associated with string world sheets and possibly also partonic 2-surfaces is consistent with the assumption that the extremal of Kähler action is in question. Indeed, the Legendrian property says that the projection of the Kähler gauge potential on braid strand vanishes and this expresses the extremality of the Kähler magnetic flux.

The assumption that Kähler action is proportional to Kähler magnetic flux seems to be consistent with the minimal surface property. The weak form of electric-magnetic duality gives a constraint on the normal derivatives of imbedding space coordinates at the string world sheet and minimal surface property strengthens these constraints. One could perhaps say that space-time surface chooses its shape in such a manner that the string world sheet has a minimal area.

The open questions are following.

1. Does Kähler action for the preferred extremals reduce to the area of the string world sheet or to Kähler flux, or are the representations equivalent so that the induced Kähler form would effectively define area form? If the Kähler form associated with the induced metric on string world sheet is proportional to the induced Kähler form the Kähler magnetic flux is proportional to the area and Kähler action reduces to genuine area. This condition looks like a natural additional constraint on string world sheets besides minimal surface property.
2. The proportionality of the induced Kähler form and Kähler form of the induced 2-metric implies as such only the extremal property against the symplectic variations so that one cannot have minimal surface property at imbedding space level. Minimality at space-time level is however possible since space-time surface itself can arrange the situation so that general variations deforming the string world sheet along space-time surface reduce to symplectic variations at the level of the imbedding space.
3. Does the situation depend on whether the string world sheet is in Minkowskian or Euclidian space-time region? The problem is that in Euclidian regions the value of Kähler action is positive definite and it is not obvious why the Kähler magnetic flux for Euclidian string world sheets should have a fixed sign. Could weak form of electric-magnetic duality fix the sign?

Irrespective whether the Kähler action is proportional to the total area or the Kähler electric flux over string world sheets, the theory would be exactly solvable at string world sheet level (finite measurement resolution).

#### 7.7.4 What is the interpretation of Yangian duality in TGD framework?

Minimal surfaces in both configuration space and momentum space are used in the above mentioned two articles [47, 53]. The possibility of these two descriptions must reflect the Yangian symmetry unifying the conformal symmetries of Minkowski space and momentum space in twistorial approach.

The minimal surfaces in  $X^4 \subset M^4 \times CP_2$  are natural in TGD framework. Could also the minimal surfaces in momentum space have some interpretation in TGD framework? Or more generally, what could be the interpretation of the dual descriptions provided by twistor diagrams with light-like edges and dual twistor diagrams with light-like vertices? One can imagine many interpretations but zero energy ontology suggests an especially attractive and natural interpretation of this duality as the exchange of the roles of wormhole throats carrying always on mass shell massless momenta and wormhole contacts carrying in general off-mass shell momenta and massive momenta in incoming lines.

1. For configuration space twistor diagrams vertices correspond to incoming and outgoing light-like momenta. The light-like momenta associated with the wormhole throats of the incoming and outgoing lines of generalized Feynman diagram could correspond to the light-like momenta associated with the vertices of the polygon. The internal lines defined by wormhole contacts carrying virtual off mass shell momenta would naturally correspond to edges of the twistor diagram.

2. What about dual twistor diagrams in which light-like momenta correspond to lines? Zero energy ontology implies that virtual wormhole throats carry on mass shell massless momenta whereas incoming wormhole contacts in general carry massive particles: this guarantees the absence of IR divergences. Could one identify the momenta of internal wormhole throats as light-like momenta associated with the lines dual twistor diagrams and the incoming net momenta assignable to wormhole contacts as incoming and outgoing momenta.

Also the transition from Minkowskian to Euclidian signature by Wick rotation could have interpretation in TGD framework. Space-time surfaces decompose into Minkowskian and Euclidian regions. The latter ones represent generalized Feynman diagrams. This suggests a generalization of Wick rotation. The string world sheets in Euclidian regions would define the analogs of the minimal surfaces in Euclidian  $AdS_5$  and the string world sheets in Minkowskian regions the analogs of Minkowskian  $AdS_5$ . The magnitudes of the areas would be identical so that they might be seen as analytical continuations of each other in some sense. Note that partonic 2-surfaces would belong to the intersection of Euclidian and Minkowskian space-time regions. This argument tells nothing about possible momentum space analog of  $M^4 \times CP_2$ .

## Chapter 8

# Quantum Field Theory Limit of TGD from Bosonic Emergence

### 8.1 Introduction

In TGD framework S-matrix must be constructed without the help of path integral. In TGD only fermions appear as fundamental particles. This suggests a bootstrap program in which one starts from very simple basic structures and generates the remaining n-point functions as radiative corrections. The success of twistorial unitary cut method in massless gauge theories suggests that its basic results such as recursive generation of tree diagrams might be given a status of axioms. The idea that loop momenta are light-like cannot be however be taken too seriously. Or so I thought! After an enthusiastic period with this idea I was forced to give it up only to rediscover it in a modified form inspired by the zero energy ontology and twistor approach. The idea is that both external and virtual particles are composites of massless states assignable to wormhole throats. External particles are bound states of massless states assignable to wormhole throats. For virtual particles one gives up the bound state constraint and one allows also positive and negative energy wormhole throats to obtain space-like net momenta for for wormhole throats. This framework gives extremely strong constraints on virtual momenta and implies cancellation of UV and also IR divergences. This approach is described in the [84] .

This chapter represents a humble intermediate step in the evolution of ideas. The approach is inspired by bosonic emergence which is a basic prediction of TGD and led to the approach to generalized Feynman diagrams based on Yangian symmetry [41] . Bosonic emergence suggests that one could construct the QFT limit of TGD in terms of Dirac action coupled YM gauge potentials with bosonic propagators generated radiatively. Finiteness requires that fermionic loop integrations are not free but restricted by some reasonable conditions guaranteeing finiteness and one simply tries to guess these conditions using p-adic length scale hypothesis. The so called region momenta appearing in twistor Grassmannian approach [33] have in TGD framework direct analogs as pseudo-momenta identified as generalized eigenvalues of Chern-Simons Dirac operator assigned to the wormhole throats. Pseudo-momenta are analogous to off mass shell momenta for a massless particle and for external particles they coincide with real light-like momenta. These momenta are indeed analogous to off mass shell loop momenta but not directly identifiable as net four-momenta for wormhole contacts. Number theoretic constraints suggests that pseudo-momenta are quantized and have a limited value range. Therefore the primitive QFT model of this chapter assuming that virtual momenta are restricted to a finite range in the momentum space can be said to be as a predecessor of the formulation discussed in [84] . This is the reason for why I have decided to keep it.

#### 8.1.1 The dream

Let us summarize the first variant of the dream about bootstrap approach.

1. In [15, 20] I have discussed how the "almost stringy" fermion propagator arises as one adds to the modified Dirac action a term coupling the charges in a Cartan algebra of the isometry group of  $H = M^4 \times CP_2$  to conserved fermionic currents (there are several of them). Also more

general observables allow this kind of coupling and the interpretation in terms of measurement interaction. This term also realizes quantum classical correspondence by feeding information about quantum numbers of partons to the geometry of space-time sheet so that quantum numbers entangle with the geometry of space-time sheet as holography requires. This measurement interaction was the last piece in the puzzle "What are the basic equations of quantum TGD" and unified several visions about the physics predicted by quantum TGD. "Almost stringy" means that the on mass shell fermions obey stringy mass formulas dictated by super-conformal symmetry but that propagator itself -although it depends on four-momentum- is not the inverse of super-Virasoro generator  $G_0$  as it would be in string models.

2. The identification of bosons as wormhole contacts means that bosonic propagation reduces to a propagation of fermion and antifermion at opposite throats of the wormhole throat. In this framework bosonic n-vertex would correspond to the decay of bosons to fermion-antifermion pairs in the loop. Purely bosonic gauge boson couplings would be generated radiatively from triangle and box diagrams involving only fermion-boson couplings. In particular, bosonic propagator would be generated as a self-energy loop: bosons would propagate by decaying to fermion-antifermion pair and then fusing back to the boson. TGD counterpart for gauge theory dynamics would be emergent and bosonic couplings would have form factors with IR and UV behaviors allowing finiteness of the loops constructed from them since the constraint that virtual fermion pair corresponds to wormhole contact poses strong constraint on virtual momenta of fermion and antifermion.

This picture translates to a dream about QFT limit of TGD where n-boson vertices reduce to fermionic loops defined in standard manner. Unfortunately, this dream about emergence is killed by the general arguments discussed in the chapter about twistors and TGD [82] demonstrating that one encounters UV divergences already in the construction of gauge boson propagator for both free and light-like loop momenta (suggested by twistorial ideas). The physical reason for the emergence of these divergences and also their cure at the level of principle is well-understood in TGD Universe.

1. The description in terms of number theoretic braids based on the notion of finite measurement resolution should resolve these divergences at the expense of locality. The physical picture would be provided by the identification of virtual fermion-antifermion pair as wormhole contact.
2. Zero energy ontology brings into the picture also the natural breaking of translational and Lorentz symmetries caused by the selection of the causal diamond ( $CD$ ). This breaking is compensated at the level of configuration space since all Poincare transforms of  $CD$ s are allowed in the construction of the configuration space geometry.
3. If this approach is accepted then for given  $CD$  there are natural IR and UV cutoffs for 3-momentum (perhaps more naturally for these than for mass squared). IR cutoff is quantified by the temporal distance between the tips of  $CD$  and UV cutoff by similar temporal distance of smallest  $CD$  allowed by length scale resolution. If the hypothesis that the temporal distances come as octaves of fundamental time scale given by  $CP_2$  time scale  $T_0$  and implying p-adic length scale hypothesis, the situation is fixed. A weaker condition is that the distances come as prime multiples  $pT_0$  of  $T_0$ .
4. QFT type idealization would make sense in finite measurement resolution and the loop integrals would be both IR and UV finite.

### 8.1.2 Improved dream

The arguments above lead to a modified form of the dream.

1. Only fermionic propagators are allowed and bosonic propagators emerge. Only boson-fermion coupling characterizing the decay of a wormhole contact to two  $CP_2$  type almost vacuum extremals with single wormhole throat carrying fermion and anti-fermion number would be feeded to the theory as something given and everything else would result as radiative corrections. Boson-fermion coupling would be proportional to Kähler coupling strength fixed by quantum criticality and very near or equal to fine structure constant at electron's p-adic length scale for the standard value of Planck constant. If not anything else, this approach would be predictive.

2. This approach could be tried to both free and light-like loop momenta. For free loop momenta the cutoff would be naturally associated with the mass squared of the virtual particle rather than the energy of a massless particle. Despite its Lorentz invariance one could criticize this kind of UV cutoff because it allows arbitrarily small wavelengths not in accordance with the vision about finite measurement resolution. This suggests that these cutoffs must be combined for a given p-adic length scale  $L_p$  to give  $k^\mu k_\mu \equiv M^2 \leq p$  and  $|k_0| \leq p$  using  $M_{CP_2}$  as a unit. Hence only the region defined by the intersection of the four-cube  $k_\mu \leq p$  and  $M^2 \leq p$  contributes to the phase space for cutoff defined by p-adic mass scale  $M_p$ . Its volume behaves like  $p^{3+1/2}$  rather than  $p^4$ . For space-like momenta similar situation prevails. In hyperbolic coordinates ( $k_0 = M \cosh(\eta)$ ,  $|k| = M \sinh(\eta)$ ) for time-like momenta the cutoffs correspond to ( $M \leq \sqrt{p}$ ,  $\cosh(\eta) \leq \sqrt{p}$ ). In hyperbolic coordinates for space-like momenta ( $p_0 = M \sinh(\eta)$ ,  $|p| = M \cosh(\eta)$ ) the cutoffs correspond ( $M \leq \sqrt{p}$ ,  $|\sinh(\eta)| \leq \sqrt{p}$ ).

The following considerations led to the conclusion that bosonic propagators could emerge from fermionic ones in the quantum field theory type description and that this description is also favored by the basic structure of quantum TGD. An essential element of the approach is a physical formulation for UV cutoff. A cutoff in both mass squared and hyperbolic angle is necessary since Wick rotation does not make sense in TGD framework. This approach predicts all gauge couplings and assuming a geometrically very natural hyperbolic UV cutoff motivated by zero energy ontology one can understand the evolution of standard model gauge couplings and reproduce correctly the values of fine structure constant at electron and intermediate boson length scales. Also asymptotic freedom follows as a basic prediction. The UV cutoff for the hyperbolic angle as a function of p-adic length scale is the ad hoc element of the model in its recent form, and a quantitative model for how this function could be fixed by quantum criticality is formulated and studied.

These considerations and numerical calculations lead to a general vision about how real and p-adic variants of TGD relate to each other and how p-adic fractalization takes place.

1. Only fermionic loops would be fundamental and define bosonic propagators and vertices. In twistor approach generalized Cutkosky rules allow the unitarization of the tree amplitudes in terms of  $TT^\dagger$  contribution involving only light-like momenta. Also in TGD this seems to be the only working option for the bosonic loops at massless limit and requires that  $TT^\dagger$  makes sense p-adically. The treatment of the massive case suggests the generalization of twistors to 8-D context [82].
2. The vanishing of the fermionic loops defining bosonic vertices for the incoming massless momenta emerges as a consistency condition suggested also by quantum criticality and by the fact that only BFF vertex is fundamental vertex if bosonic emergence is accepted. The vanishing of on mass shell N-vertices gives an infinite number of conditions on the hyperbolic cutoff as function of the integer  $k$  labeling p-adic length scale at the limit when bosons are massless and IR cutoff for the loop mass scale is taken to zero. These condition generalize also to the massive case and even to quantum TGD proper a first principle definition of the fermionic loops allowing in turn to define bosonic loops as discontinuity of  $TT^\dagger$  obtained by putting on particles on mass shell. It is not yet clear whether dynamical symmetries, in particular super-conformal symmetries, are involved with the realization of the vanishing conditions or whether hyperbolic cutoff is all that is needed.

This picture emerged through calculations which evolved from the first trials through the discovery of an impressive number of numerical errors related to signs factors, numerical factors, and exponents but there are reasons to believe that big blunders have been eliminated now so that one can trust the results of calculations and conclusions following from them. Calculations are also far from complete. For instance, propagator has not been calculated for space-like momenta and it is not clear whether one can trust on the naive analytical continuation. Formal rigor of course does not yet guarantee that the physical picture is correct.

### 8.1.3 SUSY improved dream

The basic criticism against the first version of the improved dream is the need to introduce explicit cutoffs in hyperbolic angle and mass squared for the fermions appearing in fermion loops. These

cutoffs should emerge from dynamics alone. The realization of super-symmetry at space-time level in TGD sense [29] requires bosonic emergence as internal consistency condition, avoids these explicit cutoffs, and leads to an UV finite theory by standard arguments about cancelation of fermion and sfermion loops in SUSYs. This realizes a 31 year old dream to a surprisingly high degree. Everything would emerge radiatively from the modified Dirac operator and boson-fermion vertices (and their super counterparts) dictated by the charge matrix of the boson coding boson as a fermion-antifermion bilinear.

The super-symmetry in question corresponds to a new variant of standard SUSY having  $\mathcal{N} = \infty$ . It is natural to ask whether a natural cutoff in the value of  $\mathcal{N}$  could emerge from the theory. The notion of braid realizing at space-time level the notion of finite measurement resolution would certainly imply this kind of cutoff since the number of fermionic oscillator operators would be finite. The so called weak form of electric-magnetic duality [28] led to a dramatic integration of various ideas related to the quantum TGD. The earlier general solution ansatz for the preferred extremals was understood in much more detailed manner and dual interpretations of solution ansatz in terms of non-linear Maxwell's electrodynamics and hydrodynamics were found [8]. It was realized that this ansatz implies automatically the reduction of TGD to almost topological QFT in the sense that Kähler function of WCW reduces to Chern-Simons term. Also Kähler Dirac equation and Chern-Simons Dirac equation were understood. In particular, the study of generalized eigen modes of Chern-Simons Dirac equation demonstrated that braids and their number theoretic variants emerge from the basic quantum TGD. Therefore the cutoff in  $\mathcal{N}$  is coded to the dynamics.

#### 8.1.4 ZEO improved dream

A new twist in the dream about finite S-matrix emerged with the realization that in zero energy ontology (ZEO) virtual particles could correspond to wormhole contacts carrying non-parallel mass shell momenta which can also correspond to opposite energies [28, 82]. It is indeed possible to have both space-like and time-like net momenta for the wormhole contact in this manner so that one would end up with a variant of the original idea about the replacement of virtual particles with on mass shell massless particles, which as such was a failure. It is strange how even the silliest looking idea seems to be an attempt of some bigger mind to communicate to the stupid theoretician something important.

On mass shell property does not lead to a disaster since the propagator is not ordinary Dirac propagator (which would of course diverge) but is defined by the Chern-Simons Dirac operator- essentially Dirac propagator for a 2-D pseudo-momentum having discrete set of allowed values. There are good arguments that the allowed pseudo-momenta correspond to hyper-complex primes and possibly a finite number of their powers so that they do not induce divergences. Also a connection with the notion of infinite prime and corresponding arithmetic quantum field theory emerges [70].

The progress was stimulated by the simple observation that on mass shell property puts enormously strong kinematic restrictions on the loop integrations. With mild restrictions on the number of parallel fermion lines appearing in vertices (there can be several since fermionic oscillator operator algebra defining SUSY algebra generates the parton states)- all loops are manifestly finite and if particles has always mass -say small p-adic thermal mass also in case of massless particles and due to IR cutoff due to the presence largest CD- the number of diagrams is finite. Unitarity reduces to Cutkosky rules [30] automatically satisfied as in the case of ordinary Feynman diagrams. The last section of the chapter is devoted to a brief summary of this approach which should have a counterpart also in the description of QFT limit of TGD. Also SUSY is consistent with the reduction of off mass shell states to pairs of on mass shell states and guarantees finiteness of the very few loop summations that remain when kinematic conditions are applied (self energy loops remain and should vanish by SUSY).

#### 8.1.5 What can one conclude?

What one can abstract from these dreams might be the following vision.

1. Bosonic emergence and its generalization implying that fermionic propagator is the basic object. Even in standard gauge theory framework this means enormous simplification if one can define UV cutoffs.
2. Generalization of SUSY and the emergence of the notion of braids implying a reduction to SUSY algebra with a finite value of  $\mathcal{N}$ . SUSY gives excellent hopes about the finiteness of the QFT

limit even when UV cutoff is not assumed.

3. The reduction of off mass shell states to pairs of on mass shell states in ZEO modifying dramatically the physical interpretation of Feynman diagrammatics and implying a manifest finiteness and unitarity of the theory. The reduction to almost topological QFT implies that fermionic propagators are for 2-D discrete pseudo-momentum rather than for real off mass shell momentum. This description as such is certainly not directly related to QFT description.

The reader should be warned that this dreaming or might it be called dream walking represents only a story about evolution of ideas and my motivation for keeping all this material is just for the fact that I feel important to be honest and confess all the side tracks that I have made. As already mentioned in the beginning, this chapter can be seen as one step leading to the twistor approach to TGD inspired by Yangian symmetry [84] .

## 8.2 Bootstrap approach to obtain a unitary S-matrix

This section summarizes the basic mathematical realization of the modified Feynman rules hoped to give rise to a unitary M-matrix (recall that M-matrix is product of a positive square root of density matrix and unitary S-matrix in TGD framework and need not be unitary in the general case). The basic idea is that bosonic propagators emerge as fermionic loops. The approach is bottom up and leads to a precise general formulation for how the counterpart of YM action emerges from Dirac action coupled to gauge bosons and to modified Feynman rules. An essential element of the approach is a physical formulation for UV cutoff. Actually cutoff in both mass squared and hyperbolic angle is needed since Wick rotation does not make sense in TGD framework. The UV cutoff for the hyperbolic angle as a function of p-adic length scale is somewhat ad hoc element of the model and a quantitative model for how this function could follow from the requirement of quantum criticality is formulated and discussed.

### 8.2.1 Quantitative realization of UV finiteness in terms of p-adic length scale hypothesis and finite measurement resolution

p-Adic fractality suggests an elegant realization of the notion of finite measurement resolution implying the finiteness of the ordinary Feynman integrals automatically but predicting divergences for light-like loop momenta.

#### Integration measure for loop integrals and cutoff

I have considered several options for the realization of the UV cutoff but one can argue that  $CP_2$  scale or equivalently, 2-adic length scale  $L_2$  defines the natural maximal UV cutoff in quantum TGD and corresponds to the maximal measurement resolution for momentum.

1. The cutoffs will be posed on both mass squared and hyperbolic angle. This conforms with the p-adic length scale hypothesis emerging from p-adic mass calculations and with the geometry of  $CDs$ . p-Adic length scales come as  $L_p \propto \sqrt{p}$ ,  $p \simeq 2^k$  rather than  $L_p \propto p$  as the proportionality  $T(p) = pT(CP_2)$  of the temporal distance between tips of the  $CD$  combined with Uncertainty Principle would suggest. The reason is that light-like randomness of partonic 3-surfaces means Brownian motion so that  $L_p \propto \sqrt{T(p)}$  and  $M_p \propto 1/\sqrt{T(p)}$  follows. To avoid confusions note that for the conventions that I have used  $T(p)$  corresponds to the secondary p-adic length scale  $T_{p,2} = \sqrt{p}T_p$ . For electron  $T(p)$  corresponds to .1 seconds.
2. Loops involve basically integrals of form

$$\int d^4 k k^{-2n} , \quad n = 1, 2, \dots \quad (8.2.1)$$

It is far from obvious whether the usual definition based on Wick rotation of the Euclidian variant of the integral makes sense in the recent case. The definition based on Wick rotation

would eliminate the divergence in the hyperbolic angle leave only a cutoff in  $k^2 \geq 0$  and give quadratic *resp.* logarithmic divergences for  $n = 1$  *resp.*  $n = 2$ . This prescription is not favored by the picture suggested by the geometry *CDs*.

3. The most natural integration measure is just the standard  $M^4$  volume element  $d^4k$ . By introducing coordinates  $(m^0, r_M) = (\epsilon \text{acosh}(\eta), \text{asinh}(\eta))$  inside future ( $\epsilon = 1$ ) and past ( $\epsilon = -1$ ) light-cones and  $(m^0, r_M) = (\text{asinh}(\eta), \text{acosh}(\eta))$  in their complement, one can write the  $M^4$  integration measure as

$$d^4k = k^3 dk \times \sinh^2(\eta) d\eta d\Omega, \quad k^2 = k^\mu k_\mu \quad (8.2.2)$$

inside future and past light-cones and

$$d^4k = k^3 dk \times \cosh^2(\eta) d\eta d\Omega \quad (8.2.3)$$

in the complement of future and past light-cones. The integration range for  $k$  is  $(0, \infty)$  in absence of cutoff.

4. The integral in the time like region involves integration over both signs of  $k^0$ . By replacing the integrand with the sum of integrand and its time reversal the integral can be restricted to the future light-cone. It should be noticed that the integrals given mass term to the bosonic propagator do not vanish unless the cutoffs for hyperbolic angle  $\eta$  in space-like and time-like regions are related in a specific manner. The reason is that  $\sinh^2(\eta)$  in time-like region is replaced with  $\cosh^2(\eta)$  space-like region.
5. The geometry of *CDs* requires IR and UV cutoffs in both mass squared and hyperbolic angle. The simplest cutoffs that one can imagine are given by

$$p_{max}^{-1/2} \leq \frac{m}{m(CP_2)} \leq p_{min}^{-1/2}, \quad 0 \leq |\sinh(\eta)| \leq |\sinh(\eta_{max})|. \quad (8.2.4)$$

The primes  $p_{max}$  and  $p_{min}$  correspond to IR and UV cutoffs and  $p_{min} \geq 2$  holds true naturally in QFT limit since stringy excitations having mass scale given by  $CP_2$  mass are not included. This means that all loop integrals are finite. The justification for the presence of cutoff in  $|\sinh(\eta)|$  comes either from the requirement that the Lorentz transformed sub-*CDs* to which the fermion loop can be associated remain inside *CD* within the time resolution used (depending on the p-adic length scale characterizing the sub-*CD*) or by the condition that the decomposition of the gauge boson to a pair of fermion and anti-fermion at opposite wormhole throats restricts the range of the virtual momenta to momenta almost at rest in the rest system of boson. The precise form of the hyperbolic cutoff is far from obvious and it turns out that the cutoff in hyperbolic angle must be assumed to depend on p-adic length scale.

6. The worst integrals in the asymptotic region identified as a p-adic length scale range characterized by prime pair  $(p_{min}, p_{max})$  are for the naivest cutoff of form

$$\begin{aligned}
\int \frac{1}{k^2} d^4k &= 4\pi(I_{t,2}I_t - I_{s,2}I_s) , & \int \frac{1}{k^4} d^4k &= 4\pi(I_{t,0}I_t + I_{s,0}I_s) , \\
I_{t,2} &= \int_0^{k_{max,t}} k dk = \frac{k_{max,t}^2}{2} , & I_{s,2} &= \int_0^{k_{max,s}} k dk = \frac{k_{max,s}^2}{2} , \\
I_{t,0} &= \int_0^{k_{max,t}} \frac{dk}{k} = \log\left(\frac{k_{max,t}}{k_{min,t}}\right) , & I_{s,0} &= \int_0^{k_{max,s}} \frac{dk}{k} = \log\left(\frac{k_{max,s}}{k_{min,s}}\right) , \\
I_t &= 4 \int_0^{\eta_{max,t}} \sinh^2(\eta) d\eta = \sinh(2\eta_{max,t}) - 2\eta_{max,t} , \\
I_s &= 2 \int_0^{\eta_{max,s}} \cosh^2(\eta) d\eta = \frac{1}{2} \sinh(2\eta_{max,s}) + \eta_{max,s} .
\end{aligned} \tag{8.2.5}$$

The mere finiteness of these integrals requires a cutoff in hyperbolic angle besides that for mass squared.

7. For a general Feynman graph with  $I$  internal lines and  $L$  loops and involving only fermions one obtains the UV behavior

$$\mu^{4L-I}$$

in absence of cancelations and using Wick rotation to define the loop integrals. This differs from the behavior for Minkowskian integrals. Only fermionic loops with single loop and  $n \geq 2$  boson vertices in the loop appear in the the TGD variant of gauge theory involving only Dirac action coupled to gauge bosons and this gives  $\mu^{4-n}$  behavior formally for bosonic n-vertex.

### $F\overline{F}$ self energy loop for gauge boson

It is instructive to calculate the  $F\overline{F}$  self energy loop for gauge boson propagator using standard Feynman rules.

1. In the section about calculation of the gauge boson propagator it is shown that after taking the trace over the product of gamma matrices the scalar factor of the loop integral multiplying the projector to physical polarization degrees of freedom can be written as

$$X = 2 \int d^4k \frac{1}{k^2(p+k)^2} \times (3p \cdot k + \frac{(p \cdot k)^2}{p^2} + k^2) . \tag{8.2.6}$$

2. If Wick rotation is used to define loop integrals mass squared term is generated. Minkowskian integration measure is however the only sensible choice. In this case one must introduce a cutoff in both mass squared and hyperbolic angle characterizing virtual fermion momentum estimated in the rest system of virtual gauge boson. p-Adic length scale hypothesis fixes the UV and IR cutoffs for mass to be p-adic mass scales and it is natural to divide the integration range to p-adic half octaves. In hyperbolic angle the form of the cutoff is not obvious and will be discussed later. Hyperbolic cutoff is expected to depend on the p-adic mass scale. Also in this case mass term is generated unless there is a precise relationship between hyperbolic cutoff in time-like and space-like regions.
3. Why the mass term of the propagator does not vanish automatically is due to the fact that the integration measures for space-like and time-like loop momenta have different dependence on the hyperbolic angle  $\eta$ . In the section about calculation of gauge boson propagator it is found that time-like and space-like contributions cancel if the time-like and space-like cutoffs for the hyperbolic angle are related by

$$- \sinh(2\eta_{max,s}) + \frac{1}{8} \sinh(4\eta_{max,s}) - \frac{5}{2} \eta_{max,s} = -2\sinh(2\eta_{max,t}) - \frac{1}{4} \sinh(4\eta_{max,t}) + 5\eta_{max,t} \tag{8.2.7}$$

For small values of  $\eta$  this gives

$$\eta_{max,s} = \frac{4}{3}\eta_{max,t}^3 . \quad (8.2.8)$$

The expressions for the non-vanishing contributions at this limit read as

$$\begin{aligned} X &= X_t + X_s , \\ X_t &= 4\pi \int_0^{\eta_{max,t}} d\eta \times \sinh^2(\eta) i_t , \quad i_t = -12\log(2)\cosh^2(\eta) , \\ X_s &= 4\pi \int_0^{\eta_{max,s}} d\eta \times \cosh^2(\eta) j_s , \quad j_s = \frac{\log(2)}{2}(2\cosh^2(\eta) - 1)(1 - \sinh^2(\eta)) . \end{aligned} \quad (8.2.9)$$

The values of the integrals are

$$\begin{aligned} X_t &= -\frac{3\pi\log(2)}{4} [\sinh(4\eta_{max,t}) - 4\eta_{max,t}] \simeq -8\pi\log(2)\eta_{t,max}^3 , \\ X_s &= \frac{\pi\log(2)}{2} \times \left[ \frac{1}{4}\sinh(4\eta_{max,s}) + \sinh(2\eta_{max,s}) + \eta_{max,s} - \frac{1}{6}\sinh^3(2\eta_{max,s}) \right] \\ &\simeq 2\pi\log(2)\eta_{max,s} \simeq \frac{8\pi\log(2)}{3}\eta_{max,t}^3 . \end{aligned} \quad (8.2.10)$$

For small values of  $\eta_{max,t}$  both contributions behave as  $\eta_{max,t}^3$  and are of opposite sign. Time-like contribution has three times larger magnitude than space-like contribution at this limit.

4. The normalization factor for the inverse of the propagator equals to  $X$  multiplied by the sum of charges squared for fermions coupling to the gauge boson. If the cutoff in the hyperbolic angle depends on p-adic length scale, one obtains

$$\left(\frac{1}{G_B}\right)^{\mu\nu} = i [p^2 g^{\mu\nu} - p^\mu p^\nu] \times \sum_{k=1}^{k_{max}} X(k) . \quad (8.2.11)$$

Here  $\sum_i Q_i^2$  represents sum over squares of charges of fermions coupling to the gauge boson.  $k = 1, \dots, k_{max}$  labels the p-adic mass scales. Electron corresponds to  $k = 127$ . The condition  $X = \frac{1}{4\pi\alpha_{em}(127)}$  poses a strong condition on the parameters of the model of hyperbolic cutoff  $\eta_{max,t}(k) = f(k)$ .

5. There is consistency with gauge invariance if the contraction of the propagator with  $p^\mu$  vanishes. This is true if the hyperbolic cutoffs in time-like and space-like region satisfy the proposed relationship. The result is very similar to what one would expect in quantum field theory so that the finite measurement resolution would not mean any dramatic effect on the propagator. The limit  $p_{min} = 2$  would correspond to a maximal UV cutoff defined by the  $CP_2$  mass scale.

The conclusion is that the definition of loop integrals as Euclidian integrals would lead to a catastrophe via the generation of gauge boson mass proportional to the cutoff mass whereas the Minkowskian definition with the notion of cutoff motivated by p-adic length scale hypothesis and hierarchy of  $CDs$  keeps gauge bosons massless if space-like and time-like hyperbolic cutoff are in a precise relationship and the only contribution to mass comes from mass terms in the fermionic propagators.

### Could bosonic propagators emerge?

The following argument suggests that emergent bosonic propagation is a mathematically consistent notion and conforms with the special features of quantum TGD.

1. In basic quantum TGD modified Dirac equation containing induced spinor connection as induced gauge boson field defines the theory and the exponent of Kähler action emerges as Dirac determinant. The natural guess is that this structure is preserved in the sense that Feynman diagrammatics is defined by Dirac action coupled to gauge potentials but containing no kinetic term for gauge potentials with kinetic terms emerging from the fermionic loops and the values of gauge couplings following as predictions of the formalism.
2. One can try to formulate this idea in terms of path integral formalism. Couple gauge bosonic field  $A$  *resp.* Grassmann valued fermion fields  $\Psi$  to external currents  $j$  *resp.* Grassmann valued external currents  $\xi$  and calculate the functional Fourier transform defined by the path integral

$$Z(j, \xi, \bar{\xi}) = \exp(G_c(j, \xi, \bar{\xi})) \equiv \int \exp \left[ iS(A, \Psi, \bar{\Psi}) - i \int (jA + \bar{\xi}\Psi + \bar{\Psi}\xi) \right] DAD\Psi D\bar{\Psi} . \quad (8.2.12)$$

Here  $G_c$  is the generating functional of connected Green's functions defined as a functional integral of Dirac action coupled to gauge potentials over  $\Psi$  and  $A$ . The functional derivatives of the effective action with respect to the  $\xi$ ,  $\bar{\xi}$  and  $j$  at  $(j = 0, \xi = 0, \bar{\xi} = 0)$  give the connected N-point functions.

One can also perform Legendre transform

$$\begin{aligned} i\Gamma(A, \Psi, \bar{\Psi}) &= G_c(j, \xi, \bar{\xi}) - i \int \left[ jA + \bar{\Psi}\xi + \int \bar{\xi}\Psi \right] , \\ A &= -i \frac{\delta}{\delta j} G_c , \quad \Psi = -i \frac{\delta}{\delta \bar{\xi}} G_c , \quad \bar{\Psi} = i \frac{\delta}{\delta \xi} G_c . \end{aligned} \quad (8.2.13)$$

to obtain the effective action  $\Gamma$ .

3.  $G_c$  can be calculated in two steps.
  - (a) At the first step one divides the Dirac action in presence of gauge field to free part and interaction term

$$\exp(iS(\Psi, \bar{\Psi}, A)) = \exp \left[ i\bar{\Psi}\gamma^\mu \partial_\mu \Psi + i \int \bar{\Psi}\gamma^\mu A_\mu \Psi \right] . \quad (8.2.14)$$

Gauge couplings have been included to gauge potentials since there is no manner to separate them uniquely in absence of the kinetic term. The path integral can be carried out perturbatively by using the general formula

$$\exp(S_c(A, \xi, \bar{\xi})) = \exp \left[ i \int \frac{\delta}{\delta \bar{\xi}} \gamma \cdot A \frac{\delta}{\delta \xi} \right] \times \exp [i\bar{\xi}G_F\xi] . \quad (8.2.15)$$

and Wick's reduction formulas.  $G_F$  fermionic Feynman propagator. This functional power series gives what can be regarded as a generating functional  $S_c(A, \xi, \bar{\xi})$  for connected Green's functions of spinor fields in the presence of external gauge fields or the analog of YM action induced by the presence of external spinor fields.

- (b) At the next step one can calculate the full generating functional  $G_c(j, \xi, \bar{\xi})$  for connected Green's functions using again the general reduction formulas by decomposing  $S_c(A, \xi, \bar{\xi})$  to a free part  $S_0(A)$  analogous to the linear part of YM action and interacting part  $S_{int}(A, \xi, \bar{\xi})$

$$S_c(A, \xi, \bar{\xi}) = S_0(A) + S_{int}(A, \xi, \bar{\xi}) . \quad (8.2.16)$$

$S_0$  defines the bosonic kinetic term which is of correct form by the preceding observations. The interaction terms for  $A$ ,  $\xi$ , and  $\bar{\xi}$  are included in  $S_{int}$ . Since the original system is gauge invariant also the effective action must be gauge invariant and should reduce to Yang-Mills action in the lowest orders. Perturbation theory is therefore possible and one can perform the path integral over  $A$  using the induced propagators and vertices. At this step fields  $\xi$  are in the role of non-dynamical external fields just as  $A$  was at the first step and all propagators are bosonic. From the resulting "partition function"  $Z$  one can generate connected N-point functions as functional derivatives with respect to the sources.

- (c) It seems that the proposed description avoids the most obvious divergences. In particular, the tadpole term from  $A_\mu \bar{\Psi}(x) \gamma^\mu \Psi(x)$  proportional to the fermion propagator  $D_F(x, x)$  proportional to an integral of form  $\int d^4 k k^\mu / k^2$  and thus vanishing.
- (d) The bosonic kinetic term would be proportional to the over all gauge coupling  $g^2$  if one expresses gauge potential in the form  $gA$ . This decomposition is however not natural in TGD since the induced spinor connection corresponds to  $gA$  with no explicit value of  $g$  being specified. In the case of simplest tree diagram describing  $2 \rightarrow 2$  fermion scattering that the  $g^2$  coming from the ends of the boson line is canceled by the  $1/g^2$  coming from the bosonic propagator so that the predictions of the theory do not depend on the value of  $g$  in the lowest order. This looks strange but would conform with the absence of bosonic kinetic term in the primary action making it impossible to identify the value of  $g$  in standard manner. One can however say that the numerical coefficient given by the fermionic loop integrals defining the bosonic propagator predicts the values of gauge couplings  $g$  through the comparison of their values with the prediction of standard gauge theory for say  $2 \rightarrow 2$  scattering. This picture would conform with the vision that TGD predicts all gauge couplings. Maybe the emergence of gauge boson propagators and vertices could be seen as one aspect of quantum criticality.

These arguments suggest that the notion of emergent gauge boson propagation makes sense mathematically and is favored also by the general structure of quantum TGD. Of course, the best strategy is the attempt to debunk the notion once and for all. Consistency with p-adic mass calculations might provide the needed killer argument.

1. The resulting bosonic mass squared would be in the lowest order sum over products of masses of fermion pairs coupling to the boson. It is far from clear whether this prediction is quantitatively consistent with the predictions of the p-adic mass calculations. This possibility is not of course excluded: boson mass squared is quadratic in fermion masses coupling to the boson and the p-adic primes associated with the fermions are naturally those associated with the boson rather than free fermions so that at least the mass scale comes out correctly. This picture conforms also qualitatively with the fact that mass squared is identified as conformal weight and the eigenvalue of modified Dirac operator related closely to the ground state contribution to the mass can be regarded as complex squares root of conformal weight.
2. Note that even photon is predicted to be massive unless the fermion and antifermion associated with photon and other massless particles are massless or in so low p-adic temperature that the thermal mass is negligible. Also the p-adic prime associated with massless bosons could be so large that the mass is small.
3. Boson masses are of course emergent in the sense that they are determined by the masses of the fermion and anti-fermion, which they consist of. The question is whether the emergence of masses takes place via loops rather than p-adic mass calculations in the proposed sense and whether these pictures are equivalent. That loops could provide the fundamental description for boson masses is suggested by the asymmetry between bosons and fermions in the recent form of

p-adic mass calculations. The p-adic temperature for bosons must be  $T_p \leq 1/2$  whereas  $T_p = 1$  holds true for fermions, and for fermions the analog of Higgs contribution is negligible whereas for gauge bosons it dominates.

4. It could be also possible to code p-adic thermodynamics into the Feynman diagrammatics in a more refined manner so that loops would give only corrections to the masses obtained from p-adic mass calculations. Instead of simply feeding in the results of p-adic mass calculations as mass parameters of the fermionic propagators, one could replace S-matrix with M-matrix involving the square root of density matrix describing the real counterpart of the partition function characterizing p-adic thermodynamics. Zero energy state would represent a square root of thermodynamical ensemble involving massless ground states and their conformal excitations rather than only ground states with thermal masses.

### The emergence of the fermionic and bosonic propagators at fundamental level

It took quite a long time to understand how stringy fermionic propagator emerges from quantum TGD. The problem was that the fermion propagator  $1/D$  defined by the modified Dirac operator assigned to Kähler action does not depend on momentum at all.

1. The resolution of the problem [15, 20] was based on the addition of a general coordinate invariant and Poincare invariant measurement interaction coupling fermionic currents to the Cartan charges of the isometry group of  $M^4 \times CP_2$  (note that Poincare group allows two types of 4-D Cartan algebras corresponding to linear and cylindrical Minkowski coordinates). The coupling occurs only at wormhole throats and involves Chern-Simons Dirac action and corresponding measurement interaction terms in accordance with the interpretation of wormhole throats as lines of the generalized Feynman diagrams. For vanishing momenta topological QFT results.
2. Also the measurement interactions for general observables can be represented in terms of this kind of couplings by utilizing the infinite hierarchy of conserved fermionic currents and their classical counterparts implied by quantum criticality realized as a vanishing of infinite number of second variations of Kähler action for preferred extremals. The critical deformations for Kähler action are special cases of the deformations for which the second variation of Chern-Simons action vanishes for each light-like 3-surface  $Y_l^3$  in the slicing of space-time sheet by light-like 3-surfaces parallel to the wormhole throat  $X_l^3$  and are therefore orthogonal to the Kähler magnetic field at each  $Y_l^3$ .
3. Quantum criticality states that the couplings induce only a  $U(1)$  gauge transformation of the Kähler function of WCW identified as Dirac determinant:  $K \rightarrow K + f + \bar{f}$ , where  $f$  is holomorphic function of WCW complex coordinates and arbitrary function of zero mode coordinates. This condition is expected to fix the values of the coupling parameters appearing in the measurement interaction. In particular, the values of gravitational constant and gauge couplings are expected to be dictated by this condition. p-Adic coupling constant evolution corresponds to the hierarchy of  $CDs$  whose size scales are assumed to come as powers of 2.
4. One can say that fermionic propagators emerge from the measurement interaction for momentum since in absence of the measurement interactions reducing to the measurement of momenta the theory reduces to a topological QFT involving only color Cartan charges. Also measurement interaction for longitudinal part of 4-momentum, spin, and rapidity is possible and the formalism of high energy hadron physics can be interpreted in terms of this measurement interaction.
5. One can define bosonic propagators by performing a path integral over fermionic loops identified as wormhole contacts with fermion and antifermion at opposite light-like throats and functional integral over WCW degrees of freedom (small deformations of wormhole throats). After that one can calculate bosonic loops- most naturally by using generalized Cutkosky rules and the generalization of twistor approach to 8-D context. The mere fact that fermion and antifermion are constrained to the throats of the wormhole contact suggests natural cutoffs for the mass squared and hyperbolic angle of virtual fermions so that divergences are expected to be absent in the fundamental theory even without the cutoff due to the finite measurement resolution. From the fermionic Feynman propagator and its bosonic counterpart one can therefore build all

diagrams (no fermionic loops at this level are present) and get finite results. The finiteness of the fundamental fermionic loops justifies the cutoffs for mass squared and hyperbolic angle forced by the finite measurement resolution.

One could of course worry whether the introduction of the p-adic length scale hierarchy might lead to problems with analyticity and unitarity. I am also the first one admit that the proposed scenario looks horribly ugly against the extreme elegance of gauge theories like  $N = 4$  SYM. The tough challenge is to find an elegant mathematical realization of the proposed physical picture and twistor approach generalized to 8-D context might be of considerable help here.

### 8.2.2 A more detailed summary of Feynman diagrammatics

The resulting Feynman diagrammatics deserves some more detailed comments.

1. Consider first the exponent of the action  $\exp(iS_c)$  resulting in fermionic path integral. The exponent

$$\exp\left[i \int dx^4 d^4 y \bar{\xi}(x) G_F(x-y) \xi(y)\right] = \exp\left[i \int d^4 k \bar{\xi}(-k) G_F(k) \xi(k)\right]$$

is combinatorially equivalent with the sum over n-point functions of a theory representing free fermions constructed using Wick's rules that is by connecting  $n$  Grassmann spinors and their conjugates in all possible ways by the fermion propagator  $G_F$ .

2. The action of

$$\exp\left[i \int d^4 x \frac{\delta}{\delta \bar{\xi}(x)} \gamma \cdot A(x) \frac{\delta}{\delta \xi(x)}\right] = \exp\left[i \int d^4 k d^4 k_1 \frac{\delta}{\delta \bar{\xi}(k-k_1)} \gamma \cdot A(-k) \frac{\delta}{\delta \xi(k_1)}\right]$$

on diagrams consisting of  $n$  free fermion lines gives sum over all diagrams obtained by connecting fermion and anti-fermion ends of two fermion lines and inserting to the resulting vertex  $A(-k)$  such that momentum is conserved. This gives sum over all closed and open fermion lines containing  $n \geq 2$  boson insertions. The diagram with single gauge boson insertion gives a term proportional to  $A_\mu(k=0) \cdot \int d^4 k k^\mu k^{-2}$ , which vanishes.

3.  $S_c$  as obtained in the fermionic path integral is the generating functional for connected many-fermion diagrams in an external gauge boson field and represented as sum over diagrams in which one has either closed fermion loop or open fermion line with  $n \geq 2$  bosons attached to it. The two parts of  $S_c$  have interpretation as the counterparts of YM action for gauge bosons and Dirac action for fermions involving arbitrary high gauge invariant n-boson couplings besides the standard coupling. An expansion in powers of  $\gamma^\mu D_\mu$  is suggestive. Arbitrary number of gauge bosons can appear in the bosonic vertices defined by the closed fermion loops and gauge invariance must pose strong constraints on the bosonic part of the action if expressible in terms of bosonic gauge invariants. The closed fermion loop with  $n = 2$  gauge boson insertions defines the bosonic kinetic term and bosonic propagator. The sign of the kinetic terms comes out correctly thanks to the minus sign assigned to the fermion loop.
4. Feynman diagrammatics is constructed for  $S_c$  using standard Feynman rules. In ordinary YM theory ghosts are needed for gauge fixing and this seems to be the case also now.
5. One can consider also the presence of Higgs bosons. Also the Higgs propagator would be generated radiatively and would be massless for massless fermions as the study of the fermionic self energy diagram shows. Higgs would be necessary  $CP_2$  vector in  $M^4 \times CP_2$  picture and  $E^4$  vector in  $M^8 = M^4 \times E^4$  picture. It is not clear whether one can describe Higgs simply as an  $M^4$  scalar. Note that TGD allows in principle Higgs boson but - according to the recent view - it does not play a role in particle massivation.

### Some differences from standard Feynman diagrammatics

The diagrammatics differs from the Feynman diagrammatics of standard gauge theories in some respects.

- 1-P irreducible self energy insertions involve always at least one gauge boson line since the simplest fermionic loop has become the inverse of the bosonic propagator. Fermionic self energy loops in gauge theories tends to spoil asymptotic freedom in gauge theories. In the recent case the lowest order self-energy corrections to the propagators of non-abelian gauge bosons correspond to bosonic loops since fermionic loops define propagators. Hence asymptotic freedom is suggestive.
2. The only fundamental vertex is  $AF\bar{F}$  vertex. As already found, there seems no point in attaching to the vertex an explicit gauge coupling constant  $g$ . If this is however done n-boson vertices defined by loops are proportional to  $g^n$ . In gauge theories n-boson vertices are proportional to  $g^{n-2}$  so that a formal consistency with the gauge theory picture is achieved for  $g = 1$ . In each internal boson line the  $g^2$  factor coming from the ends of the bosonic propagator line is canceled by the  $g^{-2}$  factor associated with the bosonic propagator. In S-matrix the division of the bosonic propagator from the external boson lines implies  $g^n$  proportionality of an n-point function involving  $n$  gauge bosons. This means asymmetry between fermions and bosons unless one has  $g = 1$ .  $g = 1$  above means  $g = \sqrt{\hbar_0}$ . Since fermionic propagator is proportional to  $\hbar_0^0$  and since loop integral involves the factor  $1/\hbar_0$ , the dimensions of bosonic propagator and radiatively generated vertices come out correctly. The counterparts of gauge coupling constants could be identified from the amplitudes for 2-fermion scattering by comparison with the predictions of standard gauge theories. The small value of effective gauge coupling  $g$  obtained in this manner would correspond to a large deviation of the normalization factor of the radiatively generated boson propagator from its standard value.
3. Furry's theorem holding true for Abelian gauge theories implies that all closed loops with an odd number of Abelian gauge boson insertions vanish. This conforms with the expectation that 3-vertices involving Abelian gauge bosons must vanish by gauge invariance. In the non-abelian case Furry's theorem does not hold true so that non-Abelian 3-boson vertices are obtained.

### Is it possible to understand the value of fine structure constant?

The basic test for the theory is whether it can predict correctly the value of fine structure constant for reasonable choice of the UV and IR cutoffs. In the first approximation one can assume that photons has only  $U(1)$  couplings to fermions so that the fermion-fermion scattering amplitude at electron's p-adic length scale is determined by the photon propagator alone.

The expansion in powers of  $p^2 - 2p \cdot k$  gives at the limit  $p^2 = 0$  the following estimate for the normalization factor of the inverse of the Abelian gauge boson propagator using 2-adic scale  $p_{min} = 2$  as UV cutoff.

$$\begin{aligned}
 \left(\frac{1}{G_B}\right)^{\mu\nu} &= i [p^2 g^{\mu\nu} - p^\mu p^\nu] \times X , \\
 X &= \sum_k [2G^t(\eta_{max,t}(k)) + G^s(\eta_{max,s}(k))] \times \log(2) \times 2\pi \sum_i Q_i^2 , \\
 G^t(\eta) &= -\frac{1}{4}\eta + \frac{1}{4}\sinh(2\eta) + \frac{1}{16}\sinh(4\eta) , \\
 G^s(\eta) &= +\frac{1}{4}\eta + \frac{1}{4}\sinh(2\eta) - \frac{1}{16}\sinh(4\eta) .
 \end{aligned}
 \tag{8.2.17}$$

Here  $\sum_i Q_i^2$  represents sum over squares of charges of fermions coupling to the gauge boson. For three lepton and quark generations one would have  $\sum_i Q_i^2 = 16$ . Here the same hyperbolic cutoff is assumed for both time-like and space-like momenta. The basic ad hoc element of the model is the choice of the cutoff in hyperbolic angle  $\eta$  and one can consider several trials.

The basic a hoc element is the physical interpretation and precise form of the hyperbolic cutoff.

1. The realization of the cutoff for the mass of the virtual particle in terms of p-adic mass scale  $m \leq m(CP_2)/\sqrt{p}$  is on a strong basis. The ad hoc assumption is the form  $|\sinh(\eta)| \leq p_{min}^{-1/2}$  for the cutoff in the hyperbolic angle. The cutoff means that the allowed range of 3-momenta for time-like momenta and of energies for time-like momenta of off mass shell particle is rather narrow for a given mass. What is clear is that any extension of the allowed phase space increases the value of  $X$  and requires larger  $p_{min}$  for this form of cutoff.
2. The narrow cutoff in the fermionic loop momenta could be interpreted physically in terms of the fermion-anti-fermion bound state character of bosons restricting the range of the virtual momenta of the fermion and anti-fermion to a very narrow range in the rest system of the boson. This is natural if fermion and antifermion reside at the opposite throats of the wormhole contact. In the case of virtual bosons radiated by leptons this restriction would not apply.
3. There is also second interpretation for the narrow cutoff. The rest system of sub- $CD$  in which the fermionic loop is calculated is assumed to be the rest system of the virtual particle. Otherwise one would obtain a breaking of Lorentz invariance. This requirement could provide an alternative justification for the cutoff in  $\cosh(\eta)$  since for too large values of  $\eta$  identified as the hyperbolic angle assignable to the lower tip of sub- $CD$  the Lorentz transform of the time coordinate  $T(p) = pT(CP_2)$  of the upper tip of sub- $CD$  is  $T = \cosh(\eta) \times pT(CP_2)$ , and could be so large that the upper tip belongs outside  $CD$ .

### 1. First trial

The first cutoff that comes in mind would be given by constant hyperbolic cutoff  $\sinh(\eta_{max}(k)) = a/\sqrt{p_{min}}$  and thus would depend on the UV cutoff length scale only. This cutoff would predict logarithmic dependence of form  $1/\alpha_{em} = \log(k_{max}/k_{min})$  on IR cutoff  $k_{max}$  and predict  $\alpha_{em}(127)/\alpha_{em}(89) = \log(127/89) \simeq .3556$  to be compared with the experimental value of about  $128/137$  so that the coupling constant evolution would be too fast.

### 2. Second trial

The first cutoff predicts too fast coupling constant evolution. Second cutoff can be seen representing another extreme.

1. For the cutoff of form

$$\cosh(\eta_{max}(k)) \leq 1 + a \times 2^{-k} \quad (8.2.18)$$

the maximal variation of the temporal distance between the tips of the Lorentz transformed  $CD$  is in good approximation  $\Delta T = (\cosh(\eta_{max}(k)) - 1)T(k) \simeq aT(CP_2)$ . For  $a < 2$   $\Delta T$  is below the optimal time resolution defined by the 2-adic time scale  $2T(CP_2)$  everywhere inside  $CD$ . Number theoretical universality favors simple rationals as values of  $a$ . The only p-adically problematic feature is the appearance of  $\log(2)$  factor in the integral. In the case of electron length scale the sum is from  $k_{min} = 1$  to  $k_{max} = 127$ . The sums are expressible in terms of geometric series for powers of  $2^{-nk}$ ,  $n = 1, \dots, 5$  and can be carried out explicitly. The fatal problem of this option is that coupling constant evolution with respect to IR cutoff is trivial expect immediately above the cutoff length scale.

### 3. Third trial

The basic criticism against the second trial is the approximate RG invariance only few octaves above UV cutoff due to the exponential decrease of loop corrections as a function p-adic length scale. Since the cutoff in hyperbolic angle is introduced in ad hoc manner one can ask whether one could fix the form of UV cutoff as a function of p-adic length scale by requiring the typical logarithmic evolution of fine structure constant in all length scales.

1. The cutoff in hyperbolic angle allowing to achieve this should depend on the logarithm of the p-adic length scale and in the simplest situation of the form

$$|\sinh(\eta) \leq a \times k^{-b} \quad , \tag{8.2.19}$$

where the proper time distance between the tips of  $CD$  is given by  $T = 2^k T(CP_2)$ . Note that the condition is equivalent with  $|\sinh(\eta)| \leq \sqrt{ab}^{a/2}$ .  $b = 1/3$  is favored as the Table 1 below shows. This is perhaps not too surprising since it implies that the contribution of p-adic length scale  $p \simeq 2^k$  to  $X$  is proportional to  $1/\log(p)$  since the contribution in good approximation scales as  $\eta_{k,max}^3(k)$ . The condition would state that the time scale resolution is roughly  $aT(2, k)/2k^b$  in the time scale defined by  $k$  so that Lorentz boosts increasing the time difference is measured in rest system with at most this amount are allowed even if they lead out from the  $CD$  containing the sub- $CD$  in question. Physically this resolution looks reasonable since it is smaller than p-adic time scale but of same order of magnitude. For prime values of  $k$  one could interpret the  $k^{-b}$  proportionality as dependence on the p-adic length scale  $L_k = \sqrt{k}T(CP_2)$  characterizing the size of the wormhole throats associated with the gauge boson.

2. The basic constraints on the parameters come from the assumption that the evolution of the fine structure constant is in the first approximation due to the evolution of IR resolution time scale fixed by  $k_{max}$ . This gives the condition  $\alpha(127)/\alpha(89) \simeq 137/128$  from which two constraints between  $a$  and  $b$  can be deduced. A further consistency constraint is that the value of the fine structure constant in  $CP_2$  length scale is sensible.
3. The evolution of non-Abelian gauge couplings would be essentially due to the bosonic loops and should induce the increase of these couplings as a function of p-adic length scale since purely fermionic loops are absent. The dependence of gauge coupling on  $p^2$  is predicted to be non-trivial since the logarithmic factors do not remain effectively constant anymore so that there are good hopes about a realistic coupling constant evolution. An interesting implication is the presence of sizable pole contributions in hyperbolic integrals from points  $\epsilon_1 m_k \exp^{\epsilon_2 \eta} = p/m_k$  and logarithmic principal values singularities at points  $\exp^{\pm \theta} = p/m_k$  ( $m_k = 2^{-k/2} m(CP_2)$ ) appearing in the arguments of logarithms. For long p-adic length scales these singularities correspond rather precisely to p-adic mass scale  $m_k$ . These contribution could be interpreted as genuinely p-adic effects.
4. The numerical calculations can be performed in exactly the same manner as for the simplest model. At  $p^2 = 0$  limit  $b = 1/3$  and  $a = 0.22050469512552$  allows to reproduce the value of fine structure constant at electron length scale ( $k_{max} = 127$ ) within the experimental accuracy and predicts  $1/\alpha_{em}(89) = 128.163120743053$  at the intermediate boson mass scale ( $k_{min} = 89$ ). In optimistic mood one could see this prediction as an indication that the model is on the right track. For  $k_{max} = 2$  the prediction is  $1/\alpha_{em}(2) = 38.73463833489691$ . As a matter fact,  $k = 1/3$  implies that k:th contribution to  $X$  which proportional to  $\eta^3$  in good approximation is proportional to integer power of  $\log(p)$ ,  $p \simeq 2^k$ . Therefore analyticity in with respect to 2-adic logarithm of p-adic length scale could replace the value of the fine structure constant at the intermediate gauge boson length scale as input.

Table 1. The table gives the values of the inverse of the fine structure constant at intermediate boson length scale ( $k = 89$ ) and at UV limit ( $k = 2$ ) for 5 different values of parameter  $b$  characterizing the UV cutoff. The value of  $a$  is deduced from the condition that fine structure constant in electron

length scale ( $k = 127$  is reproduced correctly.  $b = 1/3$  produces fine structure constant at intermediate boson length scale within experimental and theoretical uncertainties.

### The predictions for other gauge couplings

One can also look for the predictions for color and electro-weak coupling constants.

1. The loop is proportional to  $N(B_i) = Tr(Q_i^2)$ . The charge matrices are  $I_L^i$  for  $W$  bosons and  $I_L^3 - pQ_{em}$ ,  $p = \sin^2(\theta_w)$  for  $Z^0$ . For the coupling of Kähler gauge potential the charge matrix is  $Q_K = 1$  for leptons and  $Q_K = 1/3$  quarks: it is easy to see that in this case the normalization factor is same as photon. The traces of non-Abelian charge matrices in fundamental representations are  $Tr(T_a^2) = -1/2$  in the standard normalization. For photon and gluons both right and left handed chiralities contribute and  $W$  bosons only left handed.
2. This gives the following expressions for the normalization factors  $N(B_i)$

$$\alpha(B_i) = \frac{N(\gamma)}{N(B_i)} \times \alpha_{em} \quad , \quad (8.2.20)$$

$$(8.2.21)$$

with

$$N(\gamma) = N(U(1)) = 16 \quad , \quad N(g) = 6 \quad , \quad N(W) = 6 \quad , \quad N(Z) = 6 - 12p + 13p^2 \quad . \quad (8.2.22)$$

The values of the gauge couplings strengths are given by

$$\alpha(g) = \frac{8}{3}\alpha_{em} \quad , \quad \alpha(W) = \frac{8}{3}\alpha_{em} \quad , \quad \alpha(Z) = \frac{16}{6-12p+13p^2}\alpha_{em} \quad . \quad (8.2.23)$$

Electro-weak couplings are unified only if one has  $p = 12/13$ , which differs dramatically from  $p = 3/8$  obtained by definition the ratio  $\alpha_e m / \alpha_W$ , which is also the typical prediction of GUTs.

3. The table below summarizes the predictions for the bare couplings at  $p^2 = 0$  limit for photon and using  $k = 2$  scale as cutoff for the above described model characterized by the parameter  $b$  in  $\sinh(\eta_{max,t}) = a \times k^{-b}$  with  $a$  fixed by the condition that fine structure constant at electron length scale is reproduced within experimental precision.  $b = 1/3$  predicts smallest value for  $\alpha_s$  and  $1/\alpha_s(2) = 14.5255$  is consistent with  $1/\alpha_s(89) \simeq 10$ .

b	$\alpha_{em}^{-1}(2)$	$\alpha_s^{-1}(2)$	$\alpha_W^{-1}(2)$	$\alpha_Z^{-1}(2)$
1/2	78.0016	28.8792	28.8792	16.0189
1/4	22.2072	8.2537	8.2537	4.5782
$\Phi/2$	33.0427	12.5313	12.5313	7.1049
5/16	33.7706	12.8088	12.8088	7.1049
1/3	38.2719	14.5255	14.5255	8.0571

Table 2. The predictions for the bare gauge coupling strengths at the UV limit  $k = 2$  assuming  $M_{127}$  as IR cutoff and  $p = 2$  as UV cutoff and using the value of parameter  $a$  reproducing the values of fine structure constant at electron and intermediate boson p-adic mass scale.

### Cutoff in the general case

The previous calculations were carried by identifying the UV cutoff as 2-adic length scale. The calculations can be generalized to an UV cutoff defined by any p-adic length scale with  $p_{min} \simeq 2^{k_{min}}$ . The Lorentz transforms of sub-*CDs* must belong inside *CD* within measurement resolution. For the third trial one would have

$$\sinh(\eta_{t,max}) = a \times (k - k_{min} + 1)^{-b} . \quad (8.2.24)$$

The first guess for the values of  $a$  and  $b$  having are the values for  $k_{min} = 1$ .  $k \geq k_{min}$  holds of course true.

The definition of the UV cutoff for vertex corrections involves a delicacy.

1. In the vertex correction for *FFB* vertex the ends of the virtual boson line in general correspond to fermions with different four-momenta and the hyperbolic angle  $\eta$  must be assigned to the rest system of either initial or final state fermion. The choice means a selection of the arrow of geometric time and breaking of  $T$  invariance. The requirement of *CPT* symmetry is expected to fix the choice.
2. Similar situation is encountered also in basic quantum TGD. In the construction of the counterpart of stringy diagrammatics the CP breaking instanton variant of Kähler action contributes to the modified Dirac action a term whose appearance in the vertices makes the theory non-trivial [19] . One must decide, which end of the line carries the CP breaking *CP* term. *CPT* invariance is the natural constraint on the choice. The idea about fermions (anti-fermions) as particles propagating to the geometric future (past) suggests that CP breaking term is associated with the negative energy fermion (positive energy anti-fermion) at the future (past) end of the line. CP symmetry is broken since CP takes fermion to anti-fermion but does not permute the end of the lines. *CPT* is respected.
3. In the recent case the counterpart of CP and T breaking would be the assignment of the cutoff to the past (future) end in the case of fermions (antifermions). If one assigns the cutoff in both cases to (say) future end, *CPT* breaking results. It is important to notice that the distinction between future and past is always unique in the rest system of the sub-*CD*.
4. For instance, in N-vertices one must sum over all cyclic permutations with one of the vertices defining the rest system in which  $\eta$  is measured, which means modification of standard QFT picture.

### The hierarchy of Planck constants and radiative corrections

TGD predicts a hierarchy of Planck constants and the question concerns the dependence of the loop corrections on  $\hbar$ . Consider first a naive argument which does not consider the anatomy of the pages of the book like structure defining the generalized imbedding space.

1. Unless the p-adic cutoff for  $\cosh(\eta)$  depends on  $\hbar$ , boson propagator cannot involve  $\hbar$ , and this is achieved by putting  $g = \sqrt{\hbar}$  so that  $1/\hbar$  factor associated with the loop cancels  $g^2 = \hbar$ . This seems means that loops give no powers of  $1/\hbar$  as in ordinary quantum field theories. By checking a sufficient number of diagrams one can get convinced that the  $\hbar$  dependence of the diagram depends on the total number of particles involved with the diagram and is given by the proportionality  $\hbar^{(N_{in} + N_{out})/2 - 1}$ .
2. This simple dependence of the amplitudes on  $\hbar$  suggests that it has actually no physical content. The scaling of the incoming and outgoing wave functions by  $\hbar^{-1/2}$  and the division of the amplitude by  $\hbar$  indeed makes the amplitudes independent of  $\hbar$ . In unitarity conditions the  $1/\hbar$  factors from  $d^3k/2E$  factors assignable to intermediate states correspond to the  $\hbar^{-1/2}$  factors of the states involved. Therefore QFT limit defined in this manner would not distinguish between different values of  $\hbar$  and the difference is seen only at the level of kinematics ( $1/\hbar$  scaling of the frequencies and wave-vectors for a fixed four-momentum). The difference would become dynamically visible through the fact that the space-time surfaces associated with *CDs* with different values of  $\hbar$  are not simply scaled up versions of each other.

3. This result is in contrast with the standard QFT expectations about how the amplitudes should behave as functions of  $\hbar$ . One of the motivations for the hierarchy of Planck constants was that radiative corrections come in powers of  $1/\hbar$  so that large values of Planck constant improves the convergence of the perturbation series in powers of coupling constant strengths. If coupling constants emerge in the proposed manner, this motivation for large values of Planck constants is lost.

That Nature would take itself care that perturbation theory works by making a phase transition increasing  $\hbar$  and thus reducing the value of the gauge coupling strength is too attractive to be given up without fighting back. What could go wrong with the above argument is that it did not take into account the topological structure of the pages of the generalized imbedding space.

1. Recall that the generalized imbedding space has a book like structure with pages defined by Cartesian products of singular coverings and factor spaces of  $CD \subset M^4$  and  $CP_2$  ( $CD$  denotes the causal diamond defined as an intersection of future and past directed light-cones of  $M^4$ ). The coverings are labeled by an integer characterizing the number of sheets permuted by  $Z_n$  symmetry and factor spaces by an integer giving the number of points identified under  $Z_n$  symmetry. It is convenient to label them by a single number  $x$  having as its values positive integers and their inverses. Depending on whether a covering or factor space is involved, one has for  $M^4$   $x_a = n_a$  or  $x_a = 1/n_a$  and for  $CP_2$   $x_b = n_b$  or  $x_b = 1/n_b$ .
2. The inverse of the gauge boson propagator is by definition proportional to the inverse of the gauge coupling strength  $g^2/4\pi\hbar$  and therefore can be used to define Planck constant. The manner how the inverse propagator depends on the numbers  $x_a$  and  $x_b$  dictates the dependence of the Planck constant on these numbers.
3. QFT limit involves projection of all sheets of the covering to single sheet. Therefore one can argue that the inverse propagator at QFT limit should be proportional to  $n_a n_b$  if both  $M^4$  and  $CP_2$  correspond to coverings. This would reflect the that the kinetic part of bosonic action is simply a sum over identical terms from all pages of the covering. This would imply the general formula  $\hbar/\hbar_0 = x_a x_b$  giving  $\alpha = \alpha_0/x_a x_b$ . By increasing the number of sheets of coverings in  $M^4$  and  $CP_2$  degrees of freedom system would manage to remain in perturbative phase. The structure of physical states would of course change [57].
4. The earlier argument for how the Planck constant depends on  $n_a$  and  $n_b$  [27] was based on different definition of Planck constant and did not lead to quite the same prediction.
  - (a) The hypothesis inspired by Schrödinger equation was that the scaling factor of  $M^4$  metric at given page of the book is proportional to  $\hbar$ : this implies that Kähler action for preferred extremals codes for radiative corrections classically. This assumption guarantees that quantal length scales are proportional to  $\hbar$ .
  - (b) This requires that  $M^4$  covariant metric scales as  $x_a^2$ . It was assumed that  $CP_2$  metric scales in the same manner- that is as  $x_b^2$  but this was just a natural looking extrapolation from  $M^4$  case. The scale invariance of the Kähler action implying that one always re-scale the overall metric in such a manner that  $CP_2$  metric remains unchanged gives  $\hbar/\hbar_0 = x_a/x_b$  to be compared with  $\hbar = x_a x_b$  given by the above argument.
  - (c) If one however assumes that  $CP_2$  covariant metric scales as  $1/x_b^2$  rather than  $x_b^2$ , one obtains  $\hbar/\hbar_0 = x_a x_b$ . This modification is possible and has no implications concerning the predictions of the theory since there is a complete symmetry under the exchange covering space  $\leftrightarrow$  factor space. The only implication is tedious retyping of some basic formulas.

If the phase transitions changing Planck constant have a QFT type description it must be based on a 2-vertex proportional to the inverse of the fermionic propagator. If so, the fermionic kinetic term would be obtained by multiplying Dirac operator with a unitary matrix characterizing the transition amplitudes between sectors labeled by different values of Planck constant. CKM mixing would represent a highly analogous situation.

### Worrying about coupling constant evolution

Before starting to worry, some general comments about coupling constant evolution are in order.

1. Renormalization group equations can be deduced from the observation that propagators suffer simple scaling as both UV and IR cutoffs and external momenta of n-vertex are scaled up by a power of two. Therefore the effect of the scaling of external can be described as the effect caused by the 2-adic scaling of UV and IR cutoffs.
2. Coupling constant evolution can be seen to emerge in two manners. The variation of IR and UV resolution scales induces coupling constant evolution. If UV cutoff is fixed to  $CP_2$  length scale coupling constant evolution can be assigned to the IR cutoff having interpretation as time scale assignable to zero energy state: .1 seconds in case of electron's p-adic length scale which also happens to define a fundamental biorhythm. Coupling constant evolution emerges also from the dependence of the propagators and vertices on the masses of the virtual particles and in the chapter about calculation of the gauge boson propagator one finds explicit formulas for the propagator. For massless fermions all bare bosonic propagators are identical apart from overall scaling factors. In the case of vertex corrections there is dependence on Lorentz invariants defined by the external momenta and similar universality holds true for bare vertices. The coupling constants estimated in the previous calculations correspond to the IR  $p^2 = 0$  limit for the virtual massless particles.
3. There are two views about coupling constant evolution. The evolution induced by the dependence of the propagator on the mass or mass scale of the virtual gauge boson and the evolution induced by the dependence on the IR cutoff for loop momenta. How these views can be equivalent? The calculation of the propagator as function of mass of virtual gauge boson carried out in the chapter devoted to the calculation of the gauge boson propagator answers this question. The integral defining propagator has a pole at loop momentum representing same or nearly same p-adic length scale as the scale  $k_0$  assignable to  $p$ . If IR cutoff is smaller than the scale of  $p$ , the pole induces a large imaginary part to the inverse of the propagator and thus breaking of unitarity at loop momenta with mass scale below that of  $p$ . Also the sign of the normalization factor of the propagator changes sign due to the large contributions from the scales  $k$  near  $k_0$  so that the gauge coupling strength becomes negative in length scales longer than  $k_0$ . For instance, for the proposed parameterization of the hyperbolic cutoff fine structure constant for loop momenta above electron length scale  $k_0 = 127$  would have magnitude roughly two orders smaller than its value at the limit  $p^2 = 0$  so that  $p^2 = 0$  limit would have nothing to do with the behavior predicted by QFTs. The effect is somewhat analogous to what happens in confinement length scale for  $\alpha_s$ . The interpretation is that virtual bosons in p-adic length  $k_0$  can couple only to loop momenta, which correspond to shorter p-adic length scales and thus have  $k \leq k_0$ . The geometric interpretation in accordance with the vision about coupling constant evolution is that the states inside given  $CD$  couple only to loop states living inside smaller  $CD$ s. The absence of IR divergences is an obvious implication.
4. For the second trial the proposed cutoff predicts that self energy corrections are essentially independent of the choice of the IR cutoff under very mild conditions (for  $p_{min} = 2$  already  $p_{max} = 7$  corresponds to asymptotia). Same is true for the vertex corrections. This is not consistent with the physically attractive interpretation of IR cutoff (size of the largest  $CD$  involved) as the length scale defining the coupling constant evolution. For the third trial situation is quite satisfactory and there are good hopes that reasonable consistency with standard model predictions are obtained when bosonic loops are taken into account.

There are many things to worry about. One can start by worrying about the convergence of the perturbation theory.

1. The disappearance of  $\hbar$  from the perturbation expansion in terms of loops means formally  $g = 1$  condition so that all loop corrections are formally of same order of magnitude, and it might well happen that the expansion does not converge. The contribution to the loop correction comes from the region of momentum space near the UV cutoff only. In this region the four-momentum squared associated with the propagator is near its maximal value and bosonic

propagators behave as  $1/p^2$  only near  $p^2 = 0$ . The expansion in powers of  $1/p^2$  gives an expression of form  $X(\mu^2/p^2)p^2$  for the fermionic self energy loop and the bare propagator is multiplied by a factor  $X_2^{-1}(\mu^2/p^2)$ . In lowest order the loop integral behaves as  $\mu^6/p^4$  at this limit so that propagators would behave as  $p^4/\mu^6$  near UV cutoff.

2. The same effect would tend to reduce the values of the bosonic vertices identified as fermionic loops with  $n$  external gauge bosons. In this case one obtains bare vertex containing in general by a tensor formed from the incoming momenta  $p_i^\mu$  multiplied by a function  $X_n(\mu^2/p_i \cdot p_j)$ , and the powers from propagators emerging from  $n$ -vertex tend to compensate the powers of  $p$  from the fermionic propagators and the convergence of the perturbation theory depends essentially on the limiting values of the factors  $X_n$ . For instance, for bosonic  $n$ -vertex one obtains the scaling factor

$$\frac{X_n(\mu^2/(p_i \cdot p_j))}{\prod_{i=1}^n X_2^{-1}(\mu^2/p_i^2)} .$$

The convergence of the perturbation series is dictated by the behavior of these ratios at the limit  $p_i^2 \rightarrow \mu^2$ . These ratios should become smaller than unity in UV. The numerical constants in question would effectively replace gauge coupling strengths as expansion parameters for the loop corrections in accordance with universality of quantum criticality. For Option b) The main contribution to the coupling constant evolution would come from deep UV near the UV cutoff and would be also more or less independent of UV cutoff as long as it is much higher than incoming momentum scales.

There are also other reasons to worry. Are there hopes that the evolution of coupling constants as functions of incoming momenta is physically acceptable?

1. The most plausible manner to obtain a realistic coupling constant evolution relies on the proper choice of the cutoff for the hyperbolic angle. As found, for the third trial there are good hopes about realistic coupling constant evolution. This option gives good hopes for realistic coupling constant evolution in the range of momenta appearing in particle physics experiments.
2. It remains an open problem whether the quantitative form of this cutoff is deducible in the framework provided by QFT limit or whether it must be accepted as prediction of quantum TGD proper. A realistic coupling constant evolution requires that a very large number of p-adic length scales contributes to the loop integrals. This is typical for quantum criticality. As found, the cutoff in the hyperbolic angle codes for the presence of a large number of scales. Therefore the hyperbolic cutoff should be deducible from quantum criticality. Here also number theoretic Universality might provide strong constraints. One might also hope that the proposed cutoff represents maximal quantum criticality allowed by other constraints. The higher the quantum criticality as measured by the size of hyperbolic cutoff is, the weaker are the coupling strengths estimated from the scale factors of bosonic propagators so that a kind of compromise might be involved. For too large quantum fluctuations interactions get too weak and for too low a criticality they become too strong. The boundary between chaos and order would be in question.

One can also worry about whether the lowest order estimates for the coupling constants interpreted as their bare values are realistic. From the identification of gauge couplings in terms of 2-2 scattering of fermions one can conclude that the experimentally measured coupling strength involves sum over all radiative corrections so that their values can change considerably if the UV end indeed contributes significantly to the vertex corrections.

### 8.2.3 Could quantum criticality fix hyperbolic cutoff uniquely?

Quantum criticality fixes the value of Kähler coupling strength and therefore the p-adic length scale evolution of all gauge couplings. This inspires the question whether one could find a formulation of quantum criticality allowing to deduce the precise form of the hyperbolic cutoff and the dependence of bare gauge boson couplings on the mass of the virtual boson. A concrete formulation for the quantum criticality could be analogous to that for the preferred extremals of Kähler action. Criticality would

state that the matrix defining the second variation of the effective YM action becomes degenerate in some sense.

Several un-successful guesses about what this could mean at the level of propagator were made. The evolution of ideas is described in a separate section. The final proposal was that at quantum criticality all bosonic vertices defined by fermionic loop vanish when the incoming bosons are on mass shell (massless). The condition indeed realizes quantum criticality in the following sense. The vanishing of vertices is very much analogous to the vanishing of higher functional derivatives of the action with respect to gauge fields at criticality (or derivatives of the potential function in Thom's catastrophe theory). The conditions also emerge as consistency conditions: if the vanishing does not occur for on mass shell bosons, one obtains T-matrix expressible in terms of analytic continuation of  $TT^\dagger$  and one does not have vertex identified as something irreducible anymore. Also the fact that only BFF vertex is fundamental vertex if bosonic emergence is accepted, conforms with the conditions. The vanishing of on mass shell N-vertices gives an infinite number of conditions on the hyperbolic cutoff as a function of the integer  $k$  labeling p-adic length scale at the limit when bosons are massless and IR cutoff for the loop mass scale is taken to zero. It is not yet clear whether dynamical symmetries, in particular super-conformal symmetries, are involved with the realization of the vanishing conditions or whether hyperbolic cutoff is all that is needed.

### 8.3 Calculation of the bosonic propagator

The precise form of the bosonic propagator is interesting for obvious reasons. Also this calculation demonstrates the delicacies involved with the loop integration in Minkowski signature. In particular, the behavior of bosonic propagators at large momentum limit is decisive as far as convergence of perturbation theory is considered. Bosonic N-vertex involves  $N$  propagator lines and if single loop integral involves  $N$  vertices is proportional to a numerical factor  $a(N, p_i)$  the over all factor associated with bosonic N-vertex from which  $N$  internal lines emerge is proportional to  $a(N, \{p_i\})/a(2, p_i)^N$ . The behavior of this factor at the limit when the momenta  $p_i$  approach UV cutoff momentum determines the dominant contribution to the Feynman diagram in the case of loops and if  $a(2, p)$  is sufficiently large at this limit, there are good hopes for convergence. The following calculation of the bosonic propagator at UV limit gives good hopes in this respect.

#### 8.3.1 The basic integrals

The fermionic loop is given by

$$\begin{aligned} X &= -\frac{1}{S} \int d^2k \frac{1}{k^2(p+k)^2} \text{Tr}(\gamma^\mu i k^\rho \gamma_\rho \gamma^\nu i(p+k)^\sigma \gamma_\sigma) \\ S &= 2 . \end{aligned} \tag{8.3.1}$$

$S$  is the symmetry factor and  $-1$  is the factor associated with fermionic loop. Using

$$\text{Tr}(\gamma^\mu \gamma^\nu \gamma^\rho \gamma^\sigma) = 4(g^{\mu\nu} g^{\rho\sigma} - g^{\mu\rho} g^{\nu\sigma} + g^{\mu\sigma} g^{\nu\rho}) \tag{8.3.2}$$

the traces give

$$X = 2 \int d^4k \frac{1}{k^2(p+k)^2} \times (-p^\mu k^\nu - p^\nu k^\mu - 2k^\mu k^\nu + (k^2 + p \cdot k)g^{\mu\nu}) . \tag{8.3.3}$$

The contraction with the tensor  $P^{\mu\nu}/3$ , where

$$P^{\mu\nu} = g^{\mu\nu} - \frac{p^\mu p^\nu}{p^2} \tag{8.3.4}$$

acts as a projector dropping out polarizations in the direction of momentum, should give the integral as  $XP^{\mu\nu}$  assuming that the gauge invariance of Dirac action is not broken. The projection gives the expression

$$X = 2 \int d^4k \frac{1}{k^2(p+k)^2} \times (3p \cdot k + \frac{(p \cdot k)^2}{p^2} + k^2) \times P^{\mu\nu} . \quad (8.3.5)$$

The calculation of the integral reduces to that for the following three integrals

$$I = 6 \int d^4k \frac{p \cdot k}{k^2(p+k)^2} , \quad J = 2 \int d^4k \frac{1}{(p+k)^2} , \quad K = \frac{2}{p^2} \int d^4k \frac{(p \cdot k)^2}{k^2(p+k)^2} \quad (8.3.6)$$

using the cutoff prescription motivated by the notion of measurement resolution. It is assumed that the momentum  $p$  is time-like. It is not clear whether straightforward analytic continuation allows to deduce the propagator in space-like region.

The integrals over  $k$  can be decomposed to sums of two pieces corresponding to time-like and space-like  $k$ .

$$I = I_t + I_s , \quad J = J_t + J_s , \quad K = K_t + K_s . \quad (8.3.7)$$

In the rest system of the virtual boson the denominator reads in the two cases as

$$\begin{aligned} (p+k)^2 &= p^2 + k^2 + 2pk \times \cosh(\eta) \quad (\text{time-like case}) , \\ (p+k)^2 &= p^2 - |k^2| + 2p|k| \times \sinh(\eta) \quad (\text{space-like case}) . \end{aligned} \quad (8.3.8)$$

From hitherto  $|k^2| \equiv k^2$  will be used to simplify the notation. The space-like case differs from time-like one by  $\cosh(\eta) \rightarrow \sinh(\eta)$  replacements and by the fact that the denominator can vanish so that loop can have an imaginary "dispersive" contribution from the propagator pole which could reduce the normalization factor of the propagator.

Whatever the detailed definitions of the loop integral is, it must satisfy the basic constraint that the integral at the  $p^2 = 0$  limit behaves as  $p^2$  and also its first derivatives with respect to the momentum components vanish: or more generally, the integral is even function of  $p$ .

### 8.3.2 How to avoid generation of mass term?

$p^2 = 0$  limit of the fermionic loop can be deduced by putting  $p^\mu = 0$  in the integrals  $I$  and  $J$ . This gives

$$\begin{aligned} I_s &= 0 , & I_t &= 0 , \\ J_s &= -4\pi \int kdk \int 2\cosh^2(\eta) d\eta , & J_t &= 8\pi \int kdk \int 2\sinh^2(\eta) d\eta , \\ K_s &= 4\pi \int kdk \int 2\cosh^2(\eta) \sinh^2(\eta) d\eta & K_t &= 8\pi \int kdk \int 2\sinh^2(\eta) \cosh^2(\eta) d\eta . \end{aligned} \quad (8.3.9)$$

. Note that the two signs of  $k_0$  in the time-like case give additional factor two. A mass term is generated unless these integrals sum up to zero. The vanishing is achieved if one chooses the hyperbolic cutoffs in time-like and space-like regions to guarantee this. The condition is

$$(J_s + K_s)(\eta_{max,s}) = -(I_t + K_t)(\eta_{max,t}) . \quad (8.3.10)$$

From

$$\begin{aligned} I_s &= 0 , & I_t &= 0 , \\ J_s &= -8\pi \int kdk \int \cosh^2(\eta) d\eta , & J_t &= 16\pi \int kdk \int \sinh^2(\eta) d\eta , \\ K_s &= 8\pi \int kdk \int \cosh^2(\eta) \sinh^2(\eta) d\eta , & K_t &= 16\pi \int kdk \int \sinh^2(\eta) \cosh^2(\eta) d\eta , \end{aligned} \quad (8.3.11)$$

and using

$$\begin{aligned} \int \cosh^2(\eta) d\eta &= \frac{1}{4} \sinh(2\eta) + \frac{\eta}{2} , & \int \sinh^2(\eta) d\eta &= \frac{1}{4} \sinh(4\eta) - \frac{\eta}{2} , \\ \int \sinh^2(\eta) \cosh^2(\eta) d\eta &= \frac{1}{32} \sinh(4\eta) - \frac{1}{8} \eta \end{aligned} \quad (8.3.12)$$

one obtains

$$\begin{aligned} (J_s + K_s)(\eta_{max,s}) &\propto 4 \int_0^{\eta_{max,s}} d\eta \times [-\cosh^2(\eta) + \cosh^2(\eta) \sinh^2(\eta)] \\ &= -\sinh(2\eta_{max,s}) + \frac{1}{8} \sinh(4\eta_{max,s}) - \frac{5}{2} \eta_{max,s} , \\ (J_t + K_t)(\eta_{max,s}) &\propto 4 \int_0^{\eta_{max,s}} d\eta (2\sinh^2(\eta) + 2\cosh^2(\eta) \sinh^2(\eta)) \\ &= 2\sinh(2\eta_{max,t}) + \frac{1}{4} \sinh(4\eta_{max,t}) - 5\eta_{max,t} . \end{aligned} \quad (8.3.13)$$

This gives the condition

$$\begin{aligned} -\sinh(2\eta_{max,s}) + \frac{1}{8} \sinh(4\eta_{max,s}) - \frac{5}{2} \eta_{max,s} \\ = -2\sinh(2\eta_{max,t}) - \frac{1}{4} \sinh(4\eta_{max,t}) + 5\eta_{max,t} . \end{aligned} \quad (8.3.14)$$

The conditions should make sense for arbitrary small values of  $\eta_{max,i}$ . The Taylor expansion to third order gives

$$\eta_{max,s} = \frac{4}{3} \eta_{max,t}^3 \quad (8.3.15)$$

so that this indeed the case. The hyperbolic cutoff for space-like momenta would be considerably tighter than for time-like momenta so that in long length scales time-contributions to the loop integral expected to dominate.

As always, one can criticize.

1. The relationship between time-like and space-like hyperbolic cutoffs is number theoretically cumbersome.
2. In super-symmetric gauge theories [69] loops do not generate mass corrections because super-symmetry implies the vanishing of leading mass corrections. In TGD standard form of SUSY does not seem to be realized but the generalization of this symmetry to super-conformal symmetry might imply the same and even something much more general. This would allow the time-like and space-like hyperbolic cutoffs to be identical and one could avoid the number theoretically cumbersome relationship between the two cutoffs. In fact, in accordance with quantum criticality all loop corrections could vanish for N-point functions with massless external particles with physical polarizations. This would be consistent with the vanishing of the on mass shell inverse propagator. This line of thought will be developed in the last section of the chapter.

### 8.3.3 Explicit form of the integrals

In the space-like case one has

$$\begin{aligned}
I_1 &= I_{pole,1} + I_{P,1} , \\
I_{pole,1} &= -6i\pi p \int d^4k \times \frac{p \cdot k}{k^2} \delta((p+k)^2) , \quad I_{P,1} = 6P \int d^4k \times \frac{p \cdot k}{k^2(p+k)^2} , \\
J_1 &= J_{pole,1} + J_{P,1} , \\
J_{pole,1} &= -2i\pi \int d^4k \times \delta((p+k)^2) , \quad J_{P,1} = 2P \int d^4k \frac{1}{(p+k)^2} , \\
K_1 &= K_{pole,1} + K_{P,1} , \\
K_{pole,1} &= -2i\pi \int d^4k \frac{(p \cdot k)^2}{p^2} \times \delta((p+k)^2) , \quad K_{P,1} = 2P \int d^4k \frac{(p \cdot k)^2}{p^2} \frac{1}{(p+k)^2} .
\end{aligned} \tag{8.3.16}$$

$P$  denotes principal value integral.

### Principal value contributions

In the calculation of principal value contributions one must notice that both signs of  $k_0$  are possible in time-like case. One can also restrict the integration range over  $\eta$  to positive value of  $\eta$  by appropriate arrangement of contribution from different signs of  $\eta$ . In space-like case this gives to terms corresponding to different signs  $\epsilon_s$  of  $\sinh(\eta(2))$  and in time-like case just a factor of 2. Different signs of energy give to terms corresponding to different signs  $\epsilon_t$  of  $p \cdot k = \pm pk \cosh(\eta)$ .

The principal value contributions to space-like integrals can be written as

$$\begin{aligned}
I_P^s &= 4\pi \int_0^{\eta_{max,s}} d\eta \times \cosh^2(\eta) \times i_s , \quad i_s = -3p \sum_{\epsilon_s} \epsilon_s \sinh(\eta) \int dk \frac{k^2}{p^2 - k^2 + 2\epsilon_s pk \sinh(\eta)} , \\
J_{P,1}^s &= 4\pi \int_0^{\eta_{max,s}} d\eta \times \cosh^2(\eta) \times j_s , \quad j_s = 2 \sum_{\epsilon_s} \int dk \frac{k^3}{p^2 - k^2 + 2\epsilon_s pk \sinh(\eta)} , \\
K_{P,1}^s &= 4\pi \int_0^{\eta_{max,s}} d\eta \times \cosh^2(\eta) \times k_s , \quad k_s = 2 \sum_{\epsilon_s} \int dk \frac{k^3 \sinh^2(\eta)}{p^2 - k^2 + 2\epsilon_s pk \sinh(\eta)} .
\end{aligned} \tag{8.3.17}$$

One must be very careful with the sign factors. In the time-like case one has only principal value contributions and one obtains very similar expressions

$$\begin{aligned}
I_P^t &= 4\pi \int_0^{\eta_{max,t}} d\eta \times \sinh^2(\eta) \times i_t , \quad i_t = 6p \cosh(\eta) \sum_{\epsilon_t} \epsilon_t \int dk \frac{k^2}{p^2 + k^2 + 2\epsilon_t pk \cosh(\eta)} , \\
J_P^t &= 4\pi \int_0^{\eta_{max,t}} d\eta \times \sinh^2(\eta) \times j_t , \quad j_t = 2 \sum_{\epsilon_t} \int dk \frac{k^3}{p^2 + k^2 + 2\epsilon_t pk \cosh(\eta)} , \\
K_{P,1}^t &= 4\pi \int_0^{\eta_{max,t}} d\eta \times \cosh^2(\eta) \times k_t , \quad k_t = 2 \sum_{\epsilon_t} \int dk \frac{k^3 \cosh^2(\eta)}{p^2 - k^2 + 2\epsilon_t pk \sinh(\eta)} .
\end{aligned} \tag{8.3.18}$$

An additional factor two results from the fact that  $\eta \geq 0$  is assumed. In time-like case there is contribution from both signs of  $k^0$  so that one obtains also an integral in which  $k$  is replaced with its negative in the denominator.

### Pole contributions

The poles of the integrand are given by

$$\begin{aligned}
k_{\epsilon_1, \epsilon_2}^s &= \epsilon_1 p \times \exp(\epsilon_2 \eta) \text{ (space-like case)} , \\
k_{\epsilon_1, \epsilon_2}^t &= \epsilon_2 p \times \exp(\epsilon_1 \eta) \text{ (time-like case)} , \quad \epsilon_i = \pm 1 .
\end{aligned} \tag{8.3.19}$$

Note that  $\epsilon_1$  refers to the roots associated with the same denominator and  $\epsilon_2$  to different denominators. For space-like (time-like) case only  $\epsilon_1 = 1$  ( $\epsilon_2 = 1$ ) gives a pole in the physical region. The differences of the roots will be needed in the calculations and are given by

$$\begin{aligned} k_{+,\epsilon_2}^s - k_{-,\epsilon_2}^s &= 2p \exp(\epsilon_2 \eta) \quad (\text{space-like case}) , \\ k_{+,\epsilon_2}^t - k_{-,\epsilon_2}^t &= 2p \epsilon_2 \sinh(\eta) \quad (\text{time-like case}) . \end{aligned} \quad (8.3.20)$$

The pole contribution is present for both space-like and time-like cases. The delta function  $\delta((p+k)^2)$  can be written in terms of  $k$  and  $\eta$ . In the time-like case as

$$\begin{aligned} \delta((p+k)^2) d^4 k &= \delta(p+k)^2 \frac{\partial(k, \eta)}{\partial((p+k)^2, \eta)} d((p+k)^2) \sinh^2(\eta) d\eta d\Omega , \\ \frac{\partial(k, \eta)}{\partial((p+k)^2, \eta)} &= \frac{1}{p} \times \frac{1}{2 \cosh(\eta) + \epsilon_1 \sinh(\eta)} . \end{aligned} \quad (8.3.21)$$

In the space-like case one has

$$\begin{aligned} \delta((p+k)^2) d^4 k &= \delta(p+k)^2 \frac{\partial(k, \eta)}{\partial((p+k)^2, \eta)} d((p+k)^2) \cosh^2(\eta) d\eta d\Omega , \\ \frac{\partial(k, \eta)}{\partial((p+k)^2, \eta)} &= \frac{1}{p} \times \frac{1}{-\cosh(\eta)} . \end{aligned} \quad (8.3.22)$$

The integration over  $\Omega$  gives a factor of  $4\pi$ . By combining integrals over  $\eta$  to integral over positive values of  $\eta$  one finds that  $I_{pole}^s$  vanishes since  $\epsilon_2 \rightarrow -\epsilon_2$  is equivalent with  $\eta \rightarrow -\eta$ . Similar vanishing takes place for  $I_{pole}^t$  since different signs of energy give different sign for  $p \cdot k$  factor.  $\eta \rightarrow -\eta$  corresponds to  $\epsilon_1 \rightarrow -\epsilon_1$  for  $I_{pole}^t$  and to  $\epsilon_1 \rightarrow -\epsilon_1$  for  $J_{pole}^s$  and in both cases one obtains factor 2. Hence the contribution from the poles  $k_{\epsilon_1, \epsilon_2}$  can be written as

$$\begin{aligned} I_{pole}^s &= 0 , \quad I_{pole}^t = 0 , \\ J_{pole, \epsilon_2}^s + K_{pole, \epsilon_2}^s &= -i 16 \pi^2 p^2 \int_0^{\eta_{max, s}} d\eta \times (1 - \sinh^2(\eta)) \times \cosh^2(\eta) \frac{\exp(3\epsilon_2 \eta)}{-\cosh(\eta)} , \\ J_{pole, \epsilon_1}^t + K_{pole, \epsilon_1}^t &= -i 32 \pi^2 p^2 \int_0^{\eta_{max, t}} d\eta \times (1 + \cosh^2(\eta)) \times \sinh^2(\eta) \frac{\exp(3\epsilon_1 \eta)}{2 \cosh(\eta) + \epsilon_1 \sinh(\eta)} , \end{aligned} \quad (8.3.23)$$

Pole contributions in the time-like case involve additional factor 2 due to the two signs of  $k^0$ . One must integrate separately the pole contributions corresponding to different signs of  $\epsilon_i$ . The reason is that the integration limits for  $\eta$  are in general different because the upper or lower limit for  $\eta$  integration can be reduced or increased since  $k_{\pm}$  must belong to the half octave in question. The determination of the bounds of hyperbolic integral requires a special care. This point is discussed in the chapter devoted to the calculation of the gauge boson propagator.

Note that the poles give a small imaginary contribution to the kinetic term corresponding to free theory and imply a breaking of unitarity. The masses of the poles are in good approximation equal to  $k^2 = p^2$  for small values of  $p$ .

### 8.3.4 k-integration for the principal value parts of the integrals

The integrals over  $k$  reduce to integrals of rational functions using the general expression for poles given in Eq. 8.3.19. Each octave in momentum space gives its own contribution.

The integrals to be calculated are

$$\begin{aligned}
i_s &= -3p \sinh(\eta) \sum_{\epsilon_s} \epsilon_s \int dk \frac{k^2}{p^2 - k^2 + 2\epsilon_s p k \sinh(\eta)} , \\
i_t &= 6p \cosh(\eta) \sum_{\epsilon_t = \pm 1} \epsilon_t \int dk \frac{k^2}{p^2 + k^2 + 2\epsilon_t p k \cosh(\eta)} , \\
j_s + k_s &= (1 - \sinh^2(\eta)) \sum_{\epsilon_s} \int dk \frac{k^3}{p^2 - k^2 + 2\epsilon_s p k \sinh(\eta)} , \\
j_t + k_t &= 2(1 + \cosh^2(\eta)) \sum_{\epsilon_t} \int dk \frac{k^3}{p^2 + k^2 + 2\epsilon_t p k \cosh(\eta)} .
\end{aligned} \tag{8.3.24}$$

The  $k$ -integral is over the half-octave  $[2^{(-k-1)/2}, 2^{-k/2}]m(CP_2)$ . The poles can be written as  $k_{\epsilon_s}^s = \epsilon p \times \exp(\epsilon \epsilon_s \eta)$  in space-like case and as  $k_{\epsilon_t}^t = -\epsilon_t p \times \exp(\epsilon \epsilon_t \eta)$  in time-like case. One can express the denominators appearing in the integrands in terms of them as

$$\begin{aligned}
\frac{1}{p^2 - k^2 + 2\epsilon_s p k \sinh(\eta)} &= \frac{1}{k_{+\epsilon_s}^s - k_{-\epsilon_s}^s} \sum_{\epsilon} \frac{\epsilon}{k - p \epsilon \exp(\epsilon \epsilon_s \eta)} \\
&= \frac{1}{2p \exp(\epsilon_s \eta)} \times \left[ \frac{1}{k - p \times \exp(\epsilon_s \eta)} - \frac{1}{k + p \times \exp(-\epsilon_s \eta)} \right] , \\
\frac{1}{p^2 + k^2 + 2\epsilon_t p k \cosh(\eta)} &= \frac{1}{k_{+\epsilon_t}^t - k_{-\epsilon_t}^s} \sum_{\epsilon} \frac{\epsilon}{k - p \epsilon \exp(\epsilon \epsilon_t \eta)} \\
&= -\frac{1}{p \sinh(\eta)} \times \left[ \frac{1}{k - p \epsilon_t \exp(\epsilon_t \eta)} - \frac{1}{k - p \times \epsilon_t \exp(-\epsilon_t \eta)} \right] .
\end{aligned} \tag{8.3.25}$$

This gives

$$\begin{aligned}
i_s &= -\frac{3 \sinh(\eta)}{2} \int dk \times k^2 \left[ \exp(-\eta) \left( \frac{1}{k - p \times \exp(\eta)} - \frac{1}{k + p \times \exp(\eta)} \right) \right. \\
&\quad \left. - \exp(\eta) \left( \frac{1}{k - p \times \exp(-\eta)} - \frac{1}{k + p \times \exp(-\eta)} \right) \right] , \\
i_t &= -6 \frac{\cosh(\eta)}{\sinh(\eta)} \int dk \times k^2 \left[ \frac{1}{k - p \times \exp(\eta)} - \frac{1}{k - p \times \exp(-\eta)} \right. \\
&\quad \left. - \frac{1}{k + p \times \exp(-\eta)} + \frac{1}{k + p \times \exp(\eta)} \right] , \\
j_s + k_s &= \frac{(1 - \sinh^2(\eta))}{2p} \int dk \times k^3 \left[ \exp(-\eta) \left( \frac{1}{k - p \times \exp(\eta)} - \frac{1}{k + p \times \exp(\eta)} \right) \right. \\
&\quad \left. + \exp(\eta) \left( \frac{1}{k - p \times \exp(-\eta)} - \frac{1}{k + p \times \exp(-\eta)} \right) \right] , \\
j_t + k_t &= -\frac{2(1 + \cosh^2(\eta))}{p \sinh(\eta)} \int dk \times k^3 \left[ \frac{1}{k - p \times \exp(\eta)} + \frac{1}{k - p \times \exp(-\eta)} \right. \\
&\quad \left. + \frac{1}{k + p \times \exp(-\eta)} - \frac{1}{k + p \times \exp(\eta)} \right] ,
\end{aligned}$$

One must calculate integrals of form  $i_n = \int_a^b dk \frac{k^n}{k-K}$ . Taking  $k_1 = k - K$  as the integration variable, using binomial expansions, the transformation of integration limits  $[a, b]$  to  $[a - K, b - K]$ , and the expressions for the integration limits given by  $[a, b] = [2^{-(k+1)/2}, 2^{-k/2}] \times m(CP_2) \equiv [2^{-1/2}, 1]m_k$  (the  $k$  in  $p \simeq 2^k$  should not be confused with the integration variable) one obtains

$$\begin{aligned}
 i_n &= \int dk \frac{k^n}{k-K} = \sum_{m=1}^n \frac{b(n,m)}{m} \times K^{n-m} \left[ \sum_{r=0}^{m-1} (-1)^r \times b(m,r) \times (b^{m-r} - a^{m-r}) K^r \right] \\
 &+ K^n \log\left(\left|\frac{b-K}{a-K}\right|\right), \quad b(n,m) = \frac{n!}{(n-m)!m!}, \\
 (a,b) &= (2^{-1/2}, 1)m_k, \quad K = \epsilon_1 p \times \exp(\epsilon_2 \eta) \quad \text{or} \quad K = \epsilon_1 p \times \exp(\epsilon_2 \eta).
 \end{aligned}
 \tag{8.3.26}$$

Polynomial terms give contributions which come as powers  $K^m$ ,  $m \leq n - 1$  and would give to kinetic term a contribution which is power  $p^k$ ,  $k = 0, 1$  for  $n = 2$  and  $k = -1, 0, 1$  for  $n = 3$ . What is known about  $p^2 = 0$  limit implies that these terms must sum up to zero, for  $i_1$  and  $i_t$ . This indeed happens as explicit check shows. For  $j_s$  and  $j_t$  one must obtain a constant contribution independent of  $p$  and giving rise to mass term in the propagator. This would correspond to  $p^k$ ,  $k = 1$ . The terms must be same apart from sign and cancel each other only if the hyperbolic cutoffs are related in the proposed manner.

The logarithmic terms associated with the poles  $K = k_{\pm}^{s/t}$  can be combined to single logarithm. Getting the sign factors correctly takes some time and one must be careful with the expressions for the roots and their differences  $k_{\pm, \epsilon_2}$  which are reproduced for here for the reader's convenience.

$$\begin{aligned}
 k_{\pm, \epsilon_2}^s &= \pm p \times \exp(\epsilon_2 \eta) \quad (\text{space-like case}), \\
 k_{\pm, \epsilon_2}^t &= \epsilon_2 p \times \exp(\pm \eta) \quad (\text{time-like case}), \\
 k_+^s - k_-^s &= 2p \exp(\epsilon_2 \eta), \quad (\text{space-like case}), \\
 k_{+, \epsilon_2}^t - k_{-, \epsilon_2}^t &= 2p \epsilon_2 \sinh(\eta), \quad (\text{time-like case}).
 \end{aligned}
 \tag{8.3.27}$$

The sum over the logarithms combines to form a logarithmic term which is of following form in various cases.

$$\begin{aligned}
 i_s &= p^2 \frac{3 \sinh(\eta)}{2} \times \left[ \exp(\eta) \log(F_1(\frac{p}{m_k} \exp(\eta))) \right. \\
 &\quad \left. - \exp(-\eta) \log(F_1(\frac{p}{m_k} \exp(-\eta))) \right], \\
 i_t &= -6p^2 \frac{\cosh(\eta)}{\sinh(\eta)} \times \left[ \exp(2\eta) \log(F_2(\frac{p}{m_k} \exp(\eta))) \right. \\
 &\quad \left. - \exp(-2\eta) \log(F_2(\frac{p}{m_k} \exp(-\eta))) \right], \\
 j_s + k_s &= \frac{p^2}{2} \times (1 - \sinh^2(\eta)) \left[ \exp(2\eta) \log(F_2(\frac{p}{m_k} \exp(\eta))) \right. \\
 &\quad \left. + \exp(-2\eta) \log(F_2(\frac{p}{m_k} \exp(-\eta))) \right], \\
 j_t + k_t &= -p^2 \frac{2(1 + \cosh^2(\eta))}{\sinh(\eta)} \times \left[ \exp(3\eta) \log(F_1(\frac{p}{m_k} \exp(\eta))) \right. \\
 &\quad \left. + \exp(-3\eta) \log(F_1(\frac{p}{m_k} \exp(-\eta))) \right],
 \end{aligned}
 \tag{8.3.28}$$

where the functions  $F_i(x)$  are given by

$$\begin{aligned}
 F_1(x) &= \left| \frac{(2+x)(\sqrt{2}-x)}{(2-x)(\sqrt{2}+x)} \right|, \\
 F_2(x) &= \left| \frac{(2+x)(2-x)}{(\sqrt{2}+x)(\sqrt{2}-x)} \right|
 \end{aligned}
 \tag{8.3.29}$$

For small values of  $x$  one has  $F_1(x) \simeq 1$  and  $F_2(x) \simeq 2$  so that only  $F_1(x)$  contributes significantly to the propagator for  $p \exp(\pm \eta) \ll m_k$ . For large values of  $x$  one has  $F_i(x) \simeq 1$  so that neither of them contributes for  $p \gg m_k$ . For  $p = 2m_k \exp(\pm \eta)$   $F_i$  has infinite value so that one obtains a logarithmic singularity. Since the integration range over  $\eta$  is shortens with exponential rate as function of  $k$ , the logarithmic contribution does not have significant effects. It however means that p-adic length scale

hierarchy is visible as a small effect. If the momentum squared does not correspond to p-adic mass scale  $\log(F_1) \simeq 0$  and  $\log(F_2) \simeq \log(2)/2$  holds true and the kinetic term is in excellent approximation proportional to  $p^2$ . Since  $F_i$  are even functions of  $p$ , they are actually functions of  $p^2$  rather than  $p$  as one might indeed expect on basis of analyticity requirement.

The expressions for the non-vanishing functions at this limit read as

$$\begin{aligned} i_t &= -12\log(2)p^2\cosh^2(\eta) , \\ j_s &= \frac{\log(2)}{2}(2\cosh^2(\eta) - 1)(1 - \sinh^2(\eta)) . \end{aligned} \quad (8.3.30)$$

At the  $p^2 = 0$  limit-that is in p-adic mass scales much larger than  $p$ - one has in the next approximation

$$\begin{aligned} F_1(x) &\simeq (1 - \sqrt{2}) \times x + O(x^3) = (1 - \sqrt{2}) \times \frac{p}{m_k} u^{\pm 1} , \\ F_2(x) &\simeq \frac{x^2}{4} + O(x^3) = \frac{1}{4} \left(\frac{p}{m_k}\right)^2 u^{\pm 2} , \end{aligned} \quad (8.3.31)$$

This gives

$$\begin{aligned} i_s &\simeq p^2 \times 2(1 - \sqrt{2}) \times \frac{p}{m_k} \frac{3\sinh(\eta)}{2} \times \sinh(2\eta) , \\ i_t &\simeq -6p^2 \frac{\cosh(\eta)}{\sinh(\eta)} \times \left[ 2\log(2)\sinh(2\eta) - \frac{1}{2} \left(\frac{p}{m_k}\right)^2 \sinh(4\eta) \right] , \\ j_s + k_s &\simeq \frac{p^2}{2} \times (1 - \sinh^2(\eta)) \left[ 2\log(2)\cosh(2\eta) + \frac{1}{2} \left(\frac{p}{m_k}\right)^2 \cosh(4\eta) \right] , \\ j_t + k_t &\simeq -p^2 \times 2(1 - \sqrt{2}) \times \frac{p}{m_k} \frac{2(1+\cosh^2(\eta))}{\sinh(\eta)} \times \cosh(4\eta) , \end{aligned} \quad (8.3.32)$$

At the IR limit  $p/m_k \gg 1$  one can expand the logarithms with respect to the variable  $1/x$  and the lowest order gives

$$\begin{aligned} F_1(x) &\simeq -\frac{2}{x^2} + O(x^{-3}) = -\left(\frac{p}{m_k}\right)^{-2} u^{\mp 2} , \\ F_2(x) &\simeq 2(2 - \sqrt{2}) \times x^{-1} + O(x^{-3}) = 2(2 - \sqrt{2}) \times \left(\frac{p}{m_k}\right)^{-1} u^{\mp 1} . \end{aligned} \quad (8.3.33)$$

$$(8.3.34)$$

$$\begin{aligned} i_s &\simeq p^2 \times 2 \left(\frac{p}{m_k}\right)^{-2} \times \frac{3\sinh(\eta)}{2} \times \sinh(\eta) , \\ i_t &\simeq -6p^2 \frac{\cosh(\eta)}{\sinh(\eta)} \times \left[ 2\log(2)\sinh(2\eta) + 4(2 - \sqrt{2}) \left(\frac{p}{m_k}\right)^{-1} \sinh(\eta) \right] , \\ j_s + k_s &\simeq \frac{p^2}{2} \times 2(2 - \sqrt{2}) \times (1 - \sinh^2(\eta)) \left[ 2\log(2)\cosh(2\eta) + 4(2 - \sqrt{2}) \left(\frac{p}{m_k}\right)^{-1} \cosh(\eta) \right] , \\ j_t + k_t &\simeq -p^2 \times 2 \left(\frac{p}{m_k}\right)^{-2} \times \frac{2(1+\cosh^2(\eta))}{\sinh(\eta)} \times \cosh(2\eta) . \end{aligned} \quad (8.3.35)$$

One can write  $p/m_k$  as  $p/m_k = 2^{k/2} \times p/m(CP_2)$ . If  $p$  corresponds to the p-adic mass scale  $k_0$  one can write  $p/m_k = x \times 2^{k_0/2} m(CP_2)$  so that one has  $p/m_k = x 2^{(k_0-k)/2}$  so that the higher order contributions decrease with an exponential rate as a function of  $|k - k_0|$ .

### 8.3.5 Numerical calculation of the integrals over the hyperbolic angle

The integrals over the hyperbolic angle  $\eta$  can be computed analytically in the case of pole contributions since integrals of rational functions are in question. In the case of principal value contributions situation is different since logarithms are present. Also now approximate analytic approach is convenient since the model for how quantum criticality might dictate the hyperbolic cutoff requires calculation

of the the derivatives of the integrals with respect to momentum  $p$  and analytic approximation to integrals allows to perform this calculation in terms of elementary functions.

Predicting coupling constant evolution and the bare values of couplings constants is something which is not done every day, and it is important to make all calculations public so that the reader can detect possible errors. Therefore I have reported the calculation in all boring detail.

### Overall view about calculation

The following summary is for a reader willing to carry out the calculations himself.

1. By taking  $u = e^n$  as integration variable, the partial fraction expansion of the rational functions multiplying  $F_i$  in various integrals gives integrals of form  $\int u^n \log(|1 + xu|)$  for both signs of  $n$  and  $x$ . If  $x$  is very small, the best manner to proceed is to expand the logarithm to a Taylor polynomial. If  $x$  is very large one can expand  $\log(u + 1/x)$  into Taylor polynomial. For  $x$  not too far from unity one replace the integration variable with  $v = u + 1/x$  and expand  $u^n = (v - 1/x)^n$  using binomial formula, one obtains for  $n \geq 0$  integrals of form  $\int v^n \log(|v|)$  and partial integration allows to deduce expression for this integrals in terms of elementary functions as

$$\int (v + u_0)^n \log(v) dv = \sum_{k=0}^n b(n, k) u_0^{n-k} v^{k+1} \left( \frac{\log(v)}{k+1} - \frac{1}{(k+1)^2} \right) .$$

2. Also integrals of form  $\int v^{-n} \log(|v|) du$  are encountered. By changing the integration variable to  $v = 1/u$  these integrals can be transformed to  $v^n \log(v - v_0)$  type integrals for  $n \geq 2$ . Therefore only the integral  $\int u^{-1} \log(|u - u_0|) du$  remains.
3. For the integrals of type  $\int \frac{1}{x} \log(|1 - x|) dx$ ,  $x = u/u_0$ , one can use in the region  $u/u_0 < 1$  the expansion of the denominator in geometric series to obtain the integral function as

$$\int \frac{1}{x} \log(|1 - x|) dx = \sum \frac{(-1)^{n+1} x^n}{n^2} \equiv F(x) .$$

It seems that this function does not allow expression in terms of elementary functions.

4. If  $u - u_0$  vanishes in the integration range the situation is more delicate and the integration range must be divided into two parts. In this case one can expand  $u^{-n} = (u_0 + v)^{-n}$  in Taylor series so that one obtains integrals of  $\int v^n \log(|v|) dv$  are obtained. The integral reduces to

$$\int \frac{\log(x - x_0)}{x} dx = \log(|x - x_0|) \log\left(\left|1 - \frac{x}{x_0}\right|\right) - F\left(\frac{x - x_0}{x_0}\right) .$$

The variation range of  $v$  is very restricted since  $u$  varies in the vicinity of  $u = 1$  so that the series converges rapidly. The numerical control of the integration reduces to the control of the degree of the Taylor polynomials. An additional numerical difficulty is posed by the analytic expressions which involve large terms summing up to zero. To guarantee the cancelation also numerically, one can combine the contributions from the logarithms  $\log(|1 \pm x_k 2^{-r} u|)$  appearing in  $\log(F_i)$  to single expression. This also minimizes the possibility of sign errors.

To sum up, the completely standard integral formulas needed in the numerical calculations are

$$\begin{aligned} \int \log(x) x^m dx &= x^{m+1} \left( \frac{\log(x)}{m+1} - \frac{1}{(m+1)^2} \right) , \\ \int \log(x) x^{-m} dx &= -\frac{1}{m-1} \log(x) x^{-m+1} - \frac{1}{(m-1)^2} x^{-m+1} , \quad m \neq 1 , \\ \int \log(x) x^{-1} &= \frac{1}{2} \log(x)^2 . \end{aligned} \tag{8.3.36}$$

Explicit numerical approximations reduce to the cutoff of  $F(x)$  to Taylor polynomial.

Since I possess rather primitive calculational tools (MATLAB in home computer) the need to do the calculations fast enough to perform them within day rather than year forces a rather detailed

analysis of the calculation and also kind of re-synthesis besides the use of analytic formulas. A careful planning of calculations is necessary in order to avoid un-necessary multiple calculations and loops rather than just performing simple discretization of the integration variable disfavored also by the logarithmic singularities of the integrands. The strategy has been simple.

1. Separate the easily calculable contribution corresponding to  $p^2 = 0$  limit for which  $F_2 = \log(2)$  and  $F_1 = 0$  hold true. The remaining contribution should be small for typical values of  $p$ .
2. Calculate the coefficients of Laurent and Taylor polynomials having no dependence on cutoff, momentum, or p-adic integer  $k$  to arrays in the beginning of the calculation as loops and store them as data.
3. Calculate the coefficients depending on momentum parameter  $p$  and p-adic integer  $k$  to arrays in the same manner.
4. Identify the basic integrals depending on the hyperbolic cutoff  $u_{max,t}$  or  $u_{max,s}$ , calculate them, and store them into arrays in the beginning of calculation using loops since there are typically conditions involved with each step of calculation so that loops cannot be avoided.
5. Calculate the basic contributions to propagator normalization factor from  $i_s, i_t, j_s + k_s, j_t + k_t$  using matrix operations and element-wise operations for arrays to avoid loops.
6. Use Taylor polynomials in the case that the analytic expression in terms of elementary functions does not exist or if the exact analytic expression is numerically unstable (say involves sum of large contributions summing up to zero but failing to do this exactly in the numerical approach). For instance, this strategy inspires the calculation and storing into arrays of integrals of  $\int du \times u^n \log(F_i)$  rather than  $\int du \times u^n \log(1 + 2^{-r} x_k u)$  to which the integral decomposes.

### Representation of rational functions appearing in integrands

Since I do not have opportunity to use symbol manipulation packages I include the detailed formulas for various functions involved it is essential to keep documentation as precise as possible so that I include detailed formulas allowing immediate computerization. The inverse of the propagator is apart from the projector  $P^{\mu\nu}$  equal to the sum of the following integrals.

$$\begin{aligned}
\int d\eta \times \cosh^2(\eta) i_s &= C_1 \int du \times [r_1(u) \times \log(F_1(x_k u)) - u^{-2} r_1(u) \times \log(F_1(x_k u^{-1}))] \quad , \\
r_1(u) &= (u - u^{-1})(u + u^{-1})^2 = u^3 + u - u^{-1} - u^{-3} \quad , \\
\int d\eta \times \sinh^2(\eta) i_t &= C_2 \int du \times [r_2(u) \times \log(F_2(x_k u)) - u^{-4} r_2(u) \times \log(F_2(x_k u^{-1}))] \quad , \\
r_2(u) &= u(u + u^{-1})(u - u^{-1}) = u(u^2 - u^{-2}) \quad , \\
\int d\eta \times \cosh^2(\eta) (j_s + k_s) &= C_3 \times \int du \times r_3(u) [r_3(u) \log(F_2(x_k u)) + u^{-4} r_3(u) \times \log(F_2(x_k u^{-1}))] \quad , \\
r_3(u) &= u(4 - (u - u^{-1})^2)(u + u^{-1})^2 = u(-u^4 + 4u^2 + 10 + 4u^{-2} - u^{-4}) \quad , \\
\int d\eta \times \sinh^2(\eta) (j_t + k_t) &= C_4 \int du \times [r_4(u) \times \log(F_1(x_k u)) + u^{-6} r_4(u) \times \log(F_1(x_k u^{-1}))] \quad , \\
r_4(u) &= u^2(4 + (u + u^{-1})^2)(u - u^{-1}) = u^2(u^3 + 5u - 5u^{-1} - u^{-3}) \quad , \\
C_1 &= \frac{3\pi p^2}{2} \quad , \quad C_2 = -6\pi p^2 \quad , \quad C_3 = \frac{\pi p^2}{2} \quad , \quad C_4 = -\pi p^2 \quad .
\end{aligned} \tag{8.3.37}$$

In the integration of the latter terms containing  $\log(F_i(x_k u^{-1}))$  the simplest formulas are obtained by taking  $v = u^{-1}$  as an integration variable since there is high degree of symmetry between  $r$  and  $s$  contributions.  $du = -dv/v^2$  brings in one negative power of  $v$  and  $u^k$  goes to  $v^{-k}$  so that one has  $u^k \rightarrow v^{-k-2}$ . Since integrand apart multiplying  $d\eta$  satisfies  $F(u) = F(v)$  and since the

integration measure  $d\eta = du/u$  equals to  $-dv/v$  the overall result is that the integrand only changes sign:  $F(u)du = -F(v)dv$  and the integration limits  $[1, u_{max}]$  are replaced with  $[1, u_{max}^{-1}]$ . Hence the integrals associated with the latter terms can be reduced to the integrals defined by  $r_i(u)$ . Taking into account the symmetries of the integrand this gives the formulas

$$\begin{aligned} i_s : \quad & I = I(1, u_{max,s}) - I(1, u_{max,s}^{-1}) , \\ i_t : \quad & I = I(1, u_{max,t}) - I(1, u_{max,t}^{-1}) , \\ j_s + k_s : \quad & I = I(1, u_{max,s}) - I(1, u_{max,s}^{-1}) , \\ j_t + k_t : \quad & I = I(1, u_{max,s}) + I(1, u_{max,s}^{-1}) . \end{aligned} \tag{8.3.38}$$

For  $j_t + k_t$  the integrals obviously tend to cancel each other.

The rational functions  $r_i$  multiplying functions  $F_i$  in various cases can be expressed by giving the non-vanishing coefficients in their Laurent expansion

$$r_i(u) = \sum_k r_{i,k}^+ u^k + \sum_k r_{i,k}^- u^{-k}$$

to make the integration procedure systematic.

One obtains for the non-vanishing coefficients following expressions

$$\begin{aligned} r_{1,1}^+ = 1 , \quad r_{1,3}^+ = 1 , \quad r_{1,1}^- = -1 , \quad r_{1,3}^- = -1 , \\ r_{2,3}^+ = 1 , \quad r_{2,1}^- = -1 , \\ r_{3,1}^+ = 10 , \quad r_{3,3}^+ = 4 , \quad r_{3,5}^+ = -1 , \quad r_{3,1}^- = 4 , \quad r_{3,3}^- = -1 , \\ r_{4,1}^+ = -5 , \quad r_{4,3}^+ = 3 , \quad r_{4,5}^+ = 1 , \quad r_{4,1}^- = -1 . \end{aligned} \tag{8.3.39}$$

Only the coefficients  $r_{i,1}^-$  give rise to an integral not expressible in terms of elementary functions.

**Functions  $F_i$**

The functions  $F_i$  and their derivatives are given by

$$\begin{aligned} F_1(x) = \left| \frac{(2+x)(\sqrt{2-x})}{(2-x)(\sqrt{2+x})} \right| , \quad F_2(x) = \left| \frac{(2+x)(2-x)}{(\sqrt{2+x})(\sqrt{2-x})} \right| , \\ \log(F_1)' = \frac{1}{2+x} + \frac{1}{2-x} - \frac{1}{\sqrt{2+x}} - \frac{1}{\sqrt{2-x}} , \quad \log(F_2)' = \frac{1}{2+x} - \frac{1}{2-x} - \frac{1}{\sqrt{2+x}} + \frac{1}{\sqrt{2-x}} , \end{aligned} \tag{8.3.40}$$

It is convenient to extract from the integrals the contribution which corresponds to  $p^2 = 0$  limit given by Eq. 8.3.30. This contribution comes from  $F_2$  alone since  $F_1$  vanishes at this limit.

For systemization purposes it is convenient to introduce the functions  $V(i, \epsilon)(x, u)$  as

$$\begin{aligned} V_{1,\epsilon}(x_k, u) = \log(F_1(x_k u^\epsilon)) = \sum_{\epsilon_1, r} V(1, \epsilon_1, r) \log(|1 + \epsilon_1 2^{-r} x_k u^\epsilon|) , \\ V_{2,\epsilon}(x_k, u) = \log(F_2(x_k u^\epsilon)/2) = \sum_{\epsilon_1, r} V(2, \epsilon_1, r) \log(|1 + \epsilon_1 2^{-r} x_k u^\epsilon|) , \\ V(1, \epsilon_1, 1) = 1 , \quad V(1, \epsilon_1, 1/2) = -1 , \\ V(2, \epsilon_1, 1) = (-1)^{\epsilon_1} , \quad V(2, \epsilon_1, 1/2) = (-1)^{\epsilon_1 - 1} . \end{aligned} \tag{8.3.41}$$

The logarithms  $\log(|2^r + \epsilon_1 x_k u^{\epsilon-1}|)$  can be decomposed as

$$\log(|1 + \epsilon_1 2^{-r} x_k u^{-1}|) = \log(|u + \epsilon_1 2^{-r} x_k|) - \log(|u|) . \tag{8.3.42}$$

The contributions from  $\log(u)$  terms cancel for  $F_i$  and one obtains effectively contribution of form

$$\begin{aligned} \sum_n r_{i,n}^\pm \int u^n \log(|1 + \epsilon_1 2^{-r} x_k u|) du , \\ \sum_n s_{i,n}^\pm \int u^n \log(|u + \epsilon_1 2^{-r} x_k|) , \end{aligned} \tag{8.3.43}$$

Note that when  $x_k$  is small *resp.* large the total contributions are of order  $x_k$  *resp.*  $1/x_k$  and therefore very small.

### Expression of the integrals in terms of the basic integrals

One can express the integrals in terms of following basic integrals:

$$I_n(u_0, u_{max}) = \int_1^{u_{max}} du \times u^n \log(|u + u_0|) \quad , \quad J_n(u_{max}) = \int_1^{u_{max}} du \times u^n \quad . \quad (8.3.44)$$

Notice that for  $n < -1$  the integral can be reduced to  $n \geq 0$  case by changing the integration variable to  $v = 1/u$ .

In the following are listed the expressions of the basic integrals remaining when the contribution which is non-vanishing at  $p^2 = 0$  limit has been subtracted. As already found,  $s^\pm$  contributions are identical with  $r^\mp$  contributions so that it is enough to multiply by a factor 2 the contributions coming from  $r^\pm$ .

1. For  $r_{i,n}^+$  one obtains following integrals.

$$\begin{aligned} i_s & \sum_n r_{1n}^+ \sum_r V(1, 1, r) I(n, r, u_{max,s}) = \sum_n r_{1n}^+ I_1(n, r, u_{max,s}) \quad , \\ i_t & \sum_n r_{2n}^+ \sum_r V(2, 1, r) I(n, r, u_{max,t}) = \sum_n r_{2n}^+ I_2(n, u_{max,t}) \quad , \\ j_s + k_s & \sum_n r_{3n}^+ \sum_r V(2, 1, r) I(n, r, u_{max,s}) = \sum_n r_{3n}^+ I_2(n, u_{max,s}) \quad , \\ j_t + k_t & \sum_n r_{4n}^+ \sum_r V(1, 1, r) I(n, r, u_{max,t}) = \sum_n r_{4n}^+ I_1(n, u_{max,t}) \quad , \\ I_i(n, u_{max}) & = -(i-1) \times \log(2) J_n(u_{max}) \\ & + \sum_{r=1/2,1} (-1)^{2r} (I_n(\frac{2^r}{x_k}, u_{max}) + (-1)^i I_n(-\frac{2^r}{x_k}, u_{max})) \quad . \end{aligned} \quad (8.3.45)$$

2. The integration of negative powers requires the change of variable  $u \rightarrow u^{-1} = v$ ,  $du = -v^{-2} dv$ . For  $r_{i,n}^-$  one has

$$\begin{aligned} i_s & \sum_n r_{1n}^- \sum_r V(1, 1, r) I(n, r, u_{max,s}) = \sum_n r_{1n}^- I_1(n, u_{max,s}) \quad , \\ i_t & \sum_n r_{2n}^- \sum_r V(2, 1, r) I(n, r, u_{max,t}) = \sum_n r_{2n}^- I_2(n, u_{max,t}) \quad , \\ j_s + k_s & \sum_n r_{3n}^- \sum_r V(2, 1, r) I(n, r, u_{max,s}) = \sum_n r_{3n}^- I_2(n, u_{max,s}) \quad , \\ j_t + k_t & \sum_n r_{4n}^- \sum_r V(1, 1, r) I(n, r, u_{max,t}) = \sum_n r_{4n}^- I_1(n, u_{max,t}) \quad , \\ I_i(n > 1, u_{max}) & = - \sum_r (-1)^{2r} (I_{n-2}(\frac{x_k}{2^r}, \frac{1}{u_{max}}) + (-1)^i I_{n-2}(-\frac{x_k}{2^r}, \frac{1}{u_{max}})) \quad (8.3.46) \\ I_i(n = 1, u_{max}) & = (i-1) \times \log(2) J_{-1}(u_{max}) \\ & - \sum_{r=1/2,1} (-1)^{2r} (I_{-1}(\frac{2^r}{x_k}, u_{max}) + (-1)^i I_{-1}(-\frac{2^r}{x_k}, u_{max})) \quad . \end{aligned}$$

These expressions make sense for the values of  $|u_0|$ , which are not too far from unity. For very large or small values of  $|u_0|$   $F_i$  are very near to zero or constant. The small corrections come in powers of  $p/m_k$  and are typically extremely small. This means that in the case of  $I_i(n=1, u_{max})$  the large contribution  $(i-1) \times \log(2) J_{-1}(u_{max})$  must be compensated by the contribution from the sum term. Numerically the compensation takes place in so poor an accuracy that the error is much large than the magnitude of the actual contribution. Hence a special treatment is necessary. The large logarithmic term in  $F_2$  cancels as one expresses  $\log(|u \pm u_0|)$  terms as  $\log(|1 \mp u/u_0|) + \log(|u_0|)$  so that only  $\log(|1 \mp u/u_0|)$  terms remain and give a contribution of order  $1/u_0 \simeq p/m_k$ .

### Analytic expressions for the basic integrals

One can deduce explicit analytic expressions for almost all basic integrals in terms of elementary functions.

1. Reduction of  $k < -1$  case to  $k \geq 0$  case

The first thing is to notice that integrals  $I_{k<-1}(u_0, u_{max})$  reduce to corresponding integrals with  $k \geq 0$ .

$$I_{k<-1}(u_0, u_{max}) = I_{|k|-2}(0, u_{max}^{-1}) - I_{|k|-2}(|1/u_0|, u_{max}^{-1}) - \frac{1}{|k|-1} \log(|u_0|) \times (u_{max}^{-|k|+1} - 1) . \quad (8.3.47)$$

In the expression for  $I_i$  ( $i$  labels  $F_i$ ) the first terms cancel each other so that one has

$$I_{i,k<-1}(u_0, u_{max}) = 2 \sum_{r=1/2,1} (-1)^{2r} \left[ - (I_{|k|-2}(x_k 2^{-r}, u_{max}^{-1}) + (-1)^i I_{|k|-2}(-x_k 2^{-r}, u_{max}^{-1})) - \frac{(i-1)}{|k|-1} \log(2^r/x_k) \times (u_{max}^{-|k|+1} - 1) \right] . \quad (8.3.48)$$

For  $k \geq 0$  and  $|u_0| \leq 1$  the explicit expression for  $I_k(u_0, u_{max})$  reads as

$$I_{k \geq 0}(u_0, u_{max}) = \sum_{l=0}^k b(k, l) \frac{(-1)^{k-l} u_0^{k-l}}{l+1} \left[ (u_{max} + u_0)^{l+1} (\log(|u_{max} + u_0|) - \frac{1}{l+1}) - (1 + u_0)^{l+1} (\log(|1 + u_0|) - \frac{1}{l+1}) \right] . \quad (8.3.49)$$

### 2. Alternative form of the integrals $I_{k \geq 0}(u_0, u_{max})$

For  $|u_0| \geq 1$  it is better to use the form

$$I_{k \geq 0}(u_0, u_{max}) = \frac{\log(|u_0|)}{k+1} (u_{max}^{k+1} - 1) + u_0^{k+1} \sum_{l=0}^k b(k, l) \frac{(-1)^{k-l}}{l+1} \left[ (\frac{u_{max}}{u_0} + 1)^{l+1} (\log(|\frac{u_{max}}{u_0} + 1|) - \frac{1}{l+1}) - (\frac{1}{u_0} + 1)^{l+1} (\log(|\frac{1}{u_0} + 1|) - \frac{1}{l+1}) \right] . \quad (8.3.50)$$

This expression is numerically unstable for  $u_0 \gg 1$  (UV limit) and  $u_0 \ll 1$ . The simplest manner to avoid this kind of problems is to expand the logarithms  $\log(|1 + 2^{-r} x_k u|)$  appearing in  $F_i$  as Taylor polynomials and summing various contributions analytically.

### 3. Expression for $I_{k=-1}(u_0, u_{max})$

Only  $I_{-1}(u_0 \neq 0, u_{max})$  does not allow expression in terms of elementary functions.

1. In the regions  $u_{max} < |u_0|$  and  $|u_0| < 1$  one can write

$$I_{-1}(u_0, u_{max}) = \log(|u_0|) \log(u_{max}) + F(\frac{u_{max}}{u_0}) - F(\frac{1}{u_0}) , \quad u_{max} < |u_0| , \quad (8.3.51)$$

$$I_{-1}(u_0, u_{max}) = \frac{1}{2} \log^2(u_{max}) - F(\frac{u_0}{u_{max}}) + F(u_0) , \quad |u_0| < 1 ,$$

and approximate  $F(x)$  using Taylor polynomial.

2. For  $u_0 > 0$  and  $1 < u_0 < u_{max}$  one obtains the following expression

$$I_{-1}(u_0, u_{max}) = \log(2) \int du \times u^{-1} + \int du \times u^{-1} \log(1 + (\frac{u+u_0}{2} - 1))$$

$$= \log(2) \log(u_{max}) + I(u_{max}) - I(1) , \quad (8.3.52)$$

$$I(u) = -\frac{1}{2} \sum_{k>0} \frac{x^k}{k} \left[ \log(1+x) - \sum_{l=1}^k \frac{(-1)^{l+1} x^l}{l} \right] , \quad x = \frac{u+u_0-2}{2-u_0} .$$

The coefficient of  $\frac{x^k}{k}$  is the remainder associated with the  $k+1$ :th Taylor polynomial of  $\log(1+x)$ .

3. For  $u_0 < 0$  and  $1 < |u_0| < u_{max}$  one can expand  $u$  in  $1/u$  factor in powers of  $(u - u_0)/u_0$  and integrate the Taylor expansion term by term. This gives

$$I_{-1}(u_0, u_{max}) = I(u_{max}) - I(1) , \quad (8.3.53)$$

$$I(u) = \log(|u_0 x|) \log(1 + x) - F(x) , \quad x = \frac{u - |u_0|}{|u_0|} .$$

4. *Expression for  $I_{i,k=-1}(u_0, u_{max})$*

One can perform the sum over integrals associated with  $F_i$  and corresponding to opposite values of  $u_0$ .

1. The integrals can be combined for  $F_i$  as

$$I_{i,-1} = I_{-1}(u_0, u_{max}) + (-1)^i I_{-1}(-u_0, u_{max}) , \quad (8.3.54)$$

$$u_0 = \frac{2^r}{x_{max}} \text{ for } r^+, s^- , \quad u_0 = \frac{x_{max}}{2^r} \text{ for } r^-, s^+ .$$

The definition of  $u_0 > 0$  is dictated by whether  $x_k u$  ( $r^\pm$ ) or  $x_k/u$  ( $s^\pm$ ) appears in the logarithm and whether  $u$  ( $r^+, s^-$ ) or  $1/u$  ( $r^-, s^+$ ) is used as the integration variable.

2. In the regions  $u_{max} < |u_0|$  and  $|u_0| < 1$  the functions  $I_{i,-1}(\frac{2^r}{x_{max}}, u_{max})$  can be expressed as

$$I_{i,-1}(u_0, u_{max}) = 2(i-1) \log(2) \times \log(u_{max})$$

$$+ \sum_{r=1/2,1} (-1)^{2r} \left[ F^i\left(\frac{u_{max}}{u_0}\right) - F^i\left(\frac{1}{u_0}\right) \right] , \quad u_{max} < u_0 , \quad (8.3.55)$$

$$I_{i,-1}(u_0, u_{max}) = - \sum_{r=1/2,1} (-1)^{2r} \left[ F^i\left(\frac{u_0}{u_{max}}\right) - F^i(u_0) \right] , \quad u_0 < 1 .$$

3. In the regions  $1 < |u_0| = |u_0| < u_{max}$  the opposite signs of  $u_0$  correspond to different analytic expressions appearing in Eqs. 8.3.51 and 8.3.52 and one cannot combine them to a simpler function.

**The treatment of  $|x_k| \ll 1$  and  $|x_k| \gg 1$  cases**

The treatment of  $|x_k| \ll 1$  and  $|x_k| \gg 1$  cases requires special care since the formal approach using integral functions approach fails because of numerical in-accuracies. The best manner to proceed is to expand the logarithms in  $F_i$  as power series with respect to a suitably selected small quantity and approximate them with their Taylor polynomials.

1. *Small values of  $x_k$*

Consider first the case  $x_k \ll 1$ . This corresponds to momentum  $p \sim 2^{-k_0}$  with  $k_0 > k$  and is encountered for large loop momenta. One can express  $\log(1 + \epsilon 2^{-r} x_k u)$  as power series using  $\epsilon_{r,k} = 2^{-r} x_k$  as a small parameter to obtain

$$I_n(\epsilon, \epsilon_{r,k}) = \int u^n \log(1 + \epsilon \epsilon_{r,k} u) = \sum_{l>0} \frac{\epsilon^l \epsilon_{r,k}^l (-1)^{l+1}}{l} J_{n+l}(u_{max}) , \quad J_n = \int_1^{u_{max}} u^n du . \quad (8.3.56)$$

This gives

$$\begin{aligned}
I(n \geq 0, \epsilon, \epsilon_{r,k}) &= \sum_{l>0} \frac{\epsilon^l \epsilon_{r,k}^l (-1)^{l+1}}{l(n+l+1)} (u_{max}^{n+l+1} - 1) , \\
I(n < 0, \epsilon, \epsilon_{r,k}) &= \sum_{l>0, l \neq n-1} \frac{\epsilon^l \epsilon_{r,k}^l (-1)^{l+1}}{l(n+l+1)} (u_{max}^{n+l+1} - 1) + \frac{\epsilon_{r,k}^{n-1} (-1)^n}{n-1} \log(u_{max}) .
\end{aligned} \tag{8.3.57}$$

The contributions to  $F_i$  can be summed so that big contributions canceling each other do it also numerically.

1. For  $F_1$  contributions with  $\epsilon = \pm 1$  sum up with opposite overall sign and the overall contribution contains only odd powers of  $\epsilon_{r,k}$ .

$$\begin{aligned}
\sum_{r,\epsilon} f_1(\epsilon) I(n, \epsilon, \epsilon_{r,k}) &= \sum_{l>0} C_{2l-1} J_{n+2l-1}(u_{max}) , \\
C_l &= 2 \sum_{r=1/2,1} (-1)^{2r} \frac{\epsilon_{r,k}^l}{l} .
\end{aligned} \tag{8.3.58}$$

2. For  $F_2$  contributions with  $\epsilon = \pm 1$  sum up with same sign and the overall contribution contains only even powers of  $\epsilon_{r,k}$ .

$$\sum_{r,\epsilon} f_2(\epsilon) I(n, \epsilon, \epsilon_{r,k}) = - \sum_{l>0} C_{2l} J_{n+2l}(u_{max}) . \tag{8.3.59}$$

### 2. Large values of $x_k$

Second situation requiring special treatment corresponds to a momentum which is large in the p-adic length scale  $k$  considered so that one has  $k \gg k_0$ . Small loop momenta correspond to this case. By replacing  $\epsilon_{r,k}$  with  $M_{r,k}$  one can write

$$I_n(\epsilon, M_{r,k}) = \int du \times u^n \log(1 + \epsilon M_{r,k} u) = \int du \times u^n \log(M_{r,k}) + \int du \times u^n \log(u + M_{r,k}^{-1}) . \tag{8.3.60}$$

The sum of the first terms vanishes for  $F_1$  ( $i_s$  and  $j_t + k_t$ ). For  $F_2$  ( $i_t$  and  $j_s + k_s$ ) it gives overall contribution equal to

$$- J_n(u_{max}) \log(2) . \tag{8.3.61}$$

Note that the contribution - although large - does not depend on the scale of  $M_{r,k}$  at all. In the second term Taylor expansion in power series gives

$$\int du \times u^n \log(u) + \sum_{l>0} I_{l+n} \frac{\epsilon^n 2^{-nr} M_{r,k}^n (-1)^{l+1}}{l} , \quad J_r(u_{max}) = \int_1^{u_{max}} u^r du . \tag{8.3.62}$$

$\int du \times u^k \log(u)$  terms sum up to zero in both  $F_1$  and  $F_2$  and the overall integral reduces to the sum of the remaining terms.

1. For  $F_1$  contributions with  $\epsilon = \pm 1$  sum up with opposite overall sign and the overall contribution contains only odd powers of  $M_{r,k}$ .

$$\sum_{r,\epsilon} f_1(\epsilon) I(n, \epsilon, M_{r,k}) = \sum_{l>0} C_{2l-1} J_{n-2l+1}(u_{max}) ,$$

$$C_l = 2 \sum_{r=1/2,1} (-1)^{2r} \left(\frac{x_k}{2^r}\right)^l \frac{1}{l} . \quad (8.3.63)$$

Note that the only difference to the previous case is  $x_k/2^r \rightarrow 2^r/x_k$  in the formula of  $C_l$ .

2. For  $F_2$  contributions with  $\epsilon = \pm 1$  sum up with same sign and the overall contribution contains only even powers of  $M_{r,k}$  (recall that also the additional contribution given by Eq. 8.3.61 is present).

$$\sum_{r,\epsilon} f_2(\epsilon) I(n, \epsilon, M_{r,k}) = - \sum_{l>0} C_{2l} J_{n-2l} . \quad (8.3.64)$$

3. The total contribution in the case of  $F_i$  can be written as

$$I_{i,n} = -J_n(u_{max}) \log(2) + (-1)^{i-1} \sum_{l>0} C_{2l-1+(i-1)} J_{n-2l+1-(i-1)} . \quad (8.3.65)$$

### Pole contributions

Tedious calculation allows to derive explicit expressions for the integrals of rational functions of  $\exp(\eta)$  defining the pole contributions. There are two contributions to the integral and they can be reduced to same kind of integral by the changing the integration variable from  $u$  to  $1/u$  in the contribution. For space-like contributions the integrals can be expressed in the form

$$J_{s,+} + K_{s,+} = I(u_{max,s,+}) - I(u_{min,s,+}) ,$$

$$J_{s,-} + K_{s,-} = -I(u_{max,s,-}^{-1}) + I(u_{min,s,-}^{-1}) ,$$

$$I(u) = C_s \times \left[ \sum_{n \geq 1} \frac{p(n)}{n+1} u^{n+1} + p(-1) \log(u) \right] , \quad (8.3.66)$$

$$(8.3.67)$$

$$p(-1) = \frac{1}{8} , \quad p(1) = -\frac{1}{8} \quad p(3) = -\frac{3}{8} \quad p(5) = \frac{1}{8} .$$

$$(8.3.68)$$

Here the  $u_{max,s,+}$  and  $u_{min,s,-}$  are subject to the additional condition that the pole momentum is inside the p-adic half octave considered. Same applies to the integration boundaries in time-like case.

For time-like contributions the integrals can be expressed in the form

$$\begin{aligned}
 J_{t,+} + K_{t,+} &= I(u_{max,t,+}) - I(u_{min,t,+}) \ , \\
 J_{t,-} + K_{t,-} &= -I(u_{max,t,-}^{-1}) + I(u_{min,t,-}^{-1}) \ , \\
 I(u) &= \sum_{n>1} \frac{p(n)u^{n+1}}{n+1} + \frac{p(1)}{6} \log(3u^2 + 1) + r(-1) \left[ \log(u) - \frac{\log(3u^2+1)}{2} \right] \ , \\
 C_t &= \sqrt{-1} \times 32 \times \pi^2 \ , \\
 p(n > 0) &= \frac{1}{3} \left[ -\frac{p(n+2)}{3} + r(n+2) \right] \ , \quad p(n > 5) = 0 \ , \\
 r(-1) &= \frac{1}{8} \ , \quad r(1) = \frac{1}{2} \ , \quad r(3) = -\frac{5}{4} \ , \quad r(5) = \frac{1}{2} \ , \quad r(7) = \frac{1}{8} \ .
 \end{aligned}
 \tag{8.3.69}$$

Since the entire integration range for  $\eta$  for a given value of  $k$  need not to correspond to the roots  $k_+$  resp.  $k_-$  belonging to  $k$ :th half half octave, the determination of the bounds of hyperbolic integral requires a special care. One has two roots  $k_+ = p \exp(\eta)$  and  $k_- = p \exp(-\eta)$  in both time-like and space-like case. For  $k$ :th p-adic half octave the questions are following. Does  $p$  belong to the  $k$  :th octave? Does  $k_+(max, k) = pu_{max}(k)$  belong to it? Does  $k_-(min, k) = pu_{max}^{-1}(k)$  belong to it? The answers to these three questions determine the limits of the  $\eta$  integration. There are  $2^3$  bit combinations  $(b_0, b_+, b_-)$  formed by the answers to the question 'Does  $p$  resp.  $k_+(max, k)$  resp.  $k_-(min, k)$  belong to the  $I_k = [m_k, \sqrt{2}m_k]$ ?'. The following table gives the integration ranges for the bit combinations for which they are non-empty for either  $k_+$ ,  $k_-$  or both.

$(b_0, b_+, b_-)$	pole	$u_{lower}$	$u_{upper}$	
(111)	$k_+ : 1$ $k_- : 1$	1	$u_{max}(k)$ $u_{max}(k)$	
(110)	$k_+ : 1$ $k_- : 1$	1	$u_{max}(k)$ $Min(\frac{p}{m_k}, u_{max}(k))$	
(101)	$k_+ : 1$ $k_- : 1$	1	$Min(\frac{\sqrt{2}m_k}{p}, u_{max}(k))$ $u_{max}(k)$	(8.3.70)
(100)	$k_+ : 1$ $k_- : 1$	1	$\frac{\sqrt{2}m_k}{p}$ $\frac{p}{m_k}$	
(010)	$k_+ : \frac{m_k}{p}$		$u_{max}(k)$	
(001)	$k_- : \frac{p}{\sqrt{2}m_k}$		$u_{max}(k)$	.

**General expression for the normalization factor**

To summarize, one can write the expression for the loop integral as

$$\begin{aligned}
 X &= Ap^2 P^{\mu\nu} \ , \\
 A &= \sum_{k=k_{min}}^{k_{max}} A(k) \ , \\
 A(k) &= \frac{1}{p^2} [-I_{pole}(k) - I_{P,1}(k) - I_2 + J_{pole}(k) + J_{P,1}(k) + J_2(k)] \ .
 \end{aligned}
 \tag{8.3.71}$$

Propagator normalization factor is given by

$$N = \frac{1}{A} . \quad (8.3.72)$$

The above calculations are carried out by assuming that 2-adic length scale defines the length scale resolution. The scaling up of the UV cutoff length scale from  $\mu(2) = \sqrt{2}m(CP_2)$  to  $2^{-k/2}m(CP_2)$  requires only the replacement  $x = m(CP_2)/p$  appearing in the function  $F(x_k, \exp(\pm\eta))$  with  $x(k) = 2^{-(k-1)/2}m(CP_2)/p$ . The lowest order approximation must result if one puts  $p = 0$  in the arguments of the logarithms so that only  $p^2$  term remains in the propagator. This is indeed the case as already found.

### 8.3.6 The evolution of $1/\alpha_{em}(p)$ for given IR cutoff for loop momenta

The following plots illustrate the evolution of the fine structure constant a function of the mass of virtual photon. All the plots are associated with the model for the hyperbolic cutoff parameterized as  $\sinh(\eta_t) \leq a \times b^{-1/3}$ ,  $a = 0.22050469512552$ ,  $b = 1/3$ , reproducing the experimental value  $1/\alpha_{em} = 137.035999070$  of the fine structure constant at electron length scale for IR cutoff  $k_{max} = 127$  and its value at intermediate boson length scale for  $k_{max} = 89$ . The figures demonstrate following.

1. From figures 1 and 2 it is clear that only the scenario in which the IR cutoff  $k_{max}$  for loop momenta satisfies  $k_{max} > k_0(p)$ , where  $k_0(p)$  is the p-adic mass scale of the momentum of virtual gauge boson, makes sense.
2. For  $k_0 > k_{max}$  there are two reasons for the failure. A large imaginary pole contribution breaking unitarity (Figure 2) is generated and the evolution for gauge couplings is unrealistic (Figure 1) due to the large contributions related to the presence of the pole.
3. In the main text it is proposed that it might be possible to fix the hyperbolic cutoff from quantum criticality by requiring that the inverses of bare gauge couplings vanish at the end point of the p-adic half octave for  $k_0 = k_{max} + n$ , where  $n$  is small integer. The finding that the real part for the inverse of gauge coupling changes sign for  $k_0 = 90$  for  $k_{max} = 89$  at the lower end of the p-adic half octave (Figure 3) raises the hope that the hyperbolic cutoff for various values of  $k$  could be determined from this condition by starting from  $k_{max} = 1$  or 2.

#### Failure of the model allowing $k_0 > k_{max}$

Figures 1 and 2 demonstrate that loop momenta must be above the p-adic mass scale of the gauge boson momentum. Figure 1 demonstrates that the ratio  $r = \alpha_{em}/\alpha_{em,pred}(p_k)$  where  $\alpha_{em} = 137.035999070$  is the experimentally determined fine structure constant at electron length scale and  $\alpha_{em,pred}(p_k)$  is the predicted fine structure constant for virtual photon mass  $p_k = \sqrt{2}m_k = 2^{-(k-1)/2}xm(CP_2)$ ,  $k = 2, \dots, 127$ ,  $x \in \{2^{-1/2}, 2^{-1/4}, 1\}$ . There is a large oscillation of the ratio as a function of  $k$  at the upper end of the interval. The deviation of the prediction from unity is so large and so different from expectations that it is safe to conclude that for momentum of virtual gauge bosons characterized by the p-adic length scale  $k_0$  IR cutoff  $k_{max}$  for the loop momenta must satisfy  $k_{max} \geq k_0 + n$ ,  $n$  a small positive integer. This interpretation conforms with the general view provided by zero energy ontology and the assignment of loop corrections with sub-CDs.

Figure 2 represents the ratio  $\alpha_{em}Im \times Im(1/\alpha_{em}(p))$  as a function of virtual photon mass for  $p(k_0) = \sqrt{2}xm_k = 2^{-(k_0-1)/2}xm(CP_2)$ ,  $k = 2, \dots, 127$ ,  $x \in \{2^{-1/2}, 2^{-1/4}, 1\}$ . Unless one assumes that IR cutoff for loop momenta is larger than mass  $p$ , one encounters difficulties with unitarity since the pole in the integral defining the inverse of the bosonic propagator induces imaginary part to the normalization factor  $X$  of the propagator. In order to avoid obviously non-physical predictions the condition  $Im(X)\alpha_{em} \ll 1$  should hold true. For the model explaining the behavior of the fine structure constant at  $p^2 = 0$  limit  $Im(X)\alpha_{em}$  does not satisfy this criterion as Fig. 5 demonstrates. The value of the imaginary part of normalization is typically 10 times larger than that of real part.

Figure 8.1: The evolution of the ratio  $r = \alpha_{em}/\alpha_{em,pred}(p)$ , where  $\alpha_{em}$  is the experimentally determined value of the fine structure constant at electron length scale and  $\alpha_{em,pred}(p_k)$  for  $p_k = \sqrt{2}m_k = 2^{-(k-1)/2}xm(CP_2)$ ,  $k = 2, \dots, 127$ ,  $x \in \{2^{-1/2}, 2^{-1/4}, 1\}$ . Note that the three points correspond to the lower end, middle point, and upper end of the p-adic mass scale labeled by the integer  $k_0$ .

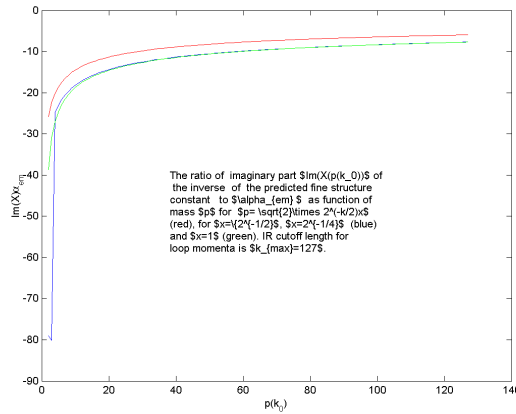

Figure 8.2: The graph represents the quantity  $Im(X)\alpha_{em}$ , where  $Im(X)$  is imaginary pole contribution to the normalization factor of the inverse propagator for momenta  $p_{k_0} = \sqrt{2}m_k = 2^{-(k_0-1)/2}xm(CP_2)$ ,  $k = 1, \dots, 127$ ,  $x \in \{2^{-1/2}, 2^{-1/4}, 1\}$  and assuming  $k_{max} = 127$ .

**Behavior of the fine structure constant for  $k_0(p) < k_{max}$  option**

Figures 1 and 2 allow to conclude that  $k_0(p) < k_{max}$  is the only sensible option. Figure 3 illustrates the evolution of the fine structure constant with the interpretation forced by the above findings for masses  $p_k = \sqrt{2}xm_{k_0} = 2^{-(k-1)/2}xm(CP_2)$ ,  $k_0 = 90, \dots, 127$ ,  $x \in \{2^{-1/2}, 2^{-1/4}, 1\}$  assuming that  $k_{max} = 89$  defining intermediate gauge boson mass scale defines the IR cutoff for the loop momenta. The behavior approaches rapidly the behavior at  $p^2 = 0$  limit. The value of the ratio is 0.9352 at electron length scale giving  $\alpha_{em}(89) = 128.1561$  to be compared with the prediction  $\alpha_{em}(89) = 128.1631$   $p^2 = 0$  limit. The value of the fine structure constant is somewhat larger for  $p = \sqrt{2}m_{89}$  than for  $p^2 = 0$  as expected for U(1) coupling constant evolution involving only fermionic loops.

From figure 3 it is clear that fine structure constant can become slightly negative at the upper end of the half octave  $k_{max} - 2$  for  $k_{max} = 89$ . This raises the hope that hyperbolic cutoff and therefore

the entire coupling constant evolution apart from corrections coming from bosonic loops could be fixed from the condition that gauge couplings vanish at this point. The physical interpretation for  $k_{max}$  would be that  $k_0 > k_{max} + 1$  zero energy states which are within the reach of the measurement resolution whereas for  $k_0 \leq k_{max} + 1$  they correspond to quantum fluctuations.

Figure 8.3: The evolution of the ratio  $r = \alpha_{em} / \alpha_{em,pred}(p_k)$  for  $k_{max} = 89$  as IR cutoff for loop corrections and for momenta  $p_k = \sqrt{2}m_k = 2^{-(k-1)/2}xm(CP_2)$ ,  $k = 90, 127$ ,  $x \in \{2^{-1/2}, 2^{-1/4}, 1\}$ .

**Contribution of a given p-adic length scale to the fine structure constant**

Figure 4 illustrates how the contribution  $X(k)$  from a given p-adic length scale  $k$  to the normalization factor of the inverse of the fine structure constant depends on  $k$  for  $k_{max} = M_{127}$  and  $p = \sqrt{2} \times 2^{-k_0/2}mCP_2$ ,  $k_0 = 89$  (this corresponds to the non-physical option) What is plotted is the contribution to the quantity  $Re(1/\alpha_{em}(p))\alpha_{em}$  as a function of  $k$ . The contributions from negative and positive powers of  $u = cosh(\eta)$  to  $1/\alpha_{em}(p)$  at given p-adic length scale  $k$  -including the p-adic scale  $k_0$  corresponding to the momentum  $p$  of gauge boson, are of opposite sign and tend to cancel each other.

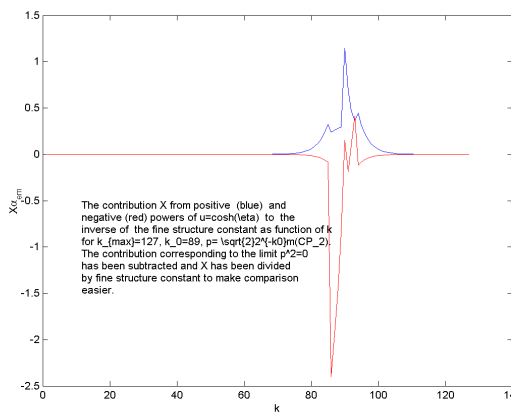

Figure 8.4: The quantity  $X(k)\alpha_{em}$  characterizing the contribution from a given p-adic length scale  $k$  to  $1/\alpha_{em}(p)$  as a function of p-adic length scale  $k$  for IR cutoff  $k_{max} = 127$  and  $p = \sqrt{2} \times 2^{-k_0/2}mCP_2$ ,  $k_0 = 89$ .

Figure 5 illustrates  $\alpha_{em}/\alpha_{em}(p)$  for the physical option  $k_{max} = 89$ ,  $k_0 = 107$ .

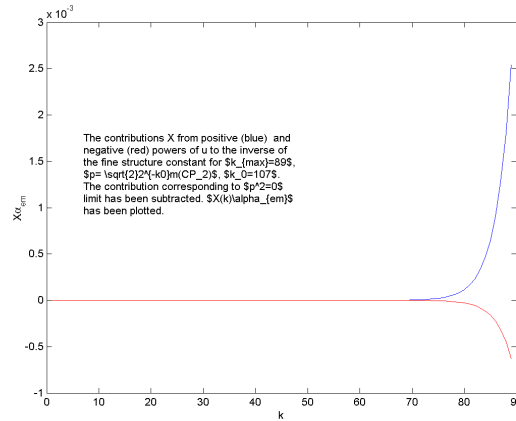

Figure 8.5: The quantity  $X(k)\alpha_{em}$  characterizing the contribution from a given p-adic length scale  $k$  to  $1/\alpha_{em}(p)$  as a function of p-adic length scale  $k$  for IR cutoff  $k_{max} = 89$  and  $k_0 = 107$ .

## 8.4 How quantum criticality could predict the evolution of hyperbolic cutoff?

In this section the path leading to the recent view about how quantum criticality fixes hyperbolic cutoff as a function of the p-adic scale  $k$  is described in detail. To help reader I have added a summary about how ideas involved and led also to a more detailed understanding of what coupling constant evolution really means. Also a connection with p-adicization and twistorialization using Cutkosky rule based unitarization emerged during this process.

### 8.4.1 Summary about how ideas about quantum criticality have evolved

This chapter like all other chapters of books reflects much more the evolution of ideas rather than its final outcome and a brief summary about what happened might minimize reader's confusion. The idea which led to the realization of what QFT limit of TGD could be is simple.

1. Only fermions are fundamental particles in quantum TGD and bosons are fermion-antifermion pairs with fermion and antifermion quantum numbers residing at the opposite 3-D light-like throats of wormhole contacts which are surfaces possessing Euclidian signature of induced metric and are glued to space-time sheets having Minkowskian signature of induced metric. Feynman diagrams can therefore be understood in terms of space-time topology and space-time metric. The interpretation of generalized Feynman diagrams differs dramatically from that for stringy diagrams since vertices are points where light-like 3-surfaces join together just like likes of ordinary Feynman diagram do. Stringy diagrams provide a space-time correlate for the propagation of particle along two different routes followed by fusion and interference.
2. Only fermions are fundamental fields in TGD. This suggests that gauge bosons, which have components of induced spinor connection and projections of  $CP_2$  Killing vector field as classical geometric correlates, should emerge in some sense at QFT limit. In other words, the action for QFT approximating TGD contains nothing but Dirac action coupled to gauge potentials, and the bosonic action containing YM term plus infinite number of vertices defined by closed fermion loops is generated radiatively. This approach leads to a generalization of Feynman rules and in principle predicts all coupling constants and their evolution without any input parameters except  $CP_2$  size and quantum criticality. p-Adic mass calculations demonstrated already 15 years

ago that one can understand the mysterious proton mass to Planck mass ratio and elementary particle mass scales and even masses number theoretically.

3. An essential element of the approach is a formulation for UV cutoff. A cutoff in both mass squared and hyperbolic angle is necessary since Wick rotation does not make sense in TGD framework. By assuming a geometrically very natural hyperbolic UV cutoff motivated by zero energy ontology one can understand the evolution of the standard model gauge couplings and reproduce correctly the values of fine structure constant at electron and intermediate boson length scales. Also asymptotic freedom follows as a basic prediction. Contrary to the original beliefs propagator generates a mass term unless the hyperbolic cutoffs for time-like and space-like gauge boson momenta are in a definite relation. One could criticize this relation and argue that perhaps super-conformal symmetries might help to get the cancelation with identical cutoffs. It seems that this is not the case.

The UV cutoff for the hyperbolic angle as a function of p-adic length scale is the ad hoc element of the model in its recent form. How to formulate quantitatively the quantum criticality in terms of the behavior of the hyperbolic cutoff as function of p-adic length scale became therefore the basic problem and led what might like a numerics inspired random walk -or perhaps better to say sleep walk - towards what I believe to be the solution of the problem. During this kind of heavy numerical calculations one realizes how important it would be to have a colleague replicating the calculations. One can never be quite sure about signs and numerical factors.

1. The process gradually led to an improved understanding of the notion of coupling constant evolution itself. The fermionic loop integral contains a propagator pole contributing imaginary part to the inverse propagator and numerical calculations demonstrated that this contribution is too large to be physically acceptable. Moreover, the sign of coupling strength becomes negative for fermion masses above certain critical mass defining the IR cutoff for the loop momenta. The only manner to avoid difficulties is to assume that loop momenta are always below the p-adic mass scale associated with the momentum of the gauge boson. The assumption eliminates the imaginary part of propagator and keeps coupling constant strength positive. This also gives precise content to the notion of coupling constant evolution since it assigns to the mass scale of p IR cutoff  $k_{max}$  such that for  $k > k_{max}$  coupling constant strength is positive. A nice geometric interpretation is possible in zero energy ontology: loop corrections corresponding to geometric details sufficiently smaller than the length scale assignable to the mass squared.
2. The next idea was that perhaps one could fix the cutoff on hyperbolic angle (hyperbolic cutoff) by some naturally occurring condition. The first guess was that the sign of the coupling constant strength changes at either end of the p-adic half octave for the mass of gauge boson. The motivation to this idea could have come from the calculation of the momentum at which the sign changes for the model reproducing physically reasonable coupling constant evolution: at long length scales the sign indeed changes very near to the end of the half-octave. Unfortunately this did not work.
3. The next guess was that the value of boson momentum at which the sign changes is as near as possible to the end of the mass squared octave. Tedious calculations in a rather arctic numerical environment demonstrated that one obtains a discrete set of coupling constant evolutions but that the hyperbolic cutoff is increasing as a function of k rather than decreasing as required by the coupling constant evolution in standard model. The increase can be understood as a positive feedback effect: the vanishing of the inverse of the coupling constant at given length scale requires a contribution, which increases as a function of the p-adic length scale since the inverse of the coupling constant itself increases. The attempts to modify the model to modify this behavior failed.
4. The next idea was that perhaps p-adic fractality helps to assign the change of the sign at the ends of half octaves or to prime for which p-adic length scale is very near to that defined by the end of the half octave ( $p \simeq 2^k$ ). p-Adic fractals were one of the first ideas about p-adic physics and quite recently that also mathematicians have discovered them. They are obtained by mapping reals to p-adics by the inverse of the canonical identification I (or a proper variant of it) performing the arithmetics, and map the result back to reals by I. I had not found any

direct application except in the case of p-adic mass calculations where p-adic mass squared is mapped to its real counterpart.

The guess was obvious. Express M-matrix element a function of standard Lorentz invariants with dimensions of mass squared so that a very close connection with mass calculations is obtained. Map the invariants to their p-adic counterparts using the inverse of  $I$ , carry out the arithmetics defining the function in the p-adicity under question, and return to the reality using  $I$ . Maybe this could allow to achieve the cancelation at the end of the p-adic octave for mass squared. I do not believe this anymore but again a wrong idea led to what looks like a real increase in the understanding of quantum TGD and how p-adic and real physics relate at the level of M-matrix. One nice finding was that p-adic existence forces the loop masses to be above the mass of virtual gauge boson forced by purely physical conditions. It however seems that one must introduce transcendentals like  $\log(2)$  and  $\pi$  so that an algebraically infinite-dimensional and basically non-algebraic extension of p-adic numbers is unavoidable.

5. The p-adicization program for M-matrix involve a technical difficulty which led to a further progress. It is not possible to perform loop integrals in the p-adic context. All loop integrals must be carried out in the real context and the resulting functions must be p-adicized. For the bosonic vertices defined as purely fermionic loops this is not a problem but the situation changes for the expansion of the M-matrix involving both bosonic and fermionic lines inside loops. The same problem is encountered in the twistorialization and the solution of the problem is based on Cutkosky rules allowing unitarization of the tree amplitudes in terms of  $TT^\dagger$  contribution involving only light-like momenta seems to be the only working option and requires that  $TT^\dagger$  makes sense p-adically. This idea is actually very near to the original idea that only light-like momenta appear in loops so that twistorialization is elegant.  $TT^\dagger$  indeed allows interpretation in terms of loops so that I was not after all totally silly. The p-adic existence of the analytic continuation of  $TT^\dagger$  by dispersion relations poses strong constraints on otherwise not completely unique continuation.
6. After these steps I was mature to realize how to formulate quantum criticality in such a manner that it could fix the hyperbolic cutoff and hence coupling constant evolution uniquely. The fermionic loops defining bosonic vertices vanish when the incoming momenta are massless. This is it! The condition emerges as a consistency condition: if the vanishing does not occur for on mass shell bosons, one obtains T-matrix expressible in terms of analytic continuation of  $TT^\dagger$  and one does not have vertex identified as something irreducible anymore. The condition is suggested also by quantum criticality: the vanishing of vertices is very much analogous to the vanishing of higher functional derivatives of the action with respect to gauge fields at criticality (or derivatives of the potential function in Thom's catastrophe theory). Also the fact that only BFF vertex is fundamental vertex if bosonic emergence is accepted suggests the conditions. The vanishing of on mass shell N-vertices gives an infinite number of conditions on the hyperbolic cutoff as a function of the integer  $k$  labeling p-adic length scale at the limit when bosons are massless and IR cutoff for the loop mass scale is taken to zero. It is not yet clear whether dynamical symmetries, in particular super-conformal symmetries, are involved with the realization of the vanishing conditions or whether hyperbolic cutoff is all that is needed.

### 8.4.2 Searching for the solutions of criticality conditions

In the following criticality conditions are formulated more precisely and the results of the search for their solutions are summarized.

#### A detailed definition of the criticality conditions

The general definition of criticality should conform with  $ak^{-b}$  model for the coupling constant evolution in the sense that a small deformation of this model should result from the quantum criticality condition. Small deformation means that power law behavior should not be modified considerably (the logarithm of hyperbolic cutoff should be linear in the logarithm of  $k$ ) and the normalization at small values of  $k$  should not change much. The evolution of fine structure constant in the range  $k_{max} \in [89, 127]$  in turn fixes the value of  $a$  with high precision.

Before continuing it is convenient to introduce some notations. Let us denote by  $O(k)$  the half octave associated with  $k$  containing momenta  $p = xm_k = x2^{-k/2}m(CP_2)$ ,  $x \in [2^{-1/2}, 1)$ . Denote by  $J(k, k-1)$  the junction of  $O(k)$  and  $O(k-1)$  containing the point  $p = m_k$ . Define a distance inside half octave as in music - that is as  $d$  in  $x = 2^{d-1/2}$  so that the  $d = 1/4$  represents the middle point of the half octave and points with  $d < 1/4$  are nearer to the lower and those with  $d > 1/4$  nearer to the upper end of  $O(k)$ .

The detailed calculations of  $1/\alpha_{em}(p, k_{max})$  as a function of  $p = xm_{k_0}$  in  $ak^{-b}$  model demonstrate that the sign of  $1/\alpha_{em}(p, k_{max})$  becomes stably positive for  $k_0 \geq k_{max} + n$ , where  $n$  depends on  $k_{max}$ . The conditions are summarized in the following. The criterion has been that 5 values with distances  $d = (i-1)/2N_{max}$  in  $O(k_{max} + n_{max})$  are positive ( $N_{max} = 4$ ).

$$\begin{aligned}
 n(k_{max}) &= 9 && \text{for } 1 \leq k_{max} \leq 4 \quad , \\
 n(k_{max}) &= 8 && \text{for } 5 \leq k_{max} \leq 8 \quad , \\
 n(k_{max}) &= 7 && \text{for } 9 \leq k_{max} \leq 14 \quad , \\
 n(k_{max}) &= 6 && \text{for } 15 \leq k_{max} \leq 22 \quad , \\
 n(k_{max}) &= 5 && \text{for } 23 \leq k_{max} \leq 39 \quad , \\
 n(k_{max}) &= 4 && \text{for } 40 \leq k_{max} \leq 71 \quad , \\
 n(k_{max}) &= 3 && \text{for } 72 \leq k_{max} \leq 109 \quad , \\
 n(k_{max}) &= 3 && \text{for } k \bmod 2 = 1 \& 110 \leq k_{max} \leq 134 \quad , \\
 n(k_{max}) &= 2 && \text{for } k \bmod 2 = 0 \& 110 \leq k_{max} \leq 134 \quad , \\
 n(k_{max}) &= 1 && \text{for } k_{max} \geq 135 \quad .
 \end{aligned}
 \tag{8.4.1}$$

For instance, for  $k_{max} \leq 4$  one has  $n(k_{max}) = 9$  and for  $k = 127$   $n(127) = 3$ .  $n(k_{max})$  is piecewise constant and monotonically decreasing as function of  $k_{max}$  except in the range  $[110, 134]$  where one has  $n(k_{max}) = 2$  for even values of  $k_{max}$  and  $n(k_{max}) = 3$  for odd values of  $k_{max}$ . Note that  $n(k_{max}) = 2$ , where oscillations set on corresponds to the p-adic length scale assignable to deuteron. The length scale range in which oscillations occur is between hadronic and atomic physics length scales.

Asymptotia is reached after  $k_{max} = 134$  - which is between electron's and atom's p-adic length scales - as  $n(k_{max})$  changes from 2 to 1.  $Y = 1/\alpha_{em}(p, k_{max})$  must vanish at the lower boundary  $O(k_{max})$  in the asymptotic region. The first prime in this range is  $k_0 = 137$  defining the p-adic length scale of atom. Note that fine structure constant  $1/\alpha_{em} \simeq 137$  is the fundamental constant of atomic physics and its value at electron length scale equals to Kähler coupling strength. .

### The behavior of the cutoff momentum as function of $k$

The attempts to realized the scenario for quantum criticality led to the question about the behavior as a function of  $k_{max}$  of the cutoff momentum  $p$  at which the inverse of propagator vanishes. If the propagator is continuous function of  $p$  this momentum should reside in the half octave  $k_{max} + n(k_{max})$ .

The calculation of the momentum value at which the inverse propagator vanishes as a function of  $k_{max}$  shows that above  $k_{max} = 61$  the cutoff momentum  $p$  tends to be very near to the upper end of the half octave for the ideal hyperbolic cutoff.

1. The first thing to notice is that there is strong correlation between the graphs of  $n(k)$  and  $p(k + n(k))/m(k + n(k))$ .
2. The behavior of  $f(k) = p(k + n(k))/m(k + n(k))$  brings in mind generalized 2-adic fractal since it typically increases essentially linearly from a minimum value  $k_0$  up to maximum value  $k_0\Delta k$  at which the value is suddenly reduced. The values of  $\Delta k$  appearing in the graph are 3, 4, 5, 7, 16, 21, 1. For  $k \geq 73$  the behave stabilizes to a 2-adic fractal for which odd values of  $k$  correspond to minima and even values of  $k$  maxima probably equal to  $\sqrt{2}$ . The numerical approach does not allow to tell whether this is the case. This means that the cutoff momenta associated with even  $k$  and its odd follower are very nearly equal. Similar situation sharpens at higher momenta and also when the end point is near 1.
3. The calculation for  $k \in [110, 134]$  gives  $n(k_{max}) = 3$  for odd  $k_{max}$  and  $n(k_{max}) = 2$  for even  $k_{max}$  and  $f(k) = 1$ . For  $k = 135$   $n = 1$  is established. This is an alternative mechanism guaranteing that the values of cutoff momentum are very near to each other. For large values of  $k_{max}$  the

Figure 8.6: The graph represents the ratio  $p(k + n(k))/m(k + n(k))$  of the critical mass to the p-adic mass scale having variation range  $[1, \sqrt{2}]$ . Second graph representing  $n(k_{max})$  demonstrates the correlation between the two plots. The values of the calculated ratio at the upper end are not exact since the convergence to the actual value, presumably equal to  $\sqrt{2}$ , is so slow that calculation does not reach the zero in the available calculation time.

4. The corresponding powers  $2^{\Delta k}$  could also correspond to primes near them so that one would have 2-adic fractality. The behavior of  $f(k)$  resembles population dynamics for which  $n(k)$  serves as a control parameter with breakdown of population induced by the reduction of  $n(k)$ .  $n(k)$  would be analogous to a temperature like parameter whose decrease reduces the population. Population however immediately adapts to the reduced value of the temperature. Above  $k = 73$  the dynamics becomes more like that of market economy and for large values of  $k$  not shown in the graph situation stabilizes to that of minimum population.

One might think that the change of the sign of the fine structure constant in apparently or genuinely discontinuous manner at the end point of the half-octave is due to the logarithmic singularity which moves from the range  $[1, u_{max}]$  outside it  $u = u_{max}$  and in this manner causes discontinuity. This cannot be the case since the value of  $n_{max}$  is 3 or 2 and even large in the region considered. At this moment the underlying mechanism is not understood.

This raises the question whether the phenomenon occurs only for the values  $a, b$  of the parameters of the model consistent with the coupling constant evolution. The emergence of p-adic mass scales as preferred ones would of course be a fantastic support for the model. The experimentation varying values of  $a$  ( $a = .1$  and  $a = .2$ ) however gives similar qualitative behavior at large values of  $k$ . For instance, for  $a = .2$   $p$  is at either end of the half octave for  $k_{max} = 107, 108, 109$ .

One can wonder whether the hyperbolic cutoff quite generally correspond to either end point of the half octave or a momentum given by p-adic mass scale as near as possible to the end point. One can consider various forms of the hypothesis.

1. The critical momentum at which the amplitude vanishes is always at either end point of the the half octave  $k_{max} + n(k_{max})$ . The following considerations demonstrate that this option fails.
2. The zero of  $X = 1/\alpha_{em}(k_{max})$  is as near as possible to either end point of the half octave  $k_{max} + n(k_{max}) - 1$ . The technical formulation is as the condition that both  $X$  and  $\partial_{u_{max}} X$  vanish so that  $du_{max}/dp$  at curve  $X = 0$  vanishes at criticality. This would mean kind of fixed point property. This option predicts the increase of  $u_{max}$  as function of  $k_{max}$  that is asymptotic freedom for all bare couplings. If the value of hyperbolic cutoff is small enough for  $k_{max} = 1$ , it could increase for small values of  $k_{max}$  and start to decrease somewhere around  $k_{max} = 74$ . Since the behavior at long length scales reflects only the net contribution from short length scales it might be possible to obtain consistency with the values of the fine structure constant at electron and intermediate boson length scales.

3. A further option is that a discontinuous change of the sign and magnitude at the end point - taking place for large values of  $k_{max}$  at least apparently - occurs quite generally. One could also argue that the inverse of coupling strength must be non-vanishing at the cutoff momentum to avoid the divergence of the propagator as momentum approaches this limit. The attempts to realize this scenario as a small deformation of  $ak^{-b}$  model however fail: it turns that  $X$  for small values of  $k$  is continuous and preserves change sign at the end point of the half-octave fixed by  $ak^{-b}$  model.
4. The behavior of  $1/\alpha_{em}(k_{max}, p)$  near critical momentum brings strongly in mind 2-adic fractals or their generalization which might be called  $2^k$ -fractals. The characteristic feature would be discontinuities at powers  $2^k$ . This behavior could be more or less equivalent with  $p \simeq 2^k$ -adic fractality. This raises the question whether the bosonic propagator should be replaced with its fractal variant so that one would obtain discontinuities and even zeros of  $1/\alpha_{em}(k_{max})$  near or at the end points half-octave for a small deformation of  $ak^{-b}$  model and whether primes  $p$  as near to  $2^k$  as possible would emerge naturally in this manner.

In the following these options are discussed in detail.

### The first model for the hyperbolic cutoff

Previous findings motivate the following concrete proposal.

1.  $Y = 1/\alpha_{em}(p, k_{max})$  vanishes at the junction  $J(k_{max} + n(k_{max}), k_{max} + n(k_{max}) - 1)$  that is for momentum  $p = m(k_{max} + n(k_{max}))$  representing the maximum momentum in  $O(k_{max} + n(k_{max}))$  if the point at which the sign changes in  $O(k_{max} + n(k_{max}) - 1)$  occurs is nearer to this junction. If the sign changes nearer to the junction of  $J(k_{max} + n - 1, k_{max} + n - 2)$  so that  $d > 1/4$  for the point in question, the sign change should take place at  $J(k_{max} + n - 1, k_{max} + n - 2)$  so that one has  $p = m(k_{max} + n(k_{max}) - 1)$ .
2. A more refined option for the identification of the cutoff momentum  $p$  would give a connection with the p-adic length scale hypothesis. The junction could be replaced with the p-adic mass scale  $p = \sqrt{q}m(CP_2) \in O(k)$  for prime  $q \in (2^{k-1}, 2^k)$  and as near as possible to the end point of the half octave. One would have  $k = k_{max} + n(k_{max})$  or  $k = k_{max} + n(k_{max}) - 1$  depending on whether the point at which sign changes is nearer to  $m(k_{max} + n)$  or  $m(k_{max} + n - 1)$ . This would provide an additional flexibility possibly significant for small values of  $k_{max}$  where small changes of the parameters affect dramatically the evolution of coupling constants in longer length scales. This option would explain the special importance of Mersenne primes and exclude Fermat primes. Note however that the primes in question are rather large and dense already for  $k_{max} = 1$ : since the prime in question is around  $2^{10}$  the variation  $\Delta p/p$  is of order  $2^{-10}$  as one moves from the end of the half octave to the nearest prime.

The computer code searching for the critical hyperbolic cutoff as a small deformation of the cutoff consistent with coupling constant evolution has rather simple structure. Similar procedure applies also if one assumes that the hyperbolic cutoff corresponds to a p-adic length scale near the end point of the half octave.

1. The program proceeds from  $k_{max} = 1$  one by one using the information obtained in previous steps to find hyperbolic cutoff at given value of  $k_{max}$  as a small deformation of that predicted by  $ak^{-b}$  model.
2. At each step the program calculates the values of  $Y = 1/\alpha_{em}(p, k_{max})$  for  $N$  points  $x(i) = 2^{-1/2+(i-1)/N}$ ,  $i = 1, N + 1$  in the interval  $O(k_{max} + n(k_{max}) - 1)$ , finds whether the sign changes occurs near the lower or upper end, and selects cutoff momentum accordingly as  $m(k_{max} + n(k_{max}))$  or  $m(k_{max} + n(k_{max}) - 1)$ . After this the program searches for two values of hyperbolic cutoff for  $k_{max}$  such that the signs of  $Y$  for them are different and finds the value of hyperbolic cutoff giving zero of  $Y$  by (say) interval halving.

This simple picture could fail and indeed seems to do it.

1.  $n(k_{max})$  need not remain same when cutoff  $ak^{-b}$  is replaced with the perturbed cutoff. Hence it seems that one must regard  $n(k_{max} = 1)$  as an integer labeling different coupling constant evolutions characterized by corresponding hyperbolic cutoff.
2. Preliminary calculations also support the conclusion that for physically sensible values of hyperbolic cutoff for  $k_{max} = 1$  the vanishing conditions can be satisfied for  $k_{max} = 1$  and  $k_{max} = 2$  at the lower end of the interval  $O(k_{max} + n(k_{max}))$  but that already for  $k_{max} = 3$  the conditions fail. The reason is that the value of  $J(k_{max} + n(k_{max}), k_{max} + n(k_{max}) - 1)$  is small and positive and  $1/\alpha_{em}(p, k_{max})$  has positive minimum here so that zero is not possible. In the junction  $J(k_{max} + n(k_{max}) - 1, k_{max} + n(k_{max}) - 2)$   $1/\alpha_{em}(p, k_{max})$  is large and negative and unrealistically large hyperbolic cutoff would be required.

These findings suggest a connection with the p-adic length scale hypothesis. In its strongest form it however cannot help in the problem at hand.

1. In the spirit of criticality one can consider the hypothesis that the p-adic prime in question is as near as possible to the zero junction but below the power of 2 characterizing it. The cutoff momentum would thus correspond to the largest possible one for the curve  $Y(u_{max}, p) = 0$  in the p-adic half octave. In this manner a finite number of scenarios would result since the parameters would be  $n(k_{max})$  and the set of values of hyperbolic cutoff labeled by these primes. For  $n(k_{max} = 1) = 9$  these primes would belong to the upper half of the octave  $[2^8, 2^9]$ . The list of these 25 primes is

367, 373, 379, 383, 389, 397, 401, 409, 419, 421, 431, 433, 439, 443, 449, 457, 461, 463, 467, 479,  
487, 491, 499, 503, 509 .

The problem of this option is that it allow in principle quite large number of alternatives since for each value of  $k_{max}$  branching becomes possible unless one poses additional conditions such as decrease of the hyperbolic cutoff.

2.  $J(k_{max} + n(k_{max}), k_{max} + n(k_{max}) - 1)$  for  $k = 3$  corresponds to a minimum of  $Y = 1/\alpha_{em}(p, k_{max})$  as a function of the hyperbolic cutoff  $u_{max}$ . This inspires a refined hypothesis attaching a genuine physical meaning to the preferred prime  $p(k_{max})$  in accordance with the notion of criticality stating that coupling strength is extremum with respect to some variable, most naturally the parameter  $u_{max}$ . Thus the hyperbolic cutoff for a given  $k_{max}$  would be such that  $Y$  vanishes for  $p(k_{max})$  and is minimum (or possibly maximum) as a function of  $u_{max}$  or momentum  $p$ . The only natural choice is  $u_{max}$ . Thus  $(Y = 0, u_{max}, p)$  could be interpreted as a fixed point of the coupling constant flow with respect to hyperbolic cutoff.
3. The geometric picture would be following. The graph of  $Y$  as a function  $Y(p, u_{max})$  of momentum  $p$  and hyperbolic cutoff  $u_{max}$  is a 2-D surface, and the zeros of  $Y$  define a curve  $X(p, u_{max}) = 0$  as the intersection of  $Y = 0$  plane and the surface  $Y(p, u_{max}) = 0$ . One would have the conditions

$$\begin{aligned}
 Y(p, u_{max}) &= 0 \quad , \\
 \frac{\partial Y}{\partial u_{max}} &= 0 \quad .
 \end{aligned}
 \tag{8.4.2}$$

The constancy of  $Y$  along  $X$  implies the condition

$$\frac{\partial Y}{\partial u_{max}} + \frac{\partial Y}{\partial p} \frac{dp}{du_{max}} = 0 \quad .
 \tag{8.4.3}$$

along the curve  $X$ . Together these conditions imply that the extremum satisfies either of the following conditions

$$\frac{\partial Y}{\partial p} = 0 \quad \text{or} \quad \frac{dp}{du_{max}} = 0 \quad . \quad (8.4.4)$$

In the generic case both partial derivatives can vanish only in a discrete set of points in the space spanned by  $Y, u_{max}$  and  $p$  and the restriction to the plane  $Y = 0$  makes the solution set empty in the generic case. Thus the physically acceptable solutions would correspond to the turning point of the curve  $X$  as  $du/dp$  changes its sign. The cutoff momentum would thus be as near as possible to the upper end of the half octave. In the case that no turning point exists, one can choose the  $u_{max}$  to correspond to the end point of half octave so that the original picture results as a special case.

4. If prime  $p(k_{max})$  as near as possible to the minimum point p-adic length scale hypothesis is realized. The really good (probably too good!) news would be that prime corresponds to the exact minimum. This variational principle fixes coupling constant evolution to a high degree even without the p-adic length scale hypothesis.

Several methods to find the zero of the derivative of  $Y$  with respect to  $u_{max}$  have been tried since the severe restrictions posed by the numerical environment require efficient calculations. The fastest numerical realization for the search of  $u_{max}$  found hitherto is based on the assumption of differentiability. The idea is of course that differentiability allows to extract global information from local information. For instance, interval halving method assumes only continuity and is much slower. Differentiability means  $Y$  can be expanded as Taylor polynomial with respect to  $p$  for a constant value of  $u_{max}$  and vice versa. Repeated use of the numerically estimated first order Taylor polynomial allows to find the zero of both  $Y$  and zero of its partial derivative with respect to  $u_{max}$ .

1. Fix the interval  $O(k_{max} + n(k_{max}))$ . By a guesswork find a value of  $u_{max}$  for which the sign of  $Y$  is different at the end points of the interval. Calculate the derivative of  $Y$  numerically with respect to  $p$  at the lower end of the half-octave and approximating  $Y$  by first order Taylor polynomial estimate the value of  $p$  at which  $Y = 0$  holds true. At this point calculate the derivative of  $Y$  again and repeat the estimate.
2. To find the zero of derivative of  $Y$  with respect to  $u_{max}$  at  $Y = 0$  estimate numerically first and second derivative of  $Y$  with respect to  $u_{max}$  numerically and from the first order Taylor polynomial for the first derivative estimate the value  $u_{max}$  at which the first derivative vanishes.

Note that there is a connection with renormalization group theory. The negative contribution from the pole must compensate the contributions from shorter p-adic length scales, which themselves must cancel to a high degree. Certainly they can do it. The contribution from highest scale would compensate the change of the contributions from shorter scales resulting from change of the p-adic length scale of momentum. The vanishing conditions give kind of renormalization group equation governing the stationary situation and states that the hyperbolic cutoff in scale  $k_{max}$  must be such that its contribution cancels the change of the  $k < k_{max}$  contributions due to the increases of the cutoff momentum. This condition is not quite all since it only assigns to  $Y = 0$  a definite value of  $p$  but leaves cutoff open. The vanishing of derivative gives additional condition.

### About the results of preliminary calculations

Preliminary calculations carried out up to  $k_{max} = 9$  lead to  $\sinh(\eta_{max})(1) = 0.20600945079286$  and to a value of hyperbolic cutoff which starts to gradually increase at  $k_{max} = 3$  as the table below shows. In the table the label 'cr' refers to the cutoff implied by quantum criticality and 'id' corresponds to the cutoff reproducing the coupling constant evolution.

$k_{max}$	1	2	3	
$cr$	0.20600945079286	0.14741274374679	0.12231921784712	
$id$	0.22050469512552	0.17501469250309	0.15288941641253	
$k_{max}$	4	5	6	
$cr$	0.12717022328504	0.13289051287886	0.13935265256642	(8.4.5)
$id$	0.13890925349465	0.12895192798125	0.12134841022403	
$k_{max}$	7	8	9	
$cr$	0.14687347939079	0.15423164581071	0.16257461579696	
$id$	0.11527058427996	0.11025234756276	0.10600760059852	

The increase can be understood as a positive feedback effect.

1. The calculation predicts  $n(k_{max}) = 9$  for all  $k_{max} \leq 9$  whereas the  $ak^{-b}$  model gives  $k_{max} = 8$  for  $4 \leq k_{max} \leq 7$  and  $k_{max} = 7$  for  $8 \leq 12$ . The problem must relate closely to the sticking to a fixed value of  $k_{max}$ .
2. For a given  $k_{max}$  the contribution from  $k_{max,i} + n(k_{max,i}), k_{max,i} < k_{max}$  to  $Y$  for  $p$  in  $O(k_{max} + n(k_{max}) - 1)$  is positive unless one has  $n_{k_{max}} < n_{k_{max}} - 1$  in which case both values of  $k_{max}$  give negative contributions. Hence the hyperbolic cutoff must increase in order to produce large enough negative contribution.
3. By a judicious choice of  $\sinh(\eta_{max})(k_{max})$  having a discrete set of possible values in one-one correspondence with different values of  $n(k_{max})$ , the feedback effect should become negative and guarantee that  $n(k_{max})$  approaches to unity fast enough. A sufficient reduction of the starting point estimate for  $\sinh(\eta_{max})$  for  $k_{max} \geq 4$  should induce a reduction  $n(k_{max})$  and allow a realistic evolution. Also the initial value  $\sinh(\eta_{max})(1)$  might require changing to a larger or smaller one.

The experimentation by varying the value of  $\sinh(\eta_{max})(1)$  does not give encouraging results. Hyperbolic cutoff begins to increase for all series listed below.

$k$	1	2	3	4
$\sinh(\eta_{max}(k))$	0.09660156250000	0.07527753426130	0.05642313113454	0.058050094309350
	0.13951072443182	0.10638078636486	0.08206464660889	0.08475010008178
	0.16883146306818	0.12598096859481	0.09976082012596	0.10329475255049
	0.20600945079286	0.14741274374679	0.12231921784712	0.13890925349465
	0.25472427728834	0.20217479286468	0.15842711440463	0.17679278339077

(8.4.6)

What could go wrong? These calculations are based on the assumption that the critical momentum is *nearer to the lower end* of the critical half-octave at which  $Y$  changes sign.  $p$  could be however also *nearer to the upper end* of the critical half-octave. The most general option allows both alternatives. If even and odd values of  $k$  correspond to different alternatives, the values of critical momenta are near to each other and  $k_{max}$  contribution must compensate a contribution from shorter scales which is as small as possible since it corresponds to the difference of the critical momenta. This could allow to avoid the increase of  $\sinh(\eta_{max})(k)$ . At the next step the distance between momenta would be however nearly two octaves in the worst case unless the value of  $n_{max}$  is reduced by unity and this could induce to the increase of the cutoff. Only numerical experimentation can tell whether this option works. The experimentation with the option  $\sinh(\eta_{max}(1)) = 0.20600945079286$  yields disappointment. For instance, the value of cutoff can be reduced for  $k_{max} = 4$  but it returns back to the earlier value at  $k_{max} = 5$ .

The increase at small values of  $k_{max}$  need not be a catastrophe as I thought first.

1. The increase of  $u_{max}$  as function of  $k_{max}$  is asymptotic freedom for all bare couplings and this is in accordance with GUT type thinking.
2. As already found, at large values of  $k_{max}$  the calculations show that critical momenta correspond to end points of the half-octaves for  $ak^{-b}$  model so that the decrease of the hyperbolic cutoff conforms with criticality. For instance, for  $a = .20, b = 1/3$  the lower end of the half-octave corresponds to the zero  $X$  in the range  $k_{max} = 89, \dots, 91$  (I have not checked how long interval gives the same result).
3. If the value of hyperbolic cutoff is small enough for  $k_{max} = 1$ , it could increase for small values of  $k_{max}$  and start to decrease for some value of  $k_{max} < 89$ . Since the behavior at long length scales reflects only the net contribution from short length scales, it might be possible to obtain consistency with the values of fine structure constant at electron and intermediate boson length scales. Unfortunately the numerical calculations are very slow with the computer resources available so that it takes time to check this.

The calculations done for the option  $\sinh(\eta_{max}(1)) = 0.09660156250000$  up to  $k_{max} = 29$  are not encouraging in this respect.

Figure 8.7: The hyperbolic cutoff  $\sinh(\eta_{max}(k))$  for the model of criticality with  $\sinh(\eta_{max}(1)) = 0.09660156250000$  assuming that critical momentum corresponds to the vanishing of both  $1/\alpha_{em}$  and  $\partial_{u_{max}}1/\alpha_{em}$  so that critical momentum as near as possible to an end point of half octave.

The growth of the hyperbolic cutoff is in good approximation exponential with a slowly increasing rate parameter  $r$ . At certain value of  $r$  starts to increase rapidly as the figure 8.4.2 demonstrates. This kind of behavior is definitely non-physical.

Could one consider any cure to the situation? As already noticed, the relationship between the time-like and space-like hyperbolic cutoffs forced by the cancelation of the radiative mass is number theoretically cumbersome, and it might be that super-conformal symmetry or some more general symmetry could guarantee the cancelation of the radiative mass just as space-time super-symmetry does this in SUSYs [69]. This would allow the time-like and space-like cutoffs to be identical and affect considerably the loop corrections since space-like corrections would dominate and one would expect behavior of the hyperbolic cutoff to be roughly  $a/k$  rather than  $ak^{-1/3}$ . At this moment it is not possible to do any quantitative calculations in this respect without making simplifying ad hoc assumptions.

### 8.4.3 Could p-adic fractality solve the problems?

The above described proposals for how quantum criticality could fix coupling constant evolution in a manner consistent with  $ak^{-b}$  model might fail. The fundamental observation is that critical momenta

Figure 8.8: The ratio  $r = \text{cut}(k+1)/\text{cut}(k)$  for the hyperbolic cutoff  $\text{cut}(k) \equiv \sinh(\eta_{\text{max}}(k))$  as function of  $k$  for three values of  $\text{cut}(1)$  is in reasonable approximation constant so that  $\text{cut}(k)$  increases exponentially. For certain critical value  $r$  begins to increase rapidly.

correspond to an end point of the half octave for large values of  $k$  automatically and  $2^k$ -adic behavior and discontinuities at the end point of the half octave emerges naturally at this limit. The obvious question is whether and how could one generalize this behavior. Superconformal invariance and some more general symmetry has been already mentioned. Or should one perhaps replace the inverse propagator with p-adic fractal to obtain discontinuities or perhaps even zeros at the end points of half-octaves for all values of  $k_{\text{max}}$ ? p-Adic thermodynamics in which mass squared and probabilities are p-adic valued and mapped to their real counterparts by canonical identification [49, 31] indeed suggests an approach based on p-adic fractalization. One can imagine several variants of this fractalization.

1. One could replace inverse propagator as a function of mass squared with its p-adic fractal variant obtained by the fractalization procedure meaning the replacement of  $p^2$  (mass squared) with its  $2^k$ -adic variant in the argument of  $1/\alpha_{em}(k_{\text{max}})$ , the replacement of ordinary algebraic operations with their  $2^k$ -adic or p-adic counterparts and the mapping of the resulting p-adic valued function back to the reals by the inverse of the canonical identification. The proposed model yielding the real propagator would remain an exact part of the model. The problem is that p-adicization respects the zeros of function so that the zeros of  $1/\alpha_{em}(k_{\text{max}})$  would not be shifted to the end points of half-octaves.
2. The loop integral for a given half octave  $O(k)$ ,  $1 \leq k \leq k_{\text{max}}$ , is the basic building block of  $1/\alpha_{em}(k_{\text{max}})$ . This suggests that it is these contributions which are  $2^k$ -adicized or p-adicized for  $p \simeq 2^k$ . The sum over these contributions carried out using  $2^k$ - or p-adic arithmetics would bring in the fractality. This would make possible to shift the zeros near the end points of the half octave with a proper choice of hyperbolic cutoff or even the replacement of zeros by discontinuous change of sign. If the detailed fractalization recipe is such that for large values of  $2^k$  or  $p$  real topology results in a good approximation, a consistency  $2^k$ -adic fractality suggested near cutoff mass also by the number based real approach for large values of  $k_{\text{max}}$  is obtained.
3. One could also consider the option in which one performs p-adic fractalization for the integrand appearing in the loop integral. This option however means quite a dramatic departure from the original model. For instance, the relationship between time-like and space-like hyperbolic cutoffs are lost guaranteeing masslessness would be lost. Also the definition of the p-adic variant of the momentum space represents a non-trivial challenges and one should treat mass squared and hyperbolic angle and other angles in non-symmetric manner in order to avoid the loss of Lorentz invariance. If all these coordinates are p-adicized there is algebraic interaction between all of them and hopes about reasonably simple numerics are lost. Already these reasons are enough to not consider this option. A further generalization would be the replacement of the

real loop integral by its possibly existing p-adic variant but the non-existence of satisfactory definition of p-adic definite integral is discouraging.

### The general recipe for p-adic fractalization

p-Adic fractals are obtained by replacing real analytic function  $f_R(x)$  with integer valued coefficients with its p-adic variant  $f_p(x)$ . One maps first the argument  $x_R$  to its p-adic variant  $x_p$  by the inverse  $I^{-1}$  of the canonical identification, calculates  $f(x_p)$  interpreted now as p-adically analytic function, and then maps the  $f(x_p)$  to a real number  $(f(x_p))_R$  by  $I$ . Since  $I$  does not commute with arithmetic operations, one obtains a fractal which has typically discontinuities at powers of  $p$ . By suitably generalizing the notion of canonical identification one can consider also functions for which the coefficients of Laurent series are rational numbers. Allowing algebraic extensions of p-adic numbers one can consider also algebraic coefficients.

Canonical identification allows several variants.

1. The simplest variant of a p-adic fractal is obtained by using the rule  $\sum x_n p^n \rightarrow f_p(x) = \sum x_n p^{-n}$  to map p-adic numbers to their real counterparts in a continuous manner. The inverse of the canonical identification is unique for numbers of form  $2^k n$ ,  $n$  a finite integer. If  $n$  is p-adic integer infinite as a real integer the inverse image of its image is two-valued. This corresponds to the fact that the binary expansion for real numbers is not unique when the number of binary digits is infinite (for instance  $-1 = (p-1)(1+p+p^2\dots)$  and  $1/p$  are mapped to same real point  $p$  in canonical identification).
2. Canonical identification is continuous but does not commute with the basic arithmetic operations since in general one has  $(x+y)_R \neq x_R + y_R$  and  $(xy)_R \neq x_R y_R$ . For integers smaller enough than  $p$  one has however commutativity so that addition and multiplication and also subtraction if it does not produce negative number commute in approximate sense with  $I$ .
3. One can consider also a canonical identification based on writing 2-adic expansion in the form  $x = \sum x_n p^{nk}$ ,  $x_n = \sum_0^{k-1} y_{nr} p^r$ . This map maps all integers smaller than  $p^k$  to itself. One might speak of  $p^k$ -adic fractal in this case. Effective p-adic topology could be interpreted in terms of  $2^k$ -adic fractality since  $2^k$ -adic thermodynamics and p-adic thermodynamics for  $p \simeq 2^k$  give very similar predictions for particle masses. p-Adic length scale  $k$  could correspond to the canonical identification labeled by  $k$  and at long length scales ordinary topology would gradually establish itself.
4. The problem of the simplest variants of canonical identification is that they do not respect even approximately real division: except in special cases  $I(m/n)$  does not have much to do with  $I(m)/I(n)$  if one expresses  $m/n$  as an infinite series in powers of  $p$  as is always possible. Physically  $I(m/n) \simeq I(m)/I(n)$  property would be however desirable approximately at least. The modification of the canonical identification respecting this property is based on the unique representation of the rational number as  $q = m/n$  ( $m$  and  $n$  have no common factors) and the definition of the canonical identification as  $q \rightarrow I(m)/I(n)$ . Here also  $p^k$ -adic variant of  $I$  could be used so that rationals with  $m < p^k, n < p^k$  would be mapped to rationals. In this manner canonical identification could be generalized to functions  $f(x)$  for which Laurent series has rational valued coefficients. Also algebraic coefficients are possible if algebraic extensions of p-adics are allowed.
5. The arithmetic operations on p-adic side - sums in the recent case - should be performed in such a manner that the outcome is a rational number mapped to real side by the inverse of the variant of canonical identification used. This is possible in a unique manner if binary cutoff for the expansions in powers of  $p$  is introduced. Also the fact that infinite series in powers of  $p$  appear makes binary cutoff necessary. The sum of the contributions from different p-adic half-octaves would reduce to sums of rationals and could be carried out in standard manner by forming a common denominator as a product of denominators. The representation as a generalized rational in which  $m$  and  $n$  are p-adic integers infinite as real integers is not unique since  $m/n$  can be always represented as an infinite integer when  $n$  is not divisible by  $p$ . The recipe for forming sums of rationals by forming common denominator would formally work but in practice binary cutoff is unavoidable in any case.

6. A conceptual problem related to the canonical identification is that it is not general coordinate invariant concept so that one encounters potential problems with symmetries. In the recent case however only mass squared defines a unique coordinate as Lorentz invariant and one circumvents this kind of problems.
7. Canonical identification maps all p-adic numbers to non-negative ones and minus sign has no natural p-adic counterpart so that p-adic fractalization of functions having also negative values requires a special care.
  - (a) The first problem is that it is not clear how to map negative real numbers to their p-adic counterparts. In the recent case however absolute value of  $p^2$  appears as the argument of the propagator so that this is not a problem. If one just takes the real analytic function with rational Laurent series and interprets it as its p-adic variant, canonical identification gives always a non-negative real function. For the inverse of the propagator one does not encounter this problem for physical values of  $p$  since non-negativity dictates the cutoff momentum. On the other hand, p-adicization would yield a non-negative value of  $1/\alpha_{em}$  everywhere and one could consider the possibility that this could be the deeper reason why for the p-adic fractalization. p-Adic fractalization might take place also in the confinement phase transition in which the coupling strength becomes negative in QFT based on real topology for mass squared.
  - (b) One could also separate the sign of real function by decomposing the domain of definition to regions in which the function has definite sign. The absolute value of the function could be mapped to its p-adic counterpart and mapped back by canonical identification in this approach. This kind of separation of sign factor is carried out also in Lebesgue integral.
8. Imaginary unit is also a potential problem, which is however absent if the physically unavoidable momentum cutoff eliminating pole contribution to the propagator is posed. For  $p \bmod 4 = 3$  imaginary unit can be introduced via an algebraic extension and it is natural to map real imaginary unit to its p-adic counterpart in this case. For  $p \bmod 4 = 1$   $\sqrt{-1}$  however exists as a p-adic number and the real image of the p-adicized complex function is real function in this case so that it seems that one must pose the condition  $p \bmod 4 = 3$  or treat the real imaginary unit just like minus sign.

#### p-Adic fractalization of propagator

The first rough sketch for the criticality realized in terms of p-adic fractalization would be as follows.

1. One begins from the analytic expression for the contribution from the half-octave  $k \leq k_{max}$ , maps momentum  $p$  to p-adic number by  $I^{-1}$ , replaces the contribution with its p-adic variant, performs the p-adic summation of the contributions with various values of  $k$  and maps the result to reals by  $I$ . For a given value of  $k_{max}$   $2^{k_{max}+n(k_{max})}$ -adic fractalization based on  $I(m/n) = I(m)/I(n)$  takes place. Alternatively, p-adic fractalization with  $p \simeq 2^{k_{max}+n(k_{max})}$  is carried out.
2. Hyperbolic cutoff as a function of  $k_{max}$  is required to be such that the cutoff momentum  $p$  is at the either end of the half-octave. Stronger condition would be that  $1/\alpha_{em}$  vanishes at the end of the interval.
3. As far as numerics is considered, the new element is the replacement of the analytic representation of the loop integral for given value of  $k$  with its p-adic variant. This representation exists with certain restrictions on the values of  $p/m_k$ .
  - (a) Integrals of rational functions with integer coefficients are in question and give rational functions and logarithms. In the case of logarithms problems are encountered unless one can reduce everything these functions to  $\log(1+x)$  existing p-adically for  $|x|_p < 1$ . One must of course introduce  $\log(2)$  since the asymptotic contribution is proportional to  $\log(2)$ . Also  $\pi$  must be introduced the extension of p-adic numbers infinite-dimensional in the algebraic sense. These restrictions might well force the p-adic momentum cutoff number theoretically.

- (b) The inspection of the formulas for the integrals involved shows that for momenta in the region where one cannot expand the logarithms of integrands as power series the logarithms make the situation very complex. This provides number theoretic justification for the introduction of the cutoff of loop momenta larger than the virtual mass of gauge boson. It also eliminates the non-physical imaginary pole contribution and one gets rid of the problems posed by the negative values of the propagator.
- (c) In the asymptotic region where  $x_{k,r} = 2^{-r} \times (p/m(k_{max}))$ ,  $r \in \{1/2, 1\}$  ( $p$  denotes mass here) is small both in real and p-adic sense, the situation is relatively simple.  $p^2$  is indeed of order  $O(p)$  or  $O(2^{k_{max}+n_{k_{max}}})$  p-adically so that this condition is satisfied. If powers of  $u_{max}$  and  $x_{k,r}$  exist p-adically, various rational integrals exist p-adically. Also  $\log(u_{max})$  must make sense p-adically and  $u_{max} = 1 + O(p)$  is the minimal requirement guaranteeing this. At least  $\sqrt{2}$ ,  $\log(2)$ , and  $\pi$  must belong to the extension of p-adic numbers used. For a genuinely p-adic topology the cutoff hierarchy depends on p-adic prime  $p$  but for  $2^k$ -adic case cutoff hierarchy is same for all values of  $k$  so that  $2^k$ -adicity looks a more appropriate option.
4. The basic challenge is the summation of the contributions from different value of  $k_{max}$ . For suitably chosen cutoffs this might be possible to carry out analytically and the condition that this is possible might be part of quantum criticality. The condition that the contribution is a function of  $p/m_k$  with rational or at most algebraic coefficients is expected to pose strong conditions on the form of the hyperbolic cutoff as function of  $k_{max}$ .

#### p-Adic fractalization of the entire perturbation theory?

p-Adic fractalization works also for the vertices and would mean the mapping of the various contributions to the n-point function to their p-adic counterparts, performing the summation, and mapping the result back to the reals by  $I$ . If all contributions depend on Lorentz invariants such as  $s_{ij} = (p_i - p_j)^2$  and  $\epsilon_i \cdot p_j$ , p-adic fractalization can be carried out in Lorentz invariant manner. The invariant mass squared  $s_U$  for any subset  $U$  of particles defines this kind of invariant and  $s_U$  is same for a subset and its complement so that for  $N_i \rightarrow N_f$  scattering there are  $2^{N_i+N_f-1}$  invariants of this kind. The set of these invariants and thus canonical identification is unique. The entire perturbation series for the coefficients of Lorentz invariant form factors could be replaced with its p-adic variant with summation over various contributions carried out using p-adic arithmetics. Unless one treats separately the minus sign and imaginary unit, the resulting amplitudes would be non-negative numbers and interference effects would occur at the p-adic level only.

There is an objection against this picture. One can speak about interference in real and p-adic sense. How does one know which sums appearing in perturbation theory are carried out at the real side and which sums are performed at the p-adic side? An illustrative example is  $F \rightarrow BF \rightarrow F$  loop diagram contributing to the fermion propagator. The integral must be carried at the real side. What bosonic propagator should one use? The real propagator or its p-adic fractal variant? If p-adic fractal variant is used, a problem is caused by the fact that it does not have any nice analytic expression and the effect of canonical identification is not on an analytic function. Hence it would seem that one must calculate the basic building blocks  $n$ :th order contribution at the real side and then p-adicize. Hence p-adicization would be applied to the bosonic propagator itself rather than to the contributions from different p-adic length scales and one would lose the original motivation for the p-adic fractality.

Loops are also the basic problem of the twistor approach since the particles in the loops are massive and twistorialization for them is not elegant. The unitarization using Cutkosky rules meaning the addition of  $TT^\dagger$  term to the tree amplitude however allows twistorialization since loops are avoided completely and only light-like momenta are involved. This procedure could be used also to perform p-adicization and p-adic fractalization. Fermionic loops giving the vertices could be calculated in the real context and continued to the p-adic side. p-Adicization works for T-matrix if  $TT^\dagger$  allows it. The same procedure would make possible twistorialization, p-adicization, and p-adic fractalization.

A more radical possibility is that the loops associated with the  $T$ -matrix vanish if the incoming and outgoing particles are on mass shell so that only tree diagrams contribute to  $T$ -matrix. The interpretation would be in terms of quantum criticality. Also in this case one must however include  $TT^\dagger$  contribution to guarantee unitarity since the cutoff on loop momenta implies that the corresponding

contribution to the discontinuity of  $T$  vanishes. Therefore this approach seems un-necessarily complicated and leads to conditions which are very probably too strong. The vanishing of the N-vertices defined by fermionic loops for on mass shell bosons however makes sense and could be interpreted as a precise quantitative realization of quantum quantum criticality and bosonic emergence. This condition has also generalization to massive case and also to full quantum TGD. In the following both these options are discussed in more detail.

### What about unitarity?

One criticism of the proposed vision is that the realization of unitarity in terms of Cutkosky rules do not seem to be consistent with the cutoff for loop momenta. In the following various options for defining unitary S-matrix are considered.

#### 1. Feynman graphics for zero energy states

1. In negative energy ontology standard view about Feynman graphics can be expressed as the rule

$$T^{+-} = T^{+-} \hat{\times} T^{+-} . \quad (8.4.7)$$

Here  $\hat{\times}$  is product involving sum over virtual momenta restricted only by the p-adic cutoffs on mass squared and hyperbolic angle. There is analogy with projection operator for the extended product  $\hat{\times}$  but with incoming and outgoing momenta restricted to on mass shell.

2. Cutkosky rules can be expressed as

$$Disc(T^{+-}) = T^{+-} T^{+-} , \quad (8.4.8)$$

where the latter product is over on mass shell states with a given particle number in the intermediate state. Cutkosky rules imply that unitarity does not depend on the values of coupling constants and is much stronger condition than mere unitarity. Quantum criticality however requires special values of coupling constants so that either Cutkosky rules fail or some additional conditions emerge.

3. The application of Cutkosky rules to the above expression however yields a cold shower since the p-adic cutoffs for the loop momenta imply that the discontinuity vanishes. The only manner to guarantee unitarity is by adding the  $TT^\dagger$  contribution from massless intermediate states by hand as is done in the unitarization of twistor diagrams. This in turn make it un-necessary to introduce other than on mass shell loops and the original idea that loop momenta are light-like [82] is realized. This method also allow p-adicization and p-adic fractalization if  $TT^\dagger$  contribution makes sense p-adically. Sceptic reader can of course wonder why p-adic effective topology in momentum space would be needed. For p-adic mass calculations the answer is clear but for T-matrix far from so.
4. The p-adic fractal variant  $T_p$  of real  $T$ -matrix satisfies unitarity conditions in standard form only if the condition

$$(TT^\dagger)_p = T_p T_p^\dagger \quad (8.4.9)$$

holds true. The simplest possible toy example about the conditions is the product of two p-adic integers  $x = \sum x_n p^n$  and  $y = \sum y_n p^n$ .  $x_p y_p = (xy)_p$  for the simplest form of canonical identification only if the conditions  $\sum_{m \leq n} x_{n-m} y_m < p$  holds true. It could be possible to satisfy unitarity conditions with a suitable cutoff for pinary digits for the canonical identification used, at least in the measurement resolution used.

5. Could also fermionic loops be defined in terms of Cutkosky rules? If so, one could not introduce cutoffs and could not understand coupling constant evolution in the proposed manner. There is also another objection against this picture. In the case of massless particles the rate  $r(B \rightarrow F\bar{F})$  in which all momenta are collinear would define the absorptive part whose continuation would define the inverse of the bosonic propagator but only at mass shell where the propagator vanishes. This would mean the vanishing of  $r$  which might make sense due to the extremely singular kinematics. Hence this approach fails.
6. The vanishing of N-vertices for on mass shell momenta of incoming bosons would however be a natural condition fixing the hyperbolic cutoff since otherwise one should add unitarizing contribution and would not have a genuine vertex anymore. The vanishing of all vertices except  $BFF$  vertex on mass shell would also conform with the fact that Dirac action defines the entire theory. One testable implication of the vanishing condition is the prediction that the box diagram for  $2 \rightarrow 2$  scattering of gauge bosons vanishes and the scattering amplitude corresponds to the absorptive contribution to the annihilation of two gauge bosons to two fermion and antifermion.
7. Furry's theorem states that fermionic loops vanish for odd number of external photons irrespective of whether they are on or off mass shell. Furry's theorem follows from the oddness of the photon under charge conjugation implying that vacuum expectation involving odd number of photon fields vanishes. At the Feynman diagram level the theorem follows from the formulas  $C\gamma^\mu C^{-1} = -\gamma^\mu$  and  $CD_F(x_1, x_2)C^{-1} = D_F(x_2, x_1)$  allowing to show that diagrams with different orientation of fermionic lines contribute with opposite signs for a odd number of external photons (there is sum over the diagrams obtained by the permutation of vertices along the loop with one vertex fixed). Furry's theorem does not hold true for fermionic loops involving odd number of non-Abelian gluons since the permutation of boson vertices involves also permutation of charge matrices and vanishing occurs only if  $Tr(T_{a_1}T_{a_2}\dots T_{a_n}) = Tr(T_{a_n}T_{a_{n-1}}\dots T_{a_1})$  holds true.
8. If the N-vertex reduces to a sum of terms for which at least one of boson legs, - say the  $i^{th}$  one is proportional to  $p_i^\mu$ , vanishing occurs when all bosons are on mass shell. Non-abelian gauge boson vertices do not vanish on mass shell so that a form factor guaranteeing the vanishing of this kind of vertices must be present and should be induced by dynamical symmetries of some kind implying that the on mass shell bosonic action effectively reduces to that of a free Abelian YM theory.
9. One can hope that the hyperbolic cutoff alone could guarantee this miracle.  $p_i^2 = 0$  limit corresponds to asymptotia as far as the hyperbolic cutoff as a function of the p-adic mass scale labeled by  $k$  is considered. The weak form of the condition would state that the vanishing takes place only at the limit when the IR cutoff for the loop mass scale approaches zero - that is at the limit  $k_{max} \rightarrow \infty$ . The contributions from various p-adic mass scales would sum up to zero at this limit for any N-vertex. The resulting infinite set of conditions could fix hyperbolic cutoff as a function of  $k$ . The fact that the loops involve both gluons and electro-weak gauge bosons strengthens the conditions further.

The form of the condition consistent with finite measurement resolution would state that on mass shell  $N$ -vertices vanish for any value of  $k_{max}$  up to some maximum value  $N_{cr}$  depending on  $k_{max}$ .  $N_{cr}(k_{max})$  would be analogous to the order of perturbation theory and correspond to the maximal number of internal propagator legs. It would also characterize the measurement resolution.

### What could be the role of super-conformal and more general symmetries?

The argument, which eventually led to p-adic fractality and vanishing of loops as a realization of quantum criticality started from the working hypothesis that  $1/\alpha_{em}$  vanishes at a point which is as near to either end of the p-adic half octave as possible. This ad hoc assumption might be wrong and must be replaced with much more general assumption that vertices vanish for on mass shell gauge bosons. The cancelation of the vertices should be based on some general mechanism. Hyperbolic cutoff is the possibility already considered but symmetries is what would be the first guess in the framework of standard QFT.

1. *Is it necessary to have different hyperbolic cutoffs for time-like and space-like momenta?*

In the proposed model for the hyperbolic cutoff the cancelation of the mass term in the bosonic propagator fixes the relationship between time-like and space-like hyperbolic cutoffs. This approach did not predict a realistic evolution of the hyperbolic cutoff in the purely real context. One could hope that p-adic fractalization could help to resolve the problem.

The question is whether mere dynamical gauge symmetry could guarantee the vanishing of the vertices when incoming bosons are massless and have physical polarizations so that loop contributions would involve  $p_i^2$  and  $\epsilon_i \cdot p_i$  factors. If the vanishing for on mass shell momenta were implied by symmetries and would not occur for off mass shell particles, hyperbolic cutoff would become unnecessary and one could have the picture of standard quantum field theory. Also the fermionic loop defining the inverse of the gauge boson propagator should cancel for  $p^2 = 0$  as it indeed does by its  $p^2$ -proportionality.

Dynamical super-conformal or gauge invariance should force the vertices to be proportional to the product  $f \prod_i(p_i^2)$  with  $f(p_i^2) = 0$ , where  $p_i$  are the momenta for the incoming and outgoing particles. Vertices other than  $BFF$  would be non-vanishing only if some bosons are off mass shell. If this kind of vertices are to mimic the vertices of YM theory, they should be slowly varying: for instance,  $\prod_i(1/\log(p_i^2/M^2))$  proportionality of N-vertices would give hopes about this kind of mimicry. Maybe massless quarks and gluons inside hadrons are effectively non-interacting because vertices vanish for on mass shell massless particles whereas massivation for the electro-weak gauge bosons by symmetry breaking would make electro-weak vertices non-trivial.

2. *Superconformal invariance replaces space-time supersymmetry in TGD framework*

1. One of the most beautiful predictions of SUSY gauge theories [69] is the cancelation of the leading order corrections to the mass of the scalar particle whereas logarithmic corrections do not vanish and could be finite in  $N = 4$  SUSY.
2. In TGD framework there are reasons to believe that space-time supersymmetry is replaced by super-conformal symmetry so that sparticles are not quite what they are in SUSY gauge theories. Sparticles would be obtained by adding to the state a right handed neutrino moving in a non-trivial color partial wave so that sparticles in the sense of the minimal supersymmetry standard model (MSSM [18] ) would not be present. There would be an infinite tower of these colored excitations. In fact, the allowed parameter space for MSSM has been shrinking continually [8] and challenges MSSM as a generalization of the standard model.
3. The notion of finite measurement resolution realized in terms of inclusions of hyperfinite factors of type  $II_1$  [83, 27] leads to the proposal that there is infinite hierarchy of dynamical gauge symmetries and that the super-conformal variants of these symmetries could act as Super Kac-Moody type dynamical symmetries and leave physical states invariant.

3. *Could dynamical symmetries make possible non-trivial bosonic vertices vanishing for on mass shell momenta?*

The question is whether super-conformal sfermions associated with some dynamical gauge symmetry possibly related to the finite measurement resolution and HFFs could allow non-trivial bosonic vertices vanishing for on mass shell momenta.

1. There should be a force binding right handed neutrino and fermion together. This would suggest that right handed neutrino and fermion are colored and the force acts between wormhole throats which corresponds to a deformation of  $CP_2$  type vacuum extremal possessing induced metric with Euclidian signature. Since the addition of a possibly colored right handed neutrino would transform particle to sparticle in TGD, sfermions in TGD framework are not what they are in SUSYs. Squarks would be leptoquarks containing right-handed neutrino and sleptons would involve a contraction of  $M^4$  or  $CP_2$  gamma matrices with some naturally occurring classical vector field. Candidates for this kind of vector fields emerge in the formulation based on modified Dirac action.
2. Unless one is ready to modify the original idea about bosonic emergence, the only logical manner to define the propagator associated with the bosonic super partners of the fermion is in terms of a

fermionic loop in which the vertex contains a projector to the right handed neutrino spinor and a matrix responsible for the spin structure of the state at imbedding space level. The contribution to the gauge boson propagator from these states is higher order loop contribution and should vanish at  $p^2 = 0$  limit by the general vision. Hence the introduction of super partners would not help to get rid of the radiatively generated gauge boson mass. Note that this definition of sfermion propagators treats super-partners differently and is therefore inconsistent with the notion of super symmetry. Dynamical and probably broken super-conformal symmetry could be in question.

3. One can imagine also sfermions for which fermion and right handed neutrino reside at the same wormhole throat rather than opposite wormhole throats. Also now color force could guarantee stability of the state so that colored super-conformal generators with quantum numbers of right handed neutrino would be involved as also colored fermions. In this case one could argue that the propagator is just a scalar or vector propagator at the fundamental level. Note however that gauge invariance might cause difficulties if vectorial super-partners are allowed. If the coupling of the gauge boson to the sfermion candidates boils down to the standard coupling of a gauge boson to a scalar field, one obtains  $A \cdot p$  and  $A \cdot A$  couplings for scalar super partner and only the first one contributes to the gauge boson propagator. The contribution is automatically proportional to  $p^2$  for scalar superpartner and presumably also for spin one super-partners. Since no contribution to gauge boson mass appears, the relation between the time-like and hyperbolic cutoffs would remain the only possible manner to guarantee the vanishing of gauge boson mass and hyperbolic cutoff would be indeed fundamental for the understanding also the dynamical symmetry guaranteing the cancelation of loops.
4. Somewhat disappointingly, it would seem that the contribution of the superpartners to the inverse of the propagator can affect only the evolution of the hyperbolic cutoff if determined by the condition that critical momenta for which  $1/\alpha_{em}$  vanishes are as near as possible to the end points of the half octave, and one might hope a physically sensible prediction for the coupling constant evolution. What would be needed would be the transformation of the positive feedback loop to a negative one so that hyperbolic cutoff could decrease. Sfermion couplings should transform the increase of the coupling constant strength as a function of p-adic length scale characteristic for asymptotic freedom to a decrease.

To sum up: quantum criticality, bosonic emergence, number theoretic universality, p-adic fractality, and twistor program seem to be very intimately inter-related in TGD Universe. Less clear is whether dynamical super-conformal symmetries related to finite measurement resolution and hierarchy of HFFs are involved. Needless to say, the overall situation is far from crystal clear at this moment. The great question marks are whether the hyperbolic cutoff could be avoided by symmetries and if not - whether the choice of hyperbolic cutoff is fixed by the condition that N-vertices vanish at the limit when bosons are massless and IR cutoff for loop mass scale is taken to zero. Recall that the argument, which eventually led to p-adic fractality and vanishing of loops as a realization of quantum criticality started from the working hypothesis that  $1/\alpha_{em}$  vanishes at a point which is as near to either end of the p-adic half octave as possible. This somewhat ad hoc assumption can be replaced with much more general assumption that the fermionic loops defining the vertices vanish for on mass shell bosons.

## 8.5 Further progress

### 8.5.1 Could supersymmetry make momentum cutoffs un-necessary?

Super symmetric QFTs (SUSYs) are much more well-behaved than ordinary gauge theories as far as divergences are considered. This raises the question whether supersymmetry could allow to get rid of the momentum cutoffs in the loop integrations defining the bosonic propagators.

Contrary to the original expectations, TGD seems to allow a generalization of the space-time supersymmetry. This became clear with the increased understanding of the modified Dirac action [15, 20]. The introduction of a measurement interaction term to the action allows to understand how stringy propagator results and provides profound insights about physics predicted by TGD. Also an old anomalous particle production event [15] that I learned of in the blog of Tommaso Dorigo [9] having

interpretation in terms of super-symmetry forced to reconsider the possibility of space-time super-symmetry in TGD [45].

The appearance of the momentum and color quantum numbers in the measurement interaction couples space-time degrees of freedom to quantum numbers and allows also to define SUSY algebra at fundamental level as anti-commutation relations of fermionic oscillator operators. Depending on the situation  $\mathcal{N} = 2N$  SUSY algebra or fermionic part of super-conformal algebra with infinite number of oscillator operators results. The addition of fermion in particular mode would define particular super-symmetry. Zero energy ontology implies that fermions as wormhole throats correspond to chiral super-fields assignable to positive or negative energy SUSY algebra whereas bosons as wormhole contacts with two throats correspond to the direct sum of positive and negative energy algebra and to fields which are chiral or antichiral with respect to both positive and negative energy theta parameters. This super-symmetry is badly broken due to the dynamics of the modified Dirac operator which also mixes  $M^4$  chiralities inducing massivation. Since righthanded neutrino has no electro-weak couplings the breaking of the corresponding super-symmetry should be weakest.

The question is whether this SUSY has a realization as a SUSY algebra at space-time level and whether the QFT limit of TGD could be formulated as a generalization of SUSY QFT. There are several problems involved.

1. In TGD framework super-symmetry means addition of fermion to the state and since the number of spinor modes is larger states with large spin and fermion numbers are obtained. This picture does not fit to the standard view about super-symmetry. In particular, the identification of theta parameters as Majorana spinors and super-charges as Hermitian operators is not possible.
2. The belief that Majorana spinors are somehow an intrinsic aspect of super-symmetry is however only a belief. Weyl spinors meaning complex theta parameters are also possible. Theta parameters can also carry fermion number meaning only the supercharges carry fermion number and are non-hermitian. The the general classification of super-symmetric theories indeed demonstrates that for  $D = 8$  Weyl spinors and complex and non-hermitian super-charges are possible. The original motivation for Majorana spinors might come from MSSM assuming that right handed neutrino does not exist. This belief might have also led to string theories in  $D=10$  and  $D=11$  as the only possible candidates for TOE after it turned out that chiral anomalies cancel.
3. The massivation of particles is the basic problem of both SUSYs and twistor approach. The fact that particles which are massive in  $M^4$  sense can be interpreted as massless particles in  $M^4 \times CP_2$  suggests a manner to understand super-symmetry breaking and massivation in TGD framework. In particular, the massive particle can be put in short representations of SUSY even when the massivation is by p-adic thermodynamics. The octonionic realization of twistors is a very attractive possibility in this framework and quaternionicity condition guaranteeing associativity leads to twistors which are almost equivalent with ordinary 4-D twistors.

It seems possible to formulate even quantum TGD proper in terms of super-field defined in the world of classical worlds (WCW). Super-fields would provide in this framework an elegant book-keeping apparatus for the elements of local Clifford algebra of WCW extended to fields in the  $M^4 \times CP_2$  whose points label the positions of the tips of the causal diamonds ( $CDs$ ). What the actual construction of SUSY QFT limit means depends on how strong approximations one wants to make.

1. The minimal approach to SUSY QFT limit is based on an approximation assuming only the super-multiplets generated by right-handed neutrino or both right-handed neutrino and its antineutrino. The assumption that right-handed neutrino has fermion number opposite to that of the fermion associated with the wormhole throat implies that bosons correspond to  $\mathcal{N} = (1, 1)$  SUSY and fermions to  $\mathcal{N} = 1$  SUSY identifiable also as a short representation of  $\mathcal{N} = (1, 1)$  SUSY algebra trivial with respect to positive or negative energy algebra. This means a deviation from the standard view but the standard SUSY gauge theory formalism seems to apply in this case.
2. A more ambitious approach would put the modes of induced spinor fields up to some cutoff into super-multiplets. At the level next to the one described above the lowest modes of the induced spinor fields would be included. The very large value of  $\mathcal{N}$  means that  $\mathcal{N} \leq \exists \in$  SUSY cannot define the QFT limit of TGD for higher cutoffs. One should generalize SUSYs gauge theories to

arbitrary value of  $\mathcal{N}$  but there are reasons to expect that the formalism becomes rather complex. More ambitious approach working at TGD however suggest a more general manner to avoid this problem.

- (a) One of the key predictions of TGD is that gauge bosons and Higgs can be regarded as bound states of fermion and antifermion located at opposite throats of a wormhole contact. This implies bosonic emergence meaning that its QFT limit can be defined in terms of Dirac action. Bosonic propagators and vertices can be constructed as fermionic loops so that all coupling constants follow as predictions. One must however pose cutoffs in mass squared and hyperbolic angle assignable to the momenta of fermions appearing in the loops in order to obtain finite theory and to avoid massivation of bosons. The resulting coupling constant evolution is consistent with low energy phenomenology if the cutoffs in hyperbolic angle as a function of p-adic length scale is chosen suitably.
  - (b) The generalization of bosonic emergence that the TGD counterpart of SUSY is obtained by the replacement of Dirac action with action for chiral super-field coupled to vector field as the action defining the theory so that the propagators of bosons and all their super-counterparts would emerge as fermionic loops.
  - (c) The huge super-symmetries give excellent hopes about the cancelation of infinities so that this approach would work even without the cutoffs in mass squared and hyperbolic angle assignable to the momenta of fermions appearing in the loops. Cutoffs have a physical motivation in zero energy ontology but it could be an excellent approximation to take them to infinity. Alternatively, super-symmetric dynamics provides cutoffs dynamically.
3. The intriguing formal analogy of the Kähler potential and super-potential with the Kähler function defining the Kähler metric of WCW and determined up to a real part of analytic function of the complex coordinates of WCW. This analogy suggests that the action defining the SUSY-Kähler potential- is identifiable as the Kähler function defining WCW Kähler metric at its maximum. Super-potential in turn would correspond to a holomorphic function defining the modification of Kähler function due and the space-time sheet due to measurement interaction. This beautiful correspondence would make WCW geometry directly visible in the properties of QFT limit of TGD.
  4. The condition that  $\mathcal{N} = \infty$  variants for chiral and vector superfields exist fixes completely the identification of these fields in zero energy ontology.
    - (a) In this framework chiral fields are generalizations of induced spinor fields and vector fields those of gauge potentials obtained by replacing them with their super-space counterparts. Chiral condition reduces to analyticity in theta parameters thanks to the different definition of hermitian conjugation in zero energy ontology ( $\theta$  is mapped to a derivative with respect to theta rather than to  $\bar{\theta}$ ) and conjugated super-field acts on the product of all theta parameters.
    - (b) Chiral action is a straightforward generalization of the Dirac action coupled to gauge potentials. The counterpart of YM action can emerge only radiatively as an effective action so that the notion emergence is now unavoidable and indeed basic prediction of TGD.
    - (c) The propagators associated with the monomials of  $n$  theta parameters behave as  $1/p^n$  so that only  $J = 0, 1/2, 1$  states propagate in normal manner and correspond to normal particles. The presence of monomials with number of thetas higher than 2 is necessary for the propagation of bosons since by the standard argument fermion and scalar loops cancel each other by super-symmetry. This picture conforms with the identification of graviton as a bound state of wormhole throats at opposite ends of string like object. A second element essential for the finiteness of the theory is that the super-vector bosons emitted by chiral particles move collinearly as indeed required by the wormhole contact picture. Therefore these emission vertices are local in momentum space.
    - (d) This formulation allows also to use modified gamma matrices in the measurement interaction defining the counterpart of super variant of Dirac operator. Poincare invariance is not lost since momenta and color charges act on the tip of  $CD$  rather than the coordinates of the space-time sheet. Hence what is usually regarded as a quantum theory in the

background defined by classical fields follows as exact theory. This feeds all data about space-time sheet associated with the maximum of Kähler function. In this approach WCW as a Kähler manifold is replaced by a cartesian power of  $CP_2$ , which is indeed quaternionic Kähler manifold. The replacement of light-like 3-surfaces with number theoretic braids when finite measurement resolution is introduced, leads to a similar replacement.

- (e) Quantum TGD as a "complex square root" of thermodynamics approach suggests that one should take a superposition of the amplitudes defined by the points of a coherence region (identified in terms of the slicing associated with a given wormhole throat) by weighting the points with the Kähler action density. The situation would be highly analogous to a spin glass system since the modified gamma matrices defining the propagators would be analogous to the parameters of spin glass Hamiltonian allowed to have a spatial dependence. This would predict the proportionality of the coupling strengths to Kähler coupling strength and bring in the dependence on the size of  $CD$  coming as a power of 2 and give rise to p-adic coupling constant evolution. Since TGD Universe is analogous to 4-D spin glass, also a sum over different preferred extremals assignable to a given coherence regions and weighted by  $\exp(K)$  is probably needed.
- (f) In TGD Universe graviton is necessarily a bi-local object and the emission and absorption of graviton are bi-local processes involving two wormhole contacts: a pair of particles rather than single particle emits graviton. This is definitely something new and defies a description in terms of QFT limit using point like particles. Graviton like states would be entangled states of vector bosons at both ends of stringy curve so that gravitation could be regarded as a square of YM interactions in rather concrete sense. The notion of emergence would suggest that graviton propagator is defined by a bosonic loop. Since bosonic loop is dimensionless, IR cutoff defined by the largest  $CD$  present must be actively involved. At QFT limit one can hope a description as a bi-local process using a bi-local generalization of the QFT limit. It turns out that surprisingly simple candidate for the bi-local action exists.

### 8.5.2 Generalized Feynman diagrams at fermionic and momentum space level

Negative energy ontology has already led to the idea of interpreting the virtual particles as pairs of positive and negative energy wormhole throats. Hitherto I have taken it as granted that ordinary Feynman diagrammatics generalizes more or less as such. It is however far from clear what really happens in the vertices of the generalized Feynmann diagrams. The safest approach relies on the requirement that unitarity realized in terms of Cutkosky rules in ordinary Feynman diagrammatics allows a generalization. This requires loop diagrams. In particular, photon-photon scattering can take place only via a fermionic square loop so that it seems that loops must be present at least in the topological sense.

One must be however ready for the possibility that something unexpectedly simple might emerge. For instance, the vision about algebraic physics allows naturally only finite sums for diagrams and does not favor infinite perturbative expansions. Hence the true believer on algebraic physics might dream about finite number of diagrams for a given reaction type. For simplicity generalized Feynman diagrams without the complications brought by the magnetic confinement since by the previous arguments the generalization need not bring in anything essentially new.

The basic idea of duality in early hadronic models was that the lines of the dual diagram representing particles are only re-arranged in the vertices. This however does not allow to get rid of off mass shell momenta. Zero energy ontology encourages to consider a stronger form of this principle in the sense that the virtual momenta of particles could correspond to pairs of on mass shell momenta of particles. If also interacting fermions are pairs of positive and negative energy throats in the interaction region the idea about reducing the construction of Feynman diagrams to some kind of lego rules might work.

#### Virtual particles as pairs of on mass shell particles in ZEO

The first thing is to try to define more precisely what generalized Feynman diagrams are. The direct generalization of Feynman diagrams implies that both wormhole throats and wormhole contacts join

at vertices.

1. A simple intuitive picture about what happens is provided by diagrams obtained by replacing the points of Feynman diagrams (wormhole contacts) with short lines and imagining that the throats correspond to the ends of the line. At vertices where the lines meet the incoming on mass shell quantum numbers would sum up to zero. This approach leads to a straightforward generalization of Feynman diagrams with virtual particles replaced with pairs of on mass shell throat states of type  $++$ ,  $--$ , and  $+-$ . Incoming lines correspond to  $++$  type lines and outgoing ones to  $--$  type lines. The first two line pairs allow only time like net momenta whereas  $+-$  line pairs allow also space-like virtual momenta. The sign assigned to a given throat is dictated by the the sign of the on mass shell momentum on the line. The condition that Cutkosky rules generalize as such requires  $++$  and  $--$  type virtual lines since the cut of the diagram in Cutkosky rules corresponds to on mass shell outgoing or incoming states and must therefore correspond to  $++$  or  $--$  type lines.
2. The basic difference as compared to the ordinary Feynman diagrammatics is that loop integrals are integrals over mass shell momenta and that all throats carry on mass shell momenta. In each vertex of the loop mass incoming on mass shell momenta must sum up to on mass shell momentum. These constraints improve the behavior of loop integrals dramatically and give excellent hopes about finiteness. It does not however seem that only a finite number of diagrams contribute to the scattering amplitude besides tree diagrams. The point is that if a the reactions  $N_1 \rightarrow N_2$  and  $N_2 \rightarrow N_3$ , where  $N_i$  denote particle numbers, are possible in a common kinematical region for  $N_2$ -particle states then also the diagrams  $N_1 \rightarrow N_2 \rightarrow N_2 \rightarrow N_3$  are possible. The virtual states  $N_2$  include all all states in the intersection of kinematically allow regions for  $N_1 \rightarrow N_2$  and  $N_2 \rightarrow N_3$ . Hence the dream about finite number possible diagrams is not fulfilled if one allows massless particles. If all particles are massive then the particle number  $N_2$  for given  $N_1$  is limited from above and the dream is realized.
3. For instance, loops are not possible in the massless case or are highly singular (bringing in mind twistor diagrams) since the conservation laws at vertices imply that the momenta are parallel. In the massive case and allowing mass spectrum the situation is not so simple. As a first example one can consider a loop with three vertices and thus three internal lines. Three on mass shell conditions are present so that the four-momentum can vary in 1-D subspace only. For a loop involving four vertices there are four internal lines and four mass shell conditions so that loop integrals would reduce to discrete sums. Loops involving more than four vertices are expected to be impossible.
4. The proposed replacement of the elementary fermions with bound states of elementary fermions and monopoles  $X_{\pm}$  brings in the analog of stringy diagrammatics. The 2-particle wave functions in the momentum degrees of freedom of fermions and  $X_{\pm}$  might allow more flexibility and allow more loops. Note however that there are excellent hopes about the finiteness of the theory also in this case.

### Loop integrals are manifestly finite

One can make also more detailed observations about loops.

1. The simplest situation is obtained if only 3-vertices are allowed. In this case conservation of momentum however allows only collinear momenta although the signs of energy need not be the same. Particle creation and annihilation is possible and momentum exchange is possible but is always light-like in the massless case. The scattering matrices of supersymmetric YM theories would suggest something less trivial and this raises the question whether something is missing. Magnetic monopoles are an essential element of also these theories as also massivation and symmetry breaking and this encourages to think that the formation of massive states as fermion  $X_{\pm}$  pairs is needed. Of course, in TGD framework one has also high mass excitations of the massless states making the scattering matrix non-trivial.
2. In YM theories on mass shell lines would be singular. In TGD framework this is not the case since the propagator is defined as the inverse of the 3-D dimensional reduction of the modified

Dirac operator  $D$  containing also coupling to four-momentum (this is required by quantum classical correspondence and guarantees stringy propagators),

$$\begin{aligned} D &= i\hat{\Gamma}^\alpha p_\alpha + \hat{\Gamma}^\alpha D_\alpha \ , \\ p_\alpha &= p_k \partial_\alpha h^k \ . \end{aligned} \tag{8.5.1}$$

The propagator does not diverge for on mass shell massless momenta and the propagator lines are well-defined. This is of course of essential importance also in general case. Only for the incoming lines one can consider the possibility that 3-D Dirac operator annihilates the induced spinor fields. All lines correspond to generalized eigenstates of the propagator in the sense that one has  $D_3\Psi = \lambda\gamma\Psi$ , where  $\gamma$  is modified gamma matrix in the direction of the stringy coordinate emanating from light-like surface and  $D_3$  is the 3-dimensional dimensional reduction of the 4-D modified Dirac operator. The eigenvalue  $\lambda$  is analogous to energy. Note that the eigenvalue spectrum depends on 4-momentum as a parameter.

3. Massless incoming momenta can decay to massless momenta with both signs of energy. The integration measure  $d^2k/2E$  reduces to  $dx/x$  where  $x \geq 0$  is the scaling factor of massless momentum. Only light-like momentum exchanges are however possible and scattering matrix is essentially trivial. The loop integrals are finite apart from the possible delicacies related to poles since the loop integrands for given massless wormhole contact are proportional to  $dx/x^3$  for large values of  $x$ .
4. Irrespective of whether the particles are massless or not, the divergences are obtained only if one allows too high vertices as self energy loops for which the number of momentum degrees of freedom is  $3N - 4$  for  $N$ -vertex. The construction of SUSY limit of TGD in [29] led to the conclusion that the parallelly propagating  $N$  fermions for given wormhole throat correspond to a product of  $N$  fermion propagators with same four-momentum so that for fermions and ordinary bosons one has the standard behavior but for  $N > 2$  non-standard so that these excitations are not seen as ordinary particles. Higher vertices are finite only if the total number  $N_F$  of fermions propagating in the loop satisfies  $N_F > 3N - 4$ . For instance, a 4-vertex from which  $N = 2$  states emanate is finite.

### Taking into account magnetic confinement

What has been said above is not quite enough. As shown in the accompanying article and in [28] the weak form of electric-magnetic duality [10] leads to the picture about elementary particles as pairs of magnetic monopoles inspiring the notions of weak confinement based on magnetic monopole force. Also color confinement would have magnetic counterpart. This means that elementary particles would behave like string like objects in weak boson length scale. Therefore one must also consider the stringy case with wormhole throats replaced with fermion- $X_\pm$  pairs ( $X_\pm$  is electromagnetically neutral and  $\pm$  refers to the sign of the weak isospin opposite to that of fermion) and their super partners.

1. The simplest assumption in the stringy case is that fermion- $X_\pm$  pairs behave as coherent objects, that is scatter elastically. In more general case only their higher excitations identifiable in terms of stringy degrees of freedom would be created in vertices. The massivation of these states makes possible non-collinear vertices. An open question is how the massivation fermion- $X_\pm$  pairs relates to the existing TGD based description of massivation in terms of Higgs mechanism and modified Dirac operator.
2. Mass renormalization could come from self energy loops with negative energy lines as also vertex normalization. By very general arguments supersymmetry implies the cancellation of the self energy loops but would allow non-trivial vertex renormalization [29] .
3. If only 3-vertices are allowed, the loops containing only positive energy lines are possible if on mass shell fermion- $X_\pm$  pair (or its superpartner) can decay to a pair of positive energy pair particles of same kind. Whether this is possible depends on the masses involved. For ordinary particles these decays are not kinematically possible below intermediate boson mass scale (the

decays  $F_1 \rightarrow F_2 + \gamma$  are forbidden kinematically or by the absence of flavor changing neutral currents whereas intermediate gauge bosons can decay to on mass shell fermion-antifermion pair).

4. The introduction of IR cutoff for 3-momentum in the rest system associated with the largest  $CD$  (causal diamond) looks natural as scale parameter of coupling constant evolution and p-adic length scale hypothesis favors the inverse of the size scale of  $CD$  coming in powers of two. This parameter would define the momentum resolution as a discrete parameter of the p-adic coupling constant evolution. This scale does not have any counterpart in standard physics. For electron,  $d$  quark, and  $u$  quark the proper time distance between the tips of  $CD$  corresponds to frequency of 10 Hz, 1280 Hz, and 160 Hz: all these frequencies define fundamental bio-rhythms [24] .

These considerations have left completely untouched one important aspect of generalized Feynman diagrams: the necessity to perform a functional integral over the deformations of the partonic 2-surfaces at the ends- that is integration over WCW. Number theoretical universality requires that WCW and these integrals make sense also p-adically and in the following these aspects of generalized Feynman diagrams are discussed.

## Chapter 9

# Does the QFT Limit of TGD Have Space-Time Super-Symmetry?

### 9.1 Introduction

Contrary to the original expectations, TGD seems to allow a generalization of the space-time super-symmetry. This became clear with the increased understanding of the modified Dirac action [15, 20]. The introduction of a measurement interaction term to the action allows to understand how stringy propagator results and provides profound insights about physics predicted by TGD. Also an old anomalous particle production event [15] that I learned of in the blog of Tommaso Dorigo [9] having interpretation in terms of super-symmetry forced to reconsider the possibility of space-time super-symmetry in TGD [45].

The appearance of the momentum and color quantum numbers in the measurement interaction couples space-time degrees of freedom to quantum numbers and allows also to define SUSY algebra at fundamental level as anti-commutation relations of fermionic oscillator operators. Depending on the situation  $\mathcal{N} = 2N$  SUSY algebra or fermionic part of super-conformal algebra with infinite number of oscillator operators results. The addition of fermion in particular mode would define particular super-symmetry. Zero energy ontology implies that fermions as wormhole throats correspond to chiral super-fields assignable to positive or negative energy SUSY algebra whereas bosons as wormhole contacts with two throats correspond to the direct sum of positive and negative energy algebra and to fields which are chiral or antichiral with respect to both positive and negative energy theta parameters. This super-symmetry is badly broken due to the dynamics of the modified Dirac operator which also mixes  $M^4$  chiralities inducing massivation. Since righthanded neutrino has no electro-weak couplings the breaking of the corresponding super-symmetry should be weakest.

The question is whether this SUSY has a realization as a SUSY algebra at space-time level and whether the QFT limit of TGD could be formulated as a generalization of SUSY QFT. There are several problems involved.

1. In TGD framework super-symmetry means addition of fermion to the state and since the number of spinor modes is larger states with large spin and fermion numbers are obtained. This picture does not fit to the standard view about super-symmetry. In particular, the identification of theta parameters as Majorana spinors and super-charges as Hermitian operators is not possible.
2. The belief that Majorana spinors are somehow an intrinsic aspect of super-symmetry is however only a belief. Weyl spinors meaning complex theta parameters are also possible. Theta parameters can also carry fermion number meaning only the supercharges carry fermion number and are non-hermitian. The the general classification of super-symmetric theories indeed demonstrates that for  $D = 8$  Weyl spinors and complex and non-hermitian super-charges are possible. The original motivation for Majorana spinors might come from MSSM assuming that right handed neutrino does not exist. This belief might have also led to string theories in  $D=10$  and  $D=11$  as the only possible candidates for TOE after it turned out that chiral anomalies cancel.
3. The massivation of particles is the basic problem of both SUSYs and twistor approach. The fact that particles which are massive in  $M^4$  sense can be interpreted as massless particles in

$M^4 \times CP_2$  suggests a manner to understand super-symmetry breaking and massivation in TGD framework. In particular, the massive particle can be put in short representations of SUSY even when the massivation is by p-adic thermodynamics. The octonionic realization of twistors is a very attractive possibility in this framework and quaternionicity condition guaranteeing associativity leads to twistors which are almost equivalent with ordinary 4-D twistors.

It seems possible to formulate even quantum TGD proper in terms of super-field defined in the world of classical worlds (WCW). Super-fields would provide in this framework an elegant book-keeping apparatus for the elements of local Clifford algebra of WCW extended to fields in the  $M^4 \times CP_2$  whose points label the positions of the tips of the causal diamonds ( $CDs$ ). What the actual construction of SUSY QFT limit means depends on how strong approximations one wants to make.

1. The minimal approach to SUSY QFT limit is based on an approximation assuming only the super-multiplets generated by right-handed neutrino or both right-handed neutrino and its antineutrino. The assumption that right-handed neutrino has fermion number opposite to that of the fermion associated with the wormhole throat implies that bosons correspond to  $\mathcal{N} = (1, 1)$  SUSY and fermions to  $\mathcal{N} = 1$  SUSY identifiable also as a short representation of  $\mathcal{N} = (1, 1)$  SUSY algebra trivial with respect to positive or negative energy algebra. This means a deviation from the standard view but the standard SUSY gauge theory formalism seems to apply in this case.
2. A more ambitious approach would put the modes of induced spinor fields up to some cutoff into super-multiplets. At the level next to the one described above the lowest modes of the induced spinor fields would be included. The very large value of  $\mathcal{N}$  means that  $\mathcal{N} \leq \exists \in$  SUSY cannot define the QFT limit of TGD for higher cutoffs. One should generalize SUSY's gauge theories to arbitrary value of  $\mathcal{N}$  but there are reasons to expect that the formalism becomes rather complex. More ambitious approach working at TGD however suggest a more general manner to avoid this problem.
  - (a) One of the key predictions of TGD is that gauge bosons and Higgs can be regarded as bound states of fermion and antifermion located at opposite throats of a wormhole contact. This implies bosonic emergence meaning that its QFT limit can be defined in terms of Dirac action. The resulting theory was discussed in detail in [56] and it was shown that bosonic propagators and vertices can be constructed as fermionic loops so that all coupling constant follow as predictions. One must however pose cutoffs in mass squared and hyperbolic angle assignable to the momenta of fermions appearing in the loops in order to obtain finite theory and to avoid massivation of bosons. The resulting coupling constant evolution is consistent with low energy phenomenology if the cutoffs in hyperbolic angle as a function of p-adic length scale is chosen suitably.
  - (b) The generalization of bosonic emergence that the TGD counterpart of SUSY is obtained by the replacement of Dirac action with action for chiral super-field coupled to vector field as the action defining the theory so that the propagators of bosons and all their super-counterparts would emerge as fermionic loops.
  - (c) The huge super-symmetries give excellent hopes about the cancelation of infinities so that this approach would work even without the cutoffs in mass squared and hyperbolic angle assignable to the momenta of fermions appearing in the loops. Cutoffs have a physical motivation in zero energy ontology but it could be an excellent approximation to take them to infinity. Alternatively, super-symmetric dynamics provides cutoffs dynamically.
3. The intriguing formal analogy of the Kähler potential and super-potential with the Kähler function defining the Kähler metric of WCW and determined up to a real part of analytic function of the complex coordinates of WCW. This analogy suggests that the action defining the SUSY-Kähler potential- is identifiable as the Kähler function defining WCW Kähler metric at its maximum. Super-potential in turn would correspond to a holomorphic function defining the modification of Kähler function due and the space-time sheet due to measurement interaction. This beautiful correspondence would make WCW geometry directly visible in the properties of QFT limit of TGD.

4. The condition that  $\mathcal{N} = \infty$  variants for chiral and vector superfields exist fixes completely the identification of these fields in zero energy ontology.
- (a) In this framework chiral fields are generalizations of induced spinor fields and vector fields those of gauge potentials obtained by replacing them with their super-space counterparts. Chiral condition reduces to analyticity in theta parameters thanks to the different definition of hermitian conjugation in zero energy ontology ( $\theta$  is mapped to a derivative with respect to theta rather than to  $\bar{\theta}$ ) and conjugated super-field acts on the product of all theta parameters.
  - (b) Chiral action is a straightforward generalization of the Dirac action coupled to gauge potentials. The counterpart of YM action can emerge only radiatively as an effective action so that the notion emergence is now unavoidable and indeed basic prediction of TGD.
  - (c) The propagators associated with the monomials of  $n$  theta parameters behave as  $1/p^n$  so that only  $J = 0, 1/2, 1$  states propagate in normal manner and correspond to normal particles. The presence of monomials with number of thetas higher than 2 is necessary for the propagation of bosons since by the standard argument fermion and scalar loops cancel each other by super-symmetry. This picture conforms with the identification of graviton as a bound state of wormhole throats at opposite ends of string like object. A second element essential for the finiteness of the theory is that the super-vector bosons emitted by chiral particles move collinearly as indeed required by the wormhole contact picture. Therefore these emission vertices are local in momentum space.
  - (d) This formulation allows also to use modified gamma matrices in the measurement interaction defining the counterpart of super variant of Dirac operator. Poincare invariance is not lost since momenta and color charges act on the tip of  $CD$  rather than the coordinates of the space-time sheet. Hence what is usually regarded as a quantum theory in the background defined by classical fields follows as exact theory. This feeds all data about space-time sheet associated with the maximum of Kähler function. In this approach WCW as a Kähler manifold is replaced by a cartesian power of  $CP_2$ , which is indeed quaternionic Kähler manifold. The replacement of light-like 3-surfaces with number theoretic braids when finite measurement resolution is introduced, leads to a similar replacement.
  - (e) Quantum TGD as a "complex square root" of thermodynamics approach suggests that one should take a superposition of the amplitudes defined by the points of a coherence region (identified in terms of the slicing associated with a given wormhole throat) by weighting the points with the Kähler action density. The situation would be highly analogous to a spin glass system since the modified gamma matrices defining the propagators would be analogous to the parameters of spin glass Hamiltonian allowed to have a spatial dependence. This would predict the proportionality of the coupling strengths to Kähler coupling strength and bring in the dependence on the size of  $CD$  coming as a power of 2 and give rise to p-adic coupling constant evolution. Since TGD Universe is analogous to 4-D spin glass, also a sum over different preferred extremals assignable to a given coherence regions and weighted by  $\exp(K)$  is probably needed.
  - (f) In TGD Universe graviton is necessarily a bi-local object and the emission and absorption of graviton are bi-local processes involving two wormhole contacts: a pair of particles rather than single particle emits graviton. This is definitely something new and defies a description in terms of QFT limit using point like particles. Graviton like states would be entangled states of vector bosons at both ends of stringy curve so that gravitation could be regarded as a square of YM interactions in rather concrete sense. The notion of emergence would suggest that graviton propagator is defined by a bosonic loop. Since bosonic loop is dimensionless, IR cutoff defined by the largest  $CD$  present must be actively involved. At QFT limit one can hope a description as a bi-local process using a bi-local generalization of the QFT limit. It turns out that surprisingly simple candidate for the bi-local action exists.

The plan of the chapter reflects partially my own selfish needs. I have to learn space-time super-symmetry at the level of the basic formalism and the best manner to do it is to write it out.

1. The chapter begins with a brief summary of the basic concepts of SUSYs without doubt revealing my rather fragmentary knowledge about these theories. My only excuse is that I really thought that space-time super-symmetries and the formalism of SUSY theories do not generalize in TGD framework.
2. Just learning the basics led to amazing findings. First, the anti-commutation relations of the fermionic oscillator operators for the modified Dirac action can be formulated as a generalized SUSY algebra for space-time super-symmetries with large or even infinite value of  $\mathcal{N} = 2N$ . Secondly, the notion of super-field allows an elegant formulation for the local Clifford algebra of WCW. And thirdly, Kähler potential and super-potential have interpretation in terms of the Kähler function characterizing WCW geometry. I can now grasp why SUSY aficionados are so fascinated about their brain child.
3. The octonionic formulation of the modified Dirac equation leading to a general solution ansatz working also for the ordinary gamma matrix algebra is discussed to demonstrate what is involved. The notions of hyper-octonionic twistor and induced hyper-quaternionic twistor structure [15, 82] are introduced. Hyper-quaternionicity can be realized for the induced octonionic algebra and natural matrix representations are obtained using structure constants.
4. Twistors have indeed become a part of the calculational arsenal of SUSY gauge theories, and TGD leads to a proposal how to avoid the problems caused by massive particles by using the notion of masslessness in 8-D sense and the notion of induced octo-twistor. At QFT limit the idea is simple: massless free particles correspond to geodesics of  $M^4 \times CP_2$  and in QFT formulation one keeps just the knowledge that particle moves along geodesic circle  $S^1 \times CP_2$ .
5. SUSY algebras at the level of quantum TGD proper and its QFT limit are discussed and the conditions guaranteeing that standard SUSY formalism applies are discussed: in this theory fermions *resp.* bosons correspond to  $\mathcal{N} = 1$  *resp.*  $\mathcal{N} = (1, 1)$  SUSY.
6. Finally, SUSY QFT limit of quantum TGD based on the generalization of the bosonic emergence [56] is proposed. The generalization of SUSY YM action emerges radiatively through super-symmetric fermion loops in this framework and the counterpart of chiral action is the fundamental action. The first approach applying only for small values of  $\mathcal{N}$  relies on the replacement of the Dirac action coupled to gauge potentials with the Kähler potential defined by WCW Kähler function at its maximum. Second approach is inspired by  $\mathcal{N} = \infty$  case and based on different definition of super-fields.

This chapter is a fourth one in a series containing two chapters about twistors [82, 84] and a chapter about bosonic emergence [56]. At this moment the chapter about the generalization of twistor Grassmannian approach [33] and Yangian symmetry [41] to TGD framework [84] represents the most realistic view about what quantum TGD might be. Although a lot of cognitive dust is present, this chapter together with the chapters [82, 56] might be helpful for the reader trying to get a better understanding about my motivations and goals. There is also a connection with the topological explanation of family replacation phenomenon: by combining the assumption that  $SU(3)$  acts as dynamical symmetry acting on fermion families for vertices allows only BFF type vertices and their super-symmetric generalizations at fundamental level [18]. Also bosonic emergence allows only BFF type vertices: this simplifies enormously the construction of  $M$ -matrix.

## 9.2 SUSY briefly

The Tasi 2008 lectures by Yuri Shirman [66] provide a modern introduction to 4-dimensional  $\mathcal{N} = 1$  super-symmetry and super-symmetry breaking. In TGD framework the super-symmetry is 8-dimensional super-symmetry induced to 4-D space-time surface and one  $\mathcal{N} = 2N$  can be large so that this introduction is quite not enough for the recent purposes. This section provides only a brief summary of the basic concepts related to SUSY algebras and SUSY QFTs and the breaking of super-symmetry is mentioned only by passing. I have also listed the crucial basic facts about  $\mathcal{N} > 1$  super-symmetry [5, 17] with emphasis in demonstrating that for 8-D super-gravity with one time-dimension super-charges are non-Hermitian and that Majorana spinors are absent as required by quantum TGD.

### 9.2.1 Weyl fermions

Gamma matrices in chiral basis.

$$\begin{aligned} \gamma^\mu &= \begin{pmatrix} 0 & \sigma^\mu \\ \bar{\sigma}^\mu & 0 \end{pmatrix}, & \gamma_5 &= \begin{pmatrix} \sigma_0 & 0 \\ 0 & -\sigma_0 \end{pmatrix}, \\ \sigma^0 &= \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix}, & \sigma^1 &= \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}, & \sigma^2 &= \begin{pmatrix} 0 & -i \\ i & 0 \end{pmatrix}, & \sigma^3 &= \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}, \\ \bar{\sigma}^0 &= \sigma^0, & \bar{\sigma}^i &= -\sigma^i. \end{aligned} \quad (9.2.1)$$

Note that Pauli sigma matrices can be interpreted as matrix representation for hyper-quaternion units. Dirac spinors can be expressed in terms of Weyl spinors as

$$\Psi = \begin{pmatrix} \eta^\alpha \\ \bar{\chi}_{\dot{\alpha}}^* \end{pmatrix}. \quad (9.2.2)$$

Note that  $\bar{\chi}$  does not denote complex conjugation and that complex conjugation transforms non-dotted and dotted indices to each other.  $\eta$  and  $\bar{\chi}$  are both left handed Weyl spinors and transform according to complex conjugate representations of Lorentz group and one can interpret  $\bar{\chi}$  as representing that charge conjugate of right handed Dirac fermion.

Spinor indices can be lowered and raised using antisymmetric tensors  $\epsilon^{\alpha\beta}$  and  $\epsilon_{\dot{\alpha}\dot{\beta}}$  and one has

$$\begin{aligned} \eta^\alpha \eta_\alpha &= 0, & \bar{\chi}_{\dot{\alpha}}^* \bar{\chi}_{\dot{\alpha}}^* &= 0, \\ \eta \bar{\chi} &= \bar{\chi} \eta = \epsilon^{\alpha\beta} \eta_\alpha \bar{\chi}_\beta, & \eta^* \bar{\chi}^* &= \bar{\chi}^* \eta^* = \epsilon^{\alpha\beta} \eta_\alpha^* \bar{\chi}_\beta^*. \end{aligned} \quad (9.2.3)$$

Left-handed and right handed spinors can be combined to Lorentz vectors as

$$\eta_{\dot{\alpha}}^* \sigma^{\mu\dot{\alpha}\alpha} \eta_\alpha = -\eta^{*\alpha} \sigma_{\alpha\dot{\alpha}}^\mu \eta^{*\dot{\alpha}}. \quad (9.2.4)$$

The SUSY algebra at QFT limit differs from the SUSY algebra defining the fundamental anticommutators of the fermionic oscillator operators for the induced spinor fields since the modified gamma matrices defined by the Kähler action are replaced with ordinary gamma matrices. This is quite a dramatic difference and raises two questions.

The Dirac action

$$L = i\bar{\Psi} \partial_\mu \gamma^\mu \Psi - m\bar{\Psi} \Psi \quad (9.2.5)$$

for a massive particle reads in Weyl representation as

$$L = i\eta^* \partial_\mu \sigma^\mu \eta + i\bar{\chi}^* \partial_\mu \bar{\sigma}^\mu \bar{\chi} - m\bar{\chi} \eta - m\bar{\chi}^* \eta^*. \quad (9.2.6)$$

### 9.2.2 SUSY algebras

In the following 4-D SUSY algebras are discussed first following the representation of [66]. After that basic results about higher-dimensional SUSY algebras are listed with emphasis on 8-D case.

#### $D = 4$ SUSY algebras

Poincare SUSY algebra contains as super-generators transforming as Weyl spinors transforming in complex conjugate representations of Lorentz group. The basic anti-commutation relations of Poincare SUSY algebra in Weyl fermion basis can be expressed as

$$\begin{aligned} \{Q_\alpha, Q_{\dot{\beta}}\} &= 2\sigma_{\alpha\dot{\beta}}^\mu P_\mu, \\ \{Q_\alpha, Q_\beta\} &= \{Q_{\dot{\alpha}}, Q_{\dot{\beta}}\} = 0, \\ [Q_\alpha, P_\mu] &= [Q_{\dot{\alpha}}, P_\mu] = 0. \end{aligned} \quad (9.2.7)$$

By taking a trace over spinor indices one obtains expression for energy as  $P^0 = \sum_i Q_i \bar{Q}_i + \bar{Q}_i Q_i$ . Since super-generators must annihilated super-symmetric ground states, the energy must vanish for them.

This algebra corresponds to simplest  $\mathcal{N} = 1$  SUSY in which only left-handed fermion appears. For  $\mathcal{N} = 1$  SUSY the super-charges are hermitian whereas in TGD framework supercharges carry fermion number. This implies that super-charges come in pairs of super charge so that  $\mathcal{N} = 2N$  must hold true and its hermitian conjugate and only the second half of super-charges can annihilate vacuum state. Weyl spinors must also come as pairs of right- and left-handed spinors.

The construction generalizes in a straightforward manner to allow arbitrary number of fermionic generators. The most general anti-commutation relations in this case are

$$\begin{aligned} \{Q_{i\alpha}, Q_{j\beta}^j\} &= 2\delta_i^j \sigma_{\alpha\beta}^\mu P_\mu, \\ \{Q_{i\alpha}, Q_{j\beta}\} &= \epsilon_{\alpha\beta} Z_{ij}, \\ \{Q_{\dot{\alpha}}, Q_{\dot{\beta}}\} &= \epsilon^{\dot{\alpha}\dot{\beta}} Z_{ij}^*. \end{aligned} \quad (9.2.8)$$

The complex constants are called central charges because they commute with all generators of the super-Poincare group.

### Higher-dimensional SUSY algebras

The character of supersymmetry is sensitive to the dimension  $D$  of space-time and to the signature of the space-time metric higher dimensions [5]. The available spinor representations depend on  $k$ ; the maximal compact subgroup of the little group of the Lorentz that preserves the momentum of a massless particle is  $Spin(d-1) \times Spin(D-d-1)$ , where  $d$  is the number of spatial dimensions  $D-d$  is the number time dimensions and  $k$  is defined as  $k = 2d - D$ . Due to the mod 8 Bott periodicity of the homotopy groups of the Lorentz group, really we only need to consider  $k = 2d - D$  modulo 8. In TGD framework one has  $D = 8$ ,  $d = 7$  and  $k = 6$ .

For any value of  $k$  there is a Dirac representation, which is always of real dimension  $N = [2^{1+(2d-k)/2}]$  where  $[x]$  is the greatest integer less than or equal to  $x$ . For TGD this of course gives  $2^5 = 32$  corresponding to complex 8-component quark and lepton like spinors. For  $-2 \leq k \leq 2$  not realized in TGD there is a real Majorana spinor representation, whose dimension is  $N/2$ . When  $k$  is even (TGD) there is a Weyl spinor representation, whose real dimension is  $N/2$ . For  $k \bmod 8 = 0$  (say in super-string models) there is a Majorana-Weyl spinor, whose real dimension is  $N/4$ . For  $3 \leq k \leq 5$  so called symplectic Majorana spinor with dimension  $D/2$  and for  $k = 4$  symplectic Weyl-Majorana spinors with dimension  $D/4$  is possible. The matrix  $\Gamma_{D+1}$  defined as the product of all gamma matrices has eigenvalues  $\pm(-1)^{-k/2}$ . The eigenvalue of  $\Gamma_{D+1}$  is the chirality of the spinor. CPT theorem implies that the for  $D \bmod 4 = 0$  the numbers of left and right handed super-charges are same. For  $D \bmod 4 = 2$  the numbers of left and right handed chiralities can be different and corresponding SUSYs are classified by  $\mathcal{N} = (\mathcal{N}_L, \mathcal{N}_R)$ , where  $\mathcal{N}_L$  and  $\mathcal{N}_R$  are the numbers of left and right handed super charges. Note that in TGD the chiralities are  $\pm 1$  and correspond to quark and leptons like spinors.

TGD does not allow super-symmetry with Majorana particles. It is indeed possible to have non-hermitian super-charges [17] in dimension  $D = 8$ . In  $D = 8$  SUGRA with one time dimension super-charges are non-hermitian and Majorana particles are absent. Also in  $D = 4$  SUGRA predicts super-charges are non-hermitian super-charges but Majorana particles are present.

1.  $D = 8$  super-gravity corresponds to  $\mathcal{N} = 2$  and allows complex super-charges  $Q_\alpha^i \in \bar{8}$  and their hermitian conjugates  $\bar{Q}_\alpha^i \in \bar{8}$ . The group of  $R$  symmetries is  $U(2)$ . Bosonic fields consists the metric  $g_{mn}$ , seven real scalars, six vectors, three 2-form fields and one 3-form field. Fermionic fields consist of two Weyl (left) gravitini  $\psi^{\alpha i}$ , six Weyl (right) spinors plus their hermitian conjugates of opposite chirality. There are no Majorana fermions.
2.  $D = 4, \mathcal{N} = 8$  SUGRA is second example allowing complex non-hermitian super-charges. The supercharges  $Q_\alpha^i \in 2$  and their hermitian conjugates  $\bar{Q}_\alpha^i \in \bar{2}$ . R-symmetry group is  $U(8)$ . Bosonic fields are metric  $g_{mn}$ , 70 real scalars and 28 vectors. Fermionic fields are 8 Majorana gravitini  $\Psi_m^{a,i}$  and 56 Majorana spinors.

For  $\mathcal{N} = 2N$  and at least  $D = 8$  with one time dimension the super charges can be assumed to come in hermitian conjugate pairs and the non-vanishing anti-commutators can be expressed as

$$\begin{aligned} \{Q_{i\alpha}^\dagger, Q_{j\dot{\beta}}^j\} &= 2\delta_i^j \sigma_{\alpha\dot{\beta}}^\mu P_\mu, \\ \{Q_{i\alpha}^\dagger, Q_{j\beta}\} &= \epsilon_{\alpha\beta} Z_{ij}, \\ \{Q_{\dot{\alpha}}^\dagger, Q_{\dot{\beta}}\} &= \epsilon^{\dot{\alpha}\dot{\beta}} Z_{ij}^*. \end{aligned} \quad (9.2.9)$$

In this case  $Z_{ij}$  is anti-hermitian matrix. 8-D chiral invariance (separate conservation of lepton and quark numbers) suggests strongly that the condition  $Z_{ij} = 0$  must hold true. A given pair of super-charges is analogous to creation and annihilation operators for a given fermionic chirality. In TGD framework opposite chiralities correspond to quark and lepton like spinors.

### Representations of SUSY algebras in dimension $D = 4$

The physical components of super-fields correspond to states in the irreducible representations of SUSY algebras. The representations can be constructed by using the basic anticommutation relations for  $Q_{i\alpha}$  and  $Q_{j\dot{\alpha}}$ ,  $i, j \in \{1, \dots, \mathcal{N}\}$ ,  $\alpha, \dot{\alpha} \in \{1, 2\}$ . The representations can be classified to massive and massless ones. Also the presence of central charges affects the situation. A given irreducible representation is characterized by its ground state and R-parity assignments distinguish between representations with the same spin content, say fermion and its scalar super-partner and Higgs with its fermionic super-partner.

1. In the massive case one obtains in the rest system just fermionic oscillator algebra with with  $2\mathcal{N}$  fermionic creation operators and  $2\mathcal{N}$  annihilation operators. The number of states created from a vacuum state with spin  $s_0$  is  $2\mathcal{N}$  and maximum spin is  $s_0 + \mathcal{N}/2$ . For instance, for  $\mathcal{N} = 1$  and  $s_0 = 0$  one obtains for 4 states with spins  $J \leq 1/2$ . Renormalizability requires massive matter to have  $s \leq 1/2$  so that only  $\mathcal{N} = 1$  is possible in this case. For particles massless at fundamental level and getting their masses by symmetry breaking this kind of restriction does not apply.
2. In the massless case only one half of fermionic oscillator operators have vanishing anticommutators corresponding to the fact that for massless state only the second helicity is physical. This implies that the number of states is only  $2^{\mathcal{N}}$  and the helicities vary from  $\lambda_0$  to  $\lambda_0 + \mathcal{N}/2$ . For  $\mathcal{N} = 1$  the representation is 2-dimensional.
3. In the presence of central charges  $Z_{ij} = -Z_{ji}$  the representations are in general massive ( $Z_{ij}$  has dimensions of mass),  $U(N)$  acts as symmetries of  $Z$ , and since  $Z^2$  is symmetric its diagonalizability implies that  $Z$  matrix can be cast by a unitary transformation into a direct sum of 2-D antisymmetric real matrices multiplied by constants  $Z_i$ . Therefore the super-algebra can be cast in diagonal form with anticommutators proportional to  $M \pm Z_m$  with  $M - Z_m \geq 0$  by unitarity. This implies the celebrated Bogomol'nyi bound  $M \geq \max\{Z_n\}$ . For this value of varying mass parameter it is possible to have reduction of the dimension of the representation by one half. If the eigenvalues  $Z_n$  are identical the number of states is reduced to that for a massless representation. This multiplet is known as short BPS multiplet. Although BPS multiplets are massive (mass is expressible in terms of Higgs expectation value) they form multiplets shorter than the usual massive SUSY multiplets.

### 9.2.3 Super-space

The heuristic view about super-space [16] is as a manifold with  $D$  local bosonic coordinates  $x^\mu$  and  $\mathcal{N}D/2$  complex anti-commuting spinor coordinates  $\theta_i^\alpha$  and their complex conjugates  $\bar{\theta}_\alpha^i = (\theta_i^\alpha)^*$ . For  $\mathcal{N} = 1$ , which is relevant to minimally super-symmetric standard model (MSSM), the spinors  $\theta$  can also chosen to be real that is Majorana spinors, so that one has 4 bosonic and four real coordinates. In TGD framework one must however use Weyl spinors.

The anti-commutation relations for the super-coordinates are

$$\{\theta_\alpha, \theta_\beta\} = \{\theta_{\dot{\alpha}}, \theta_{\dot{\beta}}\} = \{\theta_\alpha, \theta_{\dot{\beta}}\} = 0. \quad (9.2.10)$$

The integrals over super-space in 4-D  $\mathcal{N} = 1$  case are defined by the following formal rules which actually state that super-integration is formally analogous to derivation.

$$\begin{aligned} \int d\theta &= \int d\bar{\theta} = \int d\theta\bar{\theta} = \int d\bar{\theta}\theta = 0 , \\ \int d\theta^\alpha d\theta_\beta &= \delta_\beta^\alpha , \quad \int d\bar{\theta}_{\dot{\alpha}} d\bar{\theta}_{\dot{\beta}} = \delta_{\dot{\alpha}}^{\dot{\beta}} , \\ \int d^2\theta\theta^2 &= \int d^2\bar{\theta}\bar{\theta}^2 , \quad \int d^4\theta\theta^2\bar{\theta}^2 = 1 . \end{aligned} \quad (9.2.11)$$

Here the shorthand notations

$$\begin{aligned} d^2\theta &\equiv -\frac{1}{4}\epsilon_{\alpha\beta}d\theta^\alpha d\theta^\beta , \\ d^2\bar{\theta} &\equiv -\frac{1}{4}\epsilon^{\dot{\alpha}\dot{\beta}}d\bar{\theta}_{\dot{\alpha}}d\bar{\theta}_{\dot{\beta}} , \\ d^4\theta &\equiv d^2\theta d^2\bar{\theta} . \end{aligned} \quad (9.2.12)$$

are used.

The generalization of the formulas to  $D > 4$  and  $\mathcal{N} > 1$  cases is trivial. In infinite-dimensional case relevant for the super-symmetrization of the WCW geometry in terms of local Clifford algebra of WCW to be proposed later the infinite number of complex theta parameters poses technical problems unless one defines super-space functions properly.

### Chiral super-fields

Super-multiplets can be expressed as single super-field define in super-space. Super-field can be expanded as a Taylor series with respect to the theta parameters. In 4-dimensional  $\mathcal{N} = 1$  case one has

$$\Phi(x^\mu, \theta, \bar{\theta}) = \phi(x^\mu) + \theta\eta(x^\mu) + \bar{\theta}\eta^\dagger(x^\mu) + \bar{\theta}\sigma^\alpha\theta V_\alpha(x^\mu) + \theta^2 F(x^\mu) + \bar{\theta}^2 \bar{F}(x^\mu) \dots + \theta^2\bar{\theta}^2 D(x^\mu) \quad (9.2.13)$$

The action of super-symmetries on super-fields can be expressed in terms of super-covariant derivatives defined as

$$D_\alpha = \frac{\partial}{\partial\theta^\alpha} - i\sigma_{\alpha\dot{\alpha}}^\mu \bar{\theta}^{\dot{\alpha}} \frac{\partial}{\partial x^\mu} , \quad \bar{D}_{\dot{\alpha}} = -\frac{\partial}{\partial\bar{\theta}^{\dot{\alpha}}} + i\theta^\alpha \sigma_{\alpha\dot{\alpha}}^\mu \frac{\partial}{\partial x^\mu} . \quad (9.2.14)$$

This allows very concise realization of super-symmetries.

General super-field defines a reducible representation of super-symmetry. One can construct irreducible representations of super-fields a pair of chiral and antichiral super-fields by posing the condition

$$\bar{D}_{\dot{\alpha}}\Phi = 0 , \quad D_\alpha\Phi^\dagger = 0 . \quad (9.2.15)$$

The hermitian conjugate of chiral super-field is anti-chiral.

Chiral super-fields can be expressed in the form

$$\Phi = \Phi(\theta, y^\mu) , \quad y^\mu = x^\mu + i\bar{\theta}\sigma^\mu\theta , \quad y^{\mu\dagger} = x^\mu - i\bar{\theta}\sigma^\mu\theta . \quad (9.2.16)$$

These formulas generalize in a rather straightforward manner to  $D > 4$  and  $\mathcal{N} > 1$  case.

It is easy to check that any analytic function of a chiral super-field, call it  $W(\Phi)$ , is a chiral super-field. In super-symmetries its  $\theta^2$  component transforms by a total derivative so that the action defined by the super-space integral of  $W(\phi)$  is invariant under super-symmetries. This allows to construct

super-symmetric actions using  $W(\Phi)$  and  $W(\Phi^\dagger)$ . The so called super-potential is defined using the sum of  $W(\Phi) + W(\Phi^\dagger)$ .

Analytic functions of does not give rise to kinetic terms in the action. The observation  $\theta^2\bar{\theta}^2$  component of a real function of chiral super-fields transforms also as total derivative under super-symmetries allows to circumvent this problem by introducing the notion of Kähler potential  $K(\Phi, \Phi^\dagger)$  as a real function of chiral super-field and its conjugate. In the simplest case one has

$$K = \sum_i \Phi_i^\dagger \Phi_i . \quad (9.2.17)$$

$L_K = \int K d^4\theta$  gives rise to simple super-symmetric action for left-handed fermion and its scalar super-partner.

Kähler potential allows an interpretation as a Kähler function defining the Kähler metric for the manifold defined by the scalars  $\phi_i$ . This Kähler metric depends in the general case on  $\phi_i$  and appears in the kinetic term of the super-symmetric action. Super-potential in turn can be interpreted as a counterpart of real part of a complex function which can be added to the Kähler function without affect the Kähler metric. This geometric interpretation suggests that in TGD framework every complex coordinate  $\phi_i$  of WCW defines a chiral super-field whose bosonic part.

### Wess-Zumino model as simple example

Wess-Zumino model without interaction term serves as a simple illustration of above formal considerations. The action density of Wess-Zumino Witten model can be deduced by integration Kähler potential  $K = \Phi^\dagger \Phi$  for chiral super fields over theta parameters. The result is

$$L = \partial_u \phi^* \partial^\mu \phi + i\eta^* \partial^\mu \eta + F^* F . \quad (9.2.18)$$

The action of super-symmetry

$$\delta\Phi = \epsilon^\alpha D_\alpha \Phi , \quad \delta\Phi^\dagger = \bar{\epsilon}^{\dot{\alpha}} \bar{D}_{\dot{\alpha}} \Phi , \quad \epsilon_{\dot{\alpha}} = \epsilon^{*\alpha} \quad (9.2.19)$$

gives the transformation formulas

$$\delta\phi = \epsilon^\alpha \eta_\alpha , \quad \delta\eta = -i\eta^{*\dot{\alpha}} \sigma_{\alpha\dot{\alpha}}^\mu \partial_\mu \phi + \epsilon_\alpha F , \quad \delta F = -i\epsilon_{\dot{\alpha}} \bar{\sigma}^{\mu\dot{\alpha}\alpha} \partial_\mu \eta_\alpha \quad (9.2.20)$$

plus their hermitian conjugates. The corresponding Noether current is indeed hermitian since the transformation parameters  $\epsilon^\alpha$  and  $\bar{\epsilon}_{\dot{\alpha}} = \epsilon^{*\alpha}$  appear in it and cannot be divided away. This conserved current has as such no meaning and the statement that ground state is annihilated by the corresponding super-charge means that vacuum field configuration rather than Fock vacuum remains invariant under supersymmetries. Rather, the breaking of super-symmetry by adding a super-potential implies that  $F$  develops vacuum expectation and the vacuum solution ( $\phi = 0, \eta = 0, F = \text{constant}$ ) of field equations is not anymore invariant super super-symmetries.

The non-hermitian parts of the super current corresponding to different fermion numbers are separately conserved and corresponding super-charges are non-Hermitian and together with other charges define a super-algebra which to my best understanding is not equivalent with the super-algebra defined by allowing the presence of anti-commuting parameters  $\epsilon$ . The situation is similar in TGD where one class of non-hermitian super-currents correspond to the modes of the induced spinor fields contracted with  $\bar{\Psi}$  and their conjugates. The octonionic solution ansatz for the induced spinor field allows to express the solutions in terms of two complex scalar functions so that the super-currents in question would be analogous to those of  $\mathcal{N} = 2$  SUSY and one might see the super-symmetry of quantum TGD extended super-symmetry obtained from the fundamental  $\mathcal{N} = 2$  super-symmetry.

### Vector super-fields and supersymmetric variant of YM action

Chiral super-fields allow only the super-symmetrization of Dirac action. The super-symmetrization of YM action requires the notion of a hermitian vector super field  $V = V^\dagger$ , whose components correspond to vector bosons, their super-counterparts and additional degrees of freedom which cannot be dynamical. These degrees of freedom correspond gauge degrees of freedom.

In the Abelian case the gauge symmetries are realized as  $V \rightarrow V + \Lambda + \Lambda^\dagger$ , where  $\Lambda$  is a chiral super-field. These symmetries induce gauge transformations of the vector potential. Their action on chiral super-fields is  $\Phi \rightarrow \exp(-q\Lambda)\Phi$ ,  $\Phi^\dagger \rightarrow \Phi^\dagger \exp(-\Lambda^\dagger)$ . In non-Abelian case the realization is as  $\exp(V) \rightarrow \exp(-\Lambda^\dagger)\exp(V)\exp(\Lambda)$  so that the modified Kähler potential  $K(\Phi^\dagger, \exp(qV)\Phi)$  remains invariant.

One can assign to  $V$  a gauge invariant chiral spinor super-field as

$$\begin{aligned} W_\alpha &= -\frac{1}{4}\bar{D}^2(e^V D_\alpha e^{-V}) , \\ \bar{D}^2 &= \epsilon^{\dot{\alpha}\dot{\beta}}\bar{D}_{\dot{\alpha}}\bar{D}_{\dot{\beta}} \end{aligned} \quad (9.2.21)$$

defining the analog of gauge field.  $\bar{D}^2$  eliminates all terms the exponent of  $\bar{\theta}$  is higher than that of  $\theta$  since these would spoil the chiral super-field property (the anti-commutativity of super-covariant derivatives  $\bar{D}_{\dot{\alpha}}$  makes this obvious).  $D_\alpha$  in turn eliminates from the resulting scalar part so that one indeed has chiral spinor super-field. In higher dimensions and for larger value of  $\mathcal{N}$  the definition of  $W_\alpha$  must be modified in order to achieve this: what is needed is the product of all derivatives  $\bar{D}_{i\dot{\alpha}}$ .

The analytic functions of chiral spinor super-fields are chiral super-fields and  $\theta^2$  component of  $W^\alpha W_\alpha$  transforms as a total derivatives. The super-symmetric Lagrangian of U(1) theory can be written as

$$L = \frac{1}{4g^2} \left( \int d^2\theta W^\alpha W_\alpha + \int d^2\bar{\theta} W_{\dot{\alpha}}^\dagger W_{\dot{\alpha}}^\dagger \right) . \quad (9.2.22)$$

Note that in standard form of YM action  $1/2g^2$  appears.

### R-symmetry

R-symmetry is an important concomitant of super-symmetry. In  $\mathcal{N} = 1$  case R-symmetry performs a phase rotation  $\theta \rightarrow e^{i\alpha}\theta$  for the super-space coordinate  $\theta$  and an opposite phase rotation for the differential  $d\theta$ . For  $\mathcal{N} > 1$  R-symmetries are  $U(N)$  rotations. R-symmetry is an additional symmetry of the Lagrangian terms due to Kähler potential since both  $d^4\theta$  (and its generalization) as well as Kähler potential are real. Also super-symmetric YM action is R-invariant. R-symmetry is a symmetry of if super-potential  $W$  only if it has super-charge  $Q_R = 2$  ( $Q_R = 2\mathcal{N}$ ) in order to compensate the super-charge of  $d^{2\mathcal{N}}\theta$ .

### 9.2.4 Non-renormalization theorems

Super-symmetry gives powerful constraints on the super-symmetric Lagrangians and leads to non-renormalization theorems.

The following general results about renormalization of supersymmetric gauge theories hold true (see [66] , where heuristic justification of the non-renormalization theorems and explicit formulas are discussed).

1. Super-potential is not affected by the renormalization.
2. Kähler potential is subject to wavefunction renormalization in all orders. The renormalization depends on the parameters with dimensions of mass. In particular, quadratic divergences to masses cancel.
3. Gauge coupling suffers renormalization only by a constant which corresponds to one-loop renormalization. Any renormalization beyond one loop is due to wave function renormalization of the Kähler potential and it is possible to calculate the beta function exactly.

It is interesting to try to see these result from TGD perspective.

1. In TGD framework super-potential interpreted as defining the modification of WCW Kähler function, which does not affect Kähler metric and would reflect measurement interaction. The non-renormalization of  $W$  would mean that the measurement interaction is not subject to renormalization. The interpretation is in terms of quantum criticality which does not allow renormalization of the coefficients appearing in the measurement interaction term since otherwise Kähler metric of WCW would be affected.
2. The wavefunction renormalization of Kähler potential would correspond in TGD framework scaling of the WCW Kähler metric. Quantum criticality requires that Kähler function remains invariant. Also since no parameters with dimensions of mass are available, there is temptation to conclude that wave function renormalization is trivial.
3. Only the gauge coupling would be suffer renormalization. If one however believes in the generalization of bosonic emergence it is Kähler function which defines the SUSY QFT limit of TGD so that gauge couplings follow as predictions and their renormalization is a secondary -albeit real- effect having interpretation in terms of the dependence of the gauge coupling on the p-adic length scale. The conclusion would be that at the fundamental level the quantum TGD is RG invariant.

### 9.3 Does TGD allow the counterpart of space-time super-symmetry?

The question whether TGD allows space-time super-symmetry or something akin to it has been a longstanding problem. A considerable progress in the respect became possible with the better understanding of the modified Dirac equation. At the same time I learned about almost 15 year old striking  $e\epsilon\gamma\gamma + \not{E}$  detected by CDF collaboration [15, 11] from Tommaso Dorigo's blog [9].

#### 9.3.1 Basic data bits

Let us first summarize the data bits about possible relevance of super-symmetry for TGD before the addition of the 3-D measurement interaction term to the modified Dirac action [15, 28].

1. Right-handed covariantly constant neutrino spinor  $\nu_R$  defines a super-symmetry in  $CP_2$  degrees of freedom in the sense that Dirac equation is satisfied by covariant constancy and there is no need for the usual ansatz  $\Psi = D\Psi_0$  giving  $D^2\Psi = 0$ . This super-symmetry allows to construct solutions of Dirac equation in  $CP_2$  [119, 84, 103, 79].
2. In  $M^4 \times CP_2$  this means the existence of massless modes  $\Psi = \not{p}\Psi_0$ , where  $\Psi_0$  is the tensor product of  $M^4$  and  $CP_2$  spinors. For these solutions  $M^4$  chiralities are not mixed unlike for all other modes which are massive and carry color quantum numbers depending on the  $CP_2$  chirality and charge. As matter fact, covariantly constant right-handed neutrino spinor mode is the only color singlet. The mechanism leading to non-colored states for fermions is based on super-conformal representations for which the color is neutralized [41, 50]. The negative conformal weight of the vacuum also cancels the enormous contribution to mass squared coming from mass in  $CP_2$  degrees of freedom.
3. Right-handed covariantly constant neutrino allows to construct the gamma matrices of the world of classical worlds (WCW) as fermionic counterparts of Hamiltonians of WCW. This gives rise super-symplectic symmetry algebra having interpretation also as a conformal algebra. Also more general super-conformal symmetries exist.
4. Space-time (in the sense of Minkowski space  $M^4$ ) super-symmetry in the conventional sense of the word is impossible in TGD framework since it would require require Majorana spinors. In 8-D space-time with Minkowski signature of metric Majorana spinors are definitely ruled out by the standard argument leading to super string model. Majorana spinors would also break separate conservation of lepton and baryon numbers in TGD framework.

### 9.3.2 Could one generalize super-symmetry?

Could one then consider a more general space-time super-symmetry with "space-time" identified as space-time surface rather than Minkowski space?

1. The TGD variant of the super-symmetry could correspond quite concretely to the addition to fermion and boson states right-handed neutrinos. Since right-handed neutrinos do not have electro-weak interactions, the addition might not appreciably affect the mass formula although it could affect the p-adic prime defining the mass scale.
2. The problem is to understand what this addition of the right-handed neutrino means. To begin with, notice that in TGD Universe fermions reside at light-like 3-surfaces at which the signature of induced metric changes. Bosons correspond to pairs of light-like wormhole throats with wormhole contact having Euclidian signature of the induced metric. It is essential that either fermion or antifermion in the boson state carries what might be called un-physical polarization in the standard conceptual framework. Only in this manner the helicities can come out correctly. The assumption that the bosonic wormhole throats correspond to positive and negative energy space-time sheets realizes this constraint in the framework of zero energy ontology.
3. The super-symmetry as an addition to the fermion state a second wormhole throats carrying right handed neutrino quantum numbers does not make sense since the resulting state cannot be distinguished from gauge boson or Higgs type particle. The light-like 3-surfaces can however carry fermion numbers up to the number of modes of the induced spinor field, which is expected to be infinite inside string like objects having wormhole throats at ends and finite when one has space time sheets containing the throats [28] . In very general sense one could say that each mode defines a very large broken  $N$ -super-symmetry with the value of  $N$  depending on state and light-like 3-surface. The breaking of this super-symmetry would come from electro-weak - , color - , and gravitational interactions. Right-handed neutrino would by its electro-weak and color inertness define a minimally broken super-symmetry.
4. What this addition of the right handed neutrinos or more general fermion modes could precisely mean? One cannot assign fermionic oscillator operators to right handed neutrinos which are covariantly constant in both  $M^4$  and  $CP_2$  degrees of freedom since the modes with vanishing energy (frequency) cannot correspond to fermionic oscillator operator creating a physical state since one would have  $a = a^\dagger$ . The intuitive view is that all the spinor modes move in an exactly collinear manner -somewhat like quarks inside hadron do approximately.

### 9.3.3 Modified Dirac equation briefly

The answer to the question what "collinear motion" means mathematically emerged from the recent progress in the understanding of the modified Dirac equation.

1. The modified Dirac action involves two terms. Besides the original 4-D modified Dirac action there is measurement interaction. This term correlates space-time geometry with quantum numbers assignable to super-conformal representations and is also necessary to obtain almost-stringy propagator.
2. The modified Dirac equation with measurement action added reads as

$$(D_K + Q \times O)\Psi = 0 . \quad (9.3.1)$$

- (a)  $D_K$  corresponds formally to 4-D massless Dirac operator in  $X^4$ .  $Q$  realizes measurement interaction.
- (b)  $Q$  is linear in Cartan algebra generators of the isometry algebra of imbedding space (color isospin and hypercharge plus four-momentum or two components of four momentum and spin and boost in direction of 3-momentum).  $Q$  is expressible as

$$Q = Q_A \partial_\alpha h^k g^{AB} j_{Bk} \hat{\Gamma}_K^\alpha . \quad (9.3.2)$$

Here  $Q_A$  is Cartan algebra generator acting on physical states. Physical states must be eigen states of  $Q_A$  since otherwise the equations do not make sense.  $g^{AB}$  is the inverse of the matrix defined by the imbedding space inner product of Killing vector fields  $j_A^k$  and  $j_B^l$ : its existence allows only Cartan algebra charges.

- (c) One can add to the measurement interaction also a coupling to the modified gamma matrices defined by the instanton term  $J \wedge J$  associated with Kähler action. This term is total divergence but gives rise to a sum of Chern-Simons terms localizable to the wormhole throats or to light-like 3-surface parallel to them. This term contributes a boundary condition to the solutions of the modified Dirac equation breaking CP and T invariance. The interpretation is in terms of dissipation caused by state function reductions.
- (d) In general case the modified gamma matrices are defined in terms of action density  $L$  as

$$\hat{\Gamma}^\alpha = \frac{\partial L}{\partial_\alpha h^k} \gamma^k . \quad (9.3.3)$$

$\gamma^k$  denotes imbedding space gamma matrices.

- (e) The operator  $O$  characterizes the conserved fermionic current to which Cartan algebra generators of isometries couple. The simplest conserved currents correspond to quark or lepton currents and corresponding vectorial isospin- and spin currents [28] . Besides this there is an infinite hierarchy of conserved currents relating to quantum criticality and in one-one correspondence with vanishing second variations of Kähler action for preferred extremal. These couplings allow to represent measurement interaction for any observable.
3. The equation  $(D_K + Q)\nu_R = 0$  for right-handed neutrino would reduce for vanishing color charges and covariantly constant spinor to the analog of algebraic fermionic on mass shell condition  $p_A \gamma^A \nu_R = 0$  since  $Q$  is obtained by projecting the total four-momentum of the parton state interpreted as a vector-field of  $H$  to the space-time surface and by replacing ordinary gamma matrices with the modified ones. This equation cannot be exact since  $Q$  depends on the point of the light-like 3-surface so that covariant constancy fails and  $D_K$  cannot annihilate the state. This is the space-time correlate for the breaking of super-symmetry. The action of the Cartan algebra generators is purely algebraic and on the state of super-conformal representations rather than that of a differential operator on spinor field. The modified equation implies that all spinor modes represent fermions moving collinearly in the sense an equation with the same total four-momentum and total color quantum numbers is satisfied by all of them. Note that  $p_A$  represents the total four-momentum of the state rather than individual four-momenta of fermions.

### 9.3.4 TGD counterpart of space-time super-symmetry

This picture allows to define more precisely what one means with the approximate super-symmetries in TGD framework.

1. One can in principle construct many-fermion states containing both fermions and anti-fermions at given light-like 3-surface. The four-momenta of states related by super-symmetry need not be same. Super-symmetry breaking is present and has as the space-time correlate the deviation of the modified gamma matrices from the ordinary  $M^4$  gamma matrices. In particular, the fact that  $\hat{\Gamma}^\alpha$  possesses  $CP_2$  part in general means that different  $M^4$  chiralities are mixed: a space-time correlate for the massivation of the elementary particles.
2. For right-handed neutrino super-symmetry breaking is expected to be smallest but also in the case of the right-handed neutrino mode mixing of  $M^4$  chiralities takes place and breaks the TGD counterpart of super-symmetry.

3. The fact that all helicities in the state are physical for a given light-like 3-surface has important implications. For instance, the addition of a right-handed antineutrino to right-handed (left-handed) electron state gives scalar (spin 1) state. Also states with fermion number two are obtained from fermions. For instance, for  $e_R$  one obtains the states  $\{e_R, e_R\nu_R\bar{\nu}_R, e_R\bar{\nu}_R, e_R\nu_R\}$  with lepton numbers  $(1, 1, 0, 2)$  and spins  $(1/2, 1/2, 0, 1)$ . For  $e_L$  one obtains the states  $\{e_L, e_L\nu_R\bar{\nu}_R, e_L\bar{\nu}_R, e_L\nu_R\}$  with lepton numbers  $(1, 1, 0, 2)$  and spins  $(1/2, 1/2, 1, 0)$ . In the case of gauge boson and Higgs type particles -allowed by TGD but not required by p-adic mass calculations- gauge boson has 15 super partners with fermion numbers  $[2, 1, 0, -1, -2]$ .

The cautious conclusion is that the recent view about quantum TGD allows the analog of super-symmetry which is necessary broken and for which the multiplets are much more general than for the ordinary super-symmetry. Right-handed neutrinos might however define something resembling ordinary super-symmetry to a high extent. The question is how strong prediction one can deduce using quantum TGD and proposed super-symmetry.

1. For a minimal breaking of super-symmetry only the p-adic length scale characterizing the super-partner differs from that for partner but the mass of the state is same. This would allow only a discrete set of masses for various super-partners coming as half octaves of the mass of the particle in question. A highly predictive model results.
2. The quantum field theoretic description should be based on QFT limit of TGD formulated in terms of bosonic emergence [56] . This formulation should allow to calculate the propagators of the super-partners in terms of fermionic loops.
3. This TGD variant of space-time super-symmetry resembles ordinary super-symmetry in the sense that selection rules due to the right-handed neutrino number conservation and analogous to the conservation of R-parity hold true. The states inside super-multiplets have identical electro-weak and color quantum numbers but their p-adic mass scales can be different. It should be possible to estimate reaction reaction rates using rules very similar to those of super-symmetric gauge theories.
4. It might be even possible to find some simple generalization of standard super-symmetric gauge theory to get rough estimates for the reaction rates. There are however problems. The fact that spins  $J = 0, 1, 2, 3/2, 2$  are possible for super-partners of gauge bosons forces to ask whether these additional states define an analog of non-stringy strong gravitation. Note that graviton in TGD framework corresponds to a pair of wormhole throats connected by flux tube (counterpart of string) and for gravitons one obtains  $2^8$ -fold degeneracy.

### 9.3.5 Experimental indication for space-time super-symmetry

There is experimental indication for super-symmetry dating back to 1995 [15] . The event involves  $e^+e^-\gamma\gamma$  plus missing transverse energy  $\cancel{E}_T$ . The electron-positron pair has transversal energies  $E_T = (36, 59)$  GeV GeV and invariant mass  $M_{ee} = 165$  GeV. The two photons have transversal energies  $(30, 38)$  GeV. The missing transverse energy is  $\cancel{E}_T = 53$  GeV. The cross sections for these events in standard model are too small to be observed. Statistical fluctuation could be in question but one could also consider the event as an indication for super-symmetry.

In [11] an explanation of the event in terms of minimal super-symmetric standard model (MSSM) was proposed.

1. The collision of proton and antiproton would induce an annihilation of quark and antiquark to selectron pair  $\tilde{e}^-\tilde{e}^+$  via virtual photon or  $Z^0$  boson with the mass of  $\tilde{e}$  in the range  $(80, 130)$  GeV (the upper bound comes from the total energy of the particles involved).
2.  $\tilde{e}^\pm$  would in turn decay to  $e^\pm$  and neutralino  $\chi_2^0$  ad  $\chi_2^0$  to the lightest super-symmetric particle  $\chi_1^0$  and photon. The neutralinos are in principle mixtures of the super partners associated with  $\gamma$ ,  $Z^0$ , and neutral higgs  $h$  (there are two of them in minimal super-symmetric generalization of standard model). The highest probability for the chain is obtained if  $\chi_2^0$  is gluino and  $\chi_1^0$  is higgsino.

3. The kinematics of the event allows to deduce the bounds

$$\begin{aligned}
80 &< m(\tilde{e})/GeV < 130 \ , \\
38 &\leq m(\chi_2^0)/GeV \leq \min [1.12m(\tilde{e})/GeV - 37, 95 + 0.17m(\chi_1^0)/GeV] \ , \\
m(\chi_1^0)/GeV &\leq m(\chi_2^0)/GeV \leq \min [1.4m(\tilde{e})/GeV - 105, 1.6m(\chi_2^0)/GeV - 60] \ .
\end{aligned}
\tag{9.3.4}$$

4. Sfermion production rate depends only on masses of the sfermions, so that slepton production cross section decouples from the analysis of particular scenarios. The cross section is at the level of  $\sigma = 10$  fb and consistent with data (one event!). The parameters of MSSM are super-symmetric soft-breaking parameters, super-potential parameters, and the parameter  $\tan(\beta)$ . This allows to derive more stringent limits on the masses and parameters of MSSM.

Consider now the explanation of the event in TGD framework.

1. By the properties of super-partners the production rate for  $\tilde{e}^-\tilde{e}^+$  is predicted to be same as in MSSM for  $\tilde{e} = e_R\bar{\nu}_R$ . Same order of magnitude is predicted also for more exotic super-partners such as  $e_L\bar{\nu}_R$  with spin 1.
2. In TGD framework it is safest to use just the kinematical bounds on the masses and p-adic length scale hypothesis. If super-symmetry breaking means same mass formula from p-adic thermodynamics but in a different p-adic mass scale,  $m(\tilde{e})$  is related by a power of  $\sqrt{2}$  to  $m(e)$ . Using  $m(\tilde{e}) = 2^{(127-k(\tilde{e}))/2}m(e)$  one finds that the mass range [80, 130] GeV allows two possible masses for selectron corresponding to  $p \simeq 2^k$ ,  $k = 91$  with  $m(\tilde{e}) = 131.1$  GeV and  $k = 92$  with  $m(\tilde{e}) = 92.7$  GeV. The bounds on  $m(Z)$  leave only the option  $m(\tilde{Z}) = m(Z) = 91.2$  GeV and  $m(\tilde{e}) = 131.1$  GeV.
3. The indirect determinations of Higgs masses from experimental data seem to converge to two different values. The first one would correspond to  $m(h) = 129$  GeV and  $k(h) = 94$  and second one to  $m(h) = 91$  GeV with  $k(h) = 95$  [18, 51] . The fact that already the TGD counterpart for the Gell-Mann-Okubo mass formula in TGD framework requires quarks to exist at several p-adic mass scales [51] , suggests that Higgs can exist in both of these mass scales depending on the experimental situation. The mass of Higgsino would correspond to some half octave of  $m(h)$ . Note that the model allows to conclude that Higgs indeed exists also in TGD Universe although it does not seem to play the same role in particle massivation as in the standard model. The bounds allow only  $k(\tilde{h}) = k(h) + 3 = 97$  and  $m(\tilde{h}) = 45.6$  GeV for  $m(h) = 129$  GeV . The same mass is obtained for  $m(h) = 91$  GeV. Therefore the kinematic limits plus super-symmetry breaking at the level of p-adic mass scale fix completely the masses of the super-particles involved in absence of mixing effects for sneutralinos. To sum up, the masses of sparticles involved are predicted to be

$$m(\tilde{e}) = 131 \text{ GeV} \ , \quad m(\tilde{Z}^0) = 91.2 \text{ GeV} \ , \quad m(\tilde{h}) = 45.6 \text{ GeV} \ . \tag{9.3.5}$$

## 9.4 Octo-twistors and modified Dirac equation

Classical number fields define one vision about quantum TGD which has unexpected connection also with the problem of defining twistors in terms of octonionic analog of the Clifford algebra which serves as alternative for standard Clifford algebra in this dimension. The vision about quantum TGD has evolved gradually and involves several speculative ideas.

1. The hard core of the vision is that space-time surfaces as preferred extremals of Kähler action can be identified as what I have called hyper-quaternionic surfaces of  $M^8$  or  $M^4 \times CP_2$ . This requires only the mapping of the modified gamma matrices to octonions or to a basis of subspace of complexified octonions. This means also the mapping of spinors to octonionic spinors. There is no need to assume that imbedding space-coordinates are octonionic.

2. I have considered also the idea that quantum TGD might emerge from the mere associativity.
  - (a) Consider Clifford algebra of WCW. Treat "vibrational" degrees of freedom in terms second quantized spinor fields and add center of mass degrees of freedom by replacing 8-D gamma matrices with their octonionic counterparts - which can be constructed as tensor products of octonions providing alternative representation for the basis of 7-D Euclidian gamma matrix algebra - and of 2-D sigma matrices. Spinor components correspond to tensor products of octonions with 2-spinors: different spin states for these spinors correspond to leptons and baryons.
  - (b) Construct a local Clifford algebra by considering Clifford algebra elements depending on point of  $M^8$  or  $H$ . The octonionic 8-D Clifford algebra and its local variant are non-associative. Associative sub-algebra of 8-D Clifford algebra is obtained by restricting the elements so any quaternionic 4-plane. Doing the same for the local algebra means restriction of the Clifford algebra valued functions to any 4-D hyper-quaternionic sub-manifold of  $M^8$  or  $H$  which means that the gamma matrices span complexified quaternionic algebra at each point of space-time surface. Also spinors must be quaternionic.
  - (c) The assignment of the 4-D gamma matrix sub-algebra at each point of space-time surface can be done in many manners. If the gamma matrices correspond to the tangent space of space-time surface, one obtains just induced gamma matrices and the standard definition of quaternionic sub-manifold. In this case induced 4-volume is taken as the action principle. If Kähler action defines the space-time dynamics, the modified gamma matrices do not span the tangent space in general.
  - (d) An important additional element is involved. If the  $M^4$  projection of the space-time surface contains a preferred subspace  $M^2$  at each point, the quaternionic planes are labeled by points of  $CP_2$  and one can equivalently regard the surfaces of  $M^8$  as surfaces of  $M^4 \times CP_2$  (number-theoretical "compactification"). This generalizes:  $M^2$  can be replaced with a distribution of planes of  $M^4$  which integrates to a 2-D surface of  $M^4$  (for instance, for string like objects this is necessarily true). The presence of the preferred local plane  $M^2$  corresponds to the fact that octonionic spin matrices  $\Sigma_{AB}$  span 14-D Lie-algebra of  $G_2 \subset SO(7)$  rather than that 28-D Lie-algebra of  $SO(7, 1)$  whereas octonionic imaginary units provide 7-D fundamental representation of  $G_2$ . Also spinors must be quaternionic and this is achieved if they are created by the Clifford algebra defined by induced gamma matrices from two preferred spinors defined by real and preferred imaginary octonionic unit. Therefore the preferred plane  $M^3 \subset M^4$  and its local variant has direct counterpart at the level of induced gamma matrices and spinors.
  - (e) This framework implies the basic structures of TGD and therefore leads to the notion of world of classical worlds (WCW) and from this one ends up with the notion WCW spinor field and WCW Clifford algebra and also hyper-finite factors of type  $II_1$  and  $III_1$ . Note that  $M^8$  is exceptional: in other dimensions there is no reason for the restriction of the local Clifford algebra to lower-dimensional sub-manifold to obtain associative algebra.
3. I have used time also to wilder speculations inspired by the idea that one could treat imbedding space coordinates or space-time coordinate as single hyper-octonionic or hyper-quaternionic coordinate but this line of approach has not led to anything really interesting. For instance, I have considered the generalization of conformal fields by replacing complex coordinate  $z$  with complexified octonionic coordinate of  $M^8$  to obtain a generalization of configuration space spinor fields and Clifford algebra elements to octonion-conformal fields. The dependence of the modes of the octonion-conformal field on  $M^4$  coordinates seems however non-physical (one would expect plane waves instead of powers) so that this approach does not seem promising.

The above line of ideas leads naturally to (hyper-)quaternionic sub-manifolds and to basic quantum TGD (note that the "hyper" is un-necessary if one accepts just the notion of quaternionic sub-manifold formulated in terms of modified gamma matrices). One can pose some further questions.

1. Quantum TGD reduces basically to the second quantization of the induced spinor fields. Could it be that the theory is integrable only for 4-D hyper-quaternionic space-time surfaces in  $M^8$  (equivalently in  $M^4 \times CP_2$ ) in the sense than one can solve the modified Dirac equation exactly only in these cases?

2. The construction of quantum TGD -including the construction of vacuum functional as exponent of Kähler function reducing to Kähler action for a preferred extremal - should reduce to the modified Dirac equation defined by Kähler action. Could it be that the modified Dirac equation can be solved exactly only for Kähler action.
3. Is it possible to solve the modified Dirac equation for the octonionic gamma matrices and octonionic spinors and map the solution as such to the real context by replacing gamma matrices and sigma matrices with their standard counterparts? Could the associativity conditions for octospinors and modified Dirac equation allow to pin down the form of solutions to such a high degree that the solution can be constructed explicitly?
4. Octonionic gamma matrices provide also a non-associative representation for 8-D version of Pauli sigma matrices and encourage the identification of 8-D twistors as pairs of octonionic spinors conjectured to be highly relevant also for quantum TGD. Does the quaternionicity condition imply that octo-twistors reduce to something closely related to ordinary twistors as the fact that 2-D sigma matrices provide a matrix representation of quaternions suggests?

In the following I will try to answer these questions by developing a detailed view about the octonionic counterpart of the modified Dirac equation and proposing explicit solution ansätze for the modes of the modified Dirac equation.

#### 9.4.1 The replacement of $SO(7, 1)$ with $G_2$

The basic implication of octonionization is the replacement of  $SO(7, 1)$  as the structure group of spinor connection with  $G_2$ . This has some rather unexpected consequences.

##### Octonionic representation of 8-D gamma matrices

Consider first the representation of 8-D gamma matrices in terms of tensor products of 7-D gamma matrices and 2-D Pauli sigma matrices.

1. The gamma matrices are given by

$$\gamma^0 = 1 \times \sigma_1 \quad , \quad \gamma^i = \gamma^i \otimes \sigma_2 \quad , \quad i = 1, \dots, 7 \quad . \quad (9.4.1)$$

7-D gamma matrices in turn can be expressed in terms of 6-D gamma matrices by expressing  $\gamma^7$  as

$$\gamma_{i+1}^{(7)} = \gamma_i^{(6)} \quad , \quad i = 1, \dots, 6 \quad , \quad \gamma_1^{(7)} = \gamma_7^{(6)} = \prod_{i=1}^6 \gamma_i^{(6)} \quad . \quad (9.4.2)$$

2. The octonionic representation is obtained as

$$\gamma_0 = 1 \times \sigma_1 \quad , \quad \gamma_i = e_i \otimes \sigma_2 \quad . \quad (9.4.3)$$

where  $e_i$  are the octonionic units.  $e_i^2 = -1$  guarantees that the  $M^4$  signature of the metric comes out correctly. Note that  $\gamma_7 = \prod \gamma_i$  is the counterpart for choosing the preferred octonionic unit and plane  $M^2$ .

3. The octonionic sigma matrices are obtained as commutators of gamma matrices:

$$\Sigma_{0i} = e_i \times \sigma_3 \quad , \quad \Sigma_{ij} = f_{ij}^k e_k \otimes 1 \quad . \quad (9.4.4)$$

These matrices span  $G_2$  algebra having dimension 14 and rank 2 and having imaginary octonion units and their conjugates as the fundamental representation and its conjugate. The Cartan algebra for the sigma matrices can be chosen to be  $\Sigma_{01}$  and  $\Sigma_{23}$  and belong to a quaternionic sub-algebra.

4. The lower dimension of the  $G_2$  algebra means that some combinations of sigma matrices vanish. All left or right handed generators of the algebra are mapped to zero: this explains why the dimension is halved from 28 to 14. From the octonionic triangle expressing the multiplication rules for octonion units [22] one finds  $e_4 e_5 = e_1$  and  $e_6 e_7 = -e_1$  and analogous expressions for the cyclic permutations of  $e_4, e_5, e_6, e_7$ . From the expression of the left handed sigma matrix  $I_L^3 = \sigma_{23} + \sigma^{30}$  representing left handed weak isospin (see the Appendix of the book about the geometry of  $CP_2$ ) one can conclude that this particular sigma matrix and left handed sigma matrices in general are mapped to zero. The quaternionic sub-algebra  $SU(2)_L \times SU(2)_R$  is mapped to that for the rotation group  $SO(3)$  since in the case of Lorentz group one cannot speak of a decomposition to left and right handed subgroups. The elements of the complement of the quaternionic sub-algebra are expressible in terms of  $\Sigma_{ij}$  in the quaternionic sub-algebra.

### Some physical implications of $SO(7,1) \rightarrow G_2$ reduction

This has interesting physical implications if one believes that the octonionic description is equivalent with the standard one.

1. Since  $SU(2)_L$  is mapped to zero only the right-handed parts of electro-weak gauge field survive octonization. The right handed part is neutral containing only photon and  $Z^0$  so that the gauge field becomes Abelian.  $Z^0$  and photon fields become proportional to each other ( $Z^0 \rightarrow \sin^2(\theta_W)\gamma$ ) so that classical  $Z^0$  field disappears from the dynamics, and one would obtain just electrodynamics. This might provide a deeper reason for why electrodynamics is an excellent description of low energy physics and of classical physics. This is consistent with the fact that  $CP_2$  coordinates define 4 field degrees of freedom so that single Abelian gauge field should be enough to describe classical physics. This would remove also the interpretational problems caused by the transitions changing the charge state of fermion induced by the classical  $W$  boson fields.

Also the realization of  $M^8 - H$  duality led to the conclusion  $M^8$  spinor connection should have only neutral components. The isospin matrix associated with the electromagnetic charge is  $e_1 \times 1$  and represents the preferred imaginary octonionic unit so that that the image of the electro-weak gauge algebra respects associativity condition. An open question is whether octonionization is part of  $M^8$ -H duality or defines a completely independent duality. The objection is that information is lost in the mapping so that it becomes questionable whether the same solutions to the modified Dirac equation can work as a solution for ordinary Clifford algebra.

2. The gauge potentials and gauge fields defined by  $CP_2$  spinor connection are mapped to fields in  $SO(2) \subset SU(2) \times U(1)$  in quaternionic sub-algebra which in a well-defined sense corresponds to  $M^4$  degrees of freedom! Since the resulting interactions are of gravitational character, one might say that electro-weak interactions are mapped to manifestly gravitational interactions. Since  $SU(2)$  corresponds to rotational group one cannot say that spinor connection would give rise only to left or right handed couplings, which would be obviously a disaster.

### Octo-spinors and their relation to ordinary imbedding space spinors

Octo-spinors are identified as octonion valued 2-spinors with basis

$$\begin{aligned} \Psi_{L,i} &= e_i \begin{pmatrix} 1 \\ 0 \end{pmatrix} , \\ \Psi_{q,i} &= e_i \begin{pmatrix} 0 \\ 1 \end{pmatrix} . \end{aligned} \tag{9.4.5}$$

One obtains quark and lepton spinors and conjugation for the spinors transforms quarks to leptons. Note that octospinors can be seen as 2-dimensional spinors with components which have values in the space of complexified octonions.

The leptonic spinor corresponding to real unit and preferred imaginary unit  $e_1$  corresponds naturally to the two spin states of the right handed neutrino. In quark sector this would mean that right handed U quark corresponds to the real unit. The octonions decompose as  $1 + 1 + 3 + \bar{3}$  as representations of  $SU(3) \subset G_2$ . The concrete representations are given by

$$\begin{aligned} \{1 \pm ie_1\} &, \quad e_R \text{ and } \nu_R \text{ with spin } 1/2 , \\ \{e_2 \pm ie_3\} &, \quad e_R \text{ and } \nu_L \text{ with spin } -1/2 , \\ \{e_4 \pm ie_5\} &, \quad e_L \text{ and } \nu_L \text{ with spin } 1/2 , \\ \{e_6 \pm ie_7\} &, \quad e_L \text{ and } \nu_L \text{ with spin } 1/2 . \end{aligned} \tag{9.4.6}$$

Instead of spin one could consider helicity. All these spinors are eigenstates of  $e_1$  (and thus of the corresponding sigma matrix) with opposite values for the sign factor  $\epsilon = \pm$ . The interpretation is in terms of vectorial isospin. States with  $\epsilon = 1$  can be interpreted as charged leptons and D type quarks and those with  $\epsilon = -1$  as neutrinos and U type quarks. The interpretation would be that the states with vanishing color isospin correspond to right handed fermions and the states with non-vanishing SU(3) isospin (to be not confused with QCD color isospin) and those with non-vanishing SU(3) isospin to left handed fermions. The only difference between quarks and leptons is that the induced Kähler gauge potentials couple to them differently.

The importance of this identification is that it allows a unique map of the candidates for the solutions of the octonionic modified Dirac equation to those of ordinary one. There are some delicacies involved due to the possibility to chose the preferred unit  $e_1$  so that the preferred subspace  $M^2$  can corresponds to a sub-manifold  $M^2 \subset M^4$ .

### 9.4.2 Octonionic counterpart of the modified Dirac equation

The solution ansatz for the octonionic counterpart of the modified Dirac equation discussed below makes sense also for ordinary modified Dirac equation which raises the hope that the same ansatz, and even same solution could provide a solution in both cases.

#### The general structure of the modified Dirac equation

There are two options concerning measurement interaction corresponding to  $D_4 = D_K + Q_K$  and  $D_3 = D_{C-S} + Q_{C-S}$ . Here only the option based on  $D_K + Q_K$  is discussed since it looks more promising.

For  $D_K + Q_K$  option there is only single equation and corresponds to a 4-D modified Dirac equation defined by Kähler action with measurement interaction term:

$$(D_K + Q_K)\Psi = 0 . \tag{9.4.7}$$

Also a CP-breaking instanton could be considered. In absence of measurement interaction the dimensional reduction of this operator to a sum corresponding to  $D_{K,3}$  acting on light-like 3-surfaces and 1-D operator  $D_{K,1}$  acting on the coordinate labeling the 3-D light-like 3-surfaces in the slicing allows to assign eigenvalues to  $D_{K,3}$  as analogs of energy eigenvalues for ordinary Schrödinger equation. It is not clear whether similar reduction occurs also in presence of measurement interaction. Dirac determinant is identified as the product of these eigen values of  $D_{K,3} + Q_K$ .

### About the hyper-octonionic variant of the modified Dirac equation

What gives excellent hopes that the octonionic variant of modified Dirac equation could lead to a provide precise information about the solution spectrum of modified Dirac equation is the condition that everything in the equation should be associative. Hence the terms which are by there nature non-associative should vanish automatically. First some general comments.

1. The first implication is that the besides octonionic gamma matrices also octonionic spinors should belong to the local quaternionic plane at each point of the space-time surface. Spinors are also generated by quaternionic Clifford algebra from two preferred spinors defining a preferred plane in the space of spinors. Hence spinorial dynamics seems to mimic very closely the space-time dynamics and one might even hope that the solutions of the modified Dirac action could be seen as maps of the space-time surface to surfaces of the spinor space. The reduction to quaternionic sub-algebra suggest that some variant of ordinary twistors emerges in this manner in matrix representation.
2. The octonionic sigma matrices span  $G_2$  where as ordinary sigma matrices define  $SO(7,1)$ . On the other hand, the holonomies are identical in the two cases if right-handed charge matrices are mapped to zero so that there are indeed hopes that the solutions of the octonionic Dirac equation cannot be mapped to those of ordinary Dirac equation. If left-handed charge matrices are mapped to zero, the resulting theory is essentially the analog of electrodynamics coupled to gravitation at classical level but it is not clear whether this physically acceptable. It is not clear whether associativity condition leaves only this option under consideration.
3. The condition  $D^2\Psi = 0$  with  $D = (D_K + Q_K)$  involves products of three octonions and derivatives of the modified gamma matrices which can belong to the complement of the quaternionic sub-space. Therefore  $(D^2)D\Psi_i = D(D^2\Psi_i)$  could fail. It is not clear whether the failure of this condition is a catastrophe.

For the measurement interaction defined by Kähler action situation is very simple since commutator condition is not needed. The solution ansatz to the modified Dirac equation with interaction term is expected to be of the form  $\Psi = (D_K + Q_K)(\Psi_0 u_0 + \Psi_1 u_1)$ , where  $u_0$  and  $u_1$  are constant spinors representing real unit and the preferred unit  $e_1$ . Hence constant spinors associated with right handed electron and neutrino and right-handed d and u quark would appear in  $\Psi$  and  $\Psi_i$  could correspond to scalar coefficients of spinors with different charge. This ansatz would reduce the modified Dirac equation to  $(D_K + Q_K)^2\Psi_i = 0$  since there are no charged couplings present. The reduction of a d'Alembert type equation for single scalar function coupling to  $U(1)$  gauge potential and  $U(1)$  "gravitation" would obviously mean a dramatic simplification raising hopes about integrable theory.

### General features of the solution ansatz

The solution ansätze for Chern-Simons and Kähler option have some common features.

1. In both cases one must eliminate  $Q_K$  from the equation. The function  $\Phi_i$  -call it just  $\Phi$  - is proportional to a function, which is a generalization of plane wave and guarantees that Kähler Dirac equation is satisfied:

$$U_Q = \exp(i\Phi_Q) , \quad \Phi_Q = \int_{\gamma_{4,1}} Q_{K,\alpha} dx^\alpha . \quad (9.4.8)$$

Here the curves  $\gamma_{4,1}$  can be chosen rather freely since integrable phase factor is in question.  $\gamma_{4,1}$  can be chose so that it defines a slicing of  $X^4$  reducing to a union of the slicings of  $Y_l^3$ . The stringy slicing of  $X^4$  encourages the identification of these curves as the ends of the orbits of strings connecting different wormhole throats. For four-momentum this expression reduces to a plane wave.

2. In both cases one must eliminate the covariant derivatives from the modified Dirac equation. For the Abelian option the non-integrable phase factor is defined by the Abelian induced spinor connection and eliminates the coupling to gauge potentials in the modified Dirac equation. By abelianity these factors reduce to ordinary integrals:

$$U_{A,i} = \exp\left(i \int_{\gamma_{4,i}} A_\alpha dx^\alpha\right) \equiv \exp(i\Phi_{A,i}) \quad , \quad i = 1, 2 \quad . \tag{9.4.9}$$

The two families of curves denoted by  $\gamma_{4,i}$  correspond to stringy curves and the curves defined by their ends. The phase factors are actually diagonal  $2 \times 2$  matrix since  $A$  involves a coupling to spin. In octonionic case the Abelian phase factor is actually diagonal  $2 \times 2$  matrix since  $A$  involves a coupling to spin.

**The detailed form of the modified Dirac-Kähler equation for Kähler option**

$\hat{\Gamma}^u = \hat{\Gamma}^v$  implies the degeneracy of the effective metric so that one has  $\hat{g}^{u\alpha} = \hat{g}^{v\alpha}$ . This simplifies the equation to an effectively 2-dimensional form.

1. The integrable phase factor  $\exp(\Phi_Q)$  and non-integrable phase factors  $\exp(\Phi_{A,i})$  are present also now.
2. The general form of the solution ansatz for Kähler option differs slightly from that for Chern-Simons option since one can assume plane waves in both directions but with different "energies".

$$U_{\lambda_1, \lambda_2} = \exp(i\lambda_1 u) \exp(i\lambda_2 v) \equiv \exp(i\Phi_{\lambda_1}) \exp(i\Phi_{\lambda_2}) \quad . \tag{9.4.10}$$

3. In the recent case the factor  $R$  depends only on the transversal coordinates associated with the partonic 2-surfaces, and is analogous to oscillator wave function in an external magnetic field at  $X^2$  defined by the Abelian gauge field.
4. One can write the solution ansatz in the form

$$\Psi = (D_K + Q_K)\Psi_i = \left[ \frac{D_{K,2}R}{R} + \hat{\Gamma}^u (\partial_u \Phi_Q + \partial_u \Phi_{A,1} + \partial_v \Phi_{A,2} + \lambda_1 + \lambda_2) \right] \Psi_i \quad . \tag{9.4.11}$$

Here  $D_{K,2}$  represents 2-dimensional dimensional reduction of  $D_K$  acting at partonic 2-surface.

5. Without further assumptions it is not possible get rid of the non-integrable phase factors completely. The sum of the derivatives of non-integrable phase factors characterizes the change of the Kähler magnetic flux through a surface defined by 2 parallel stringy curves and 2 parallel string end curves as second stringy curve and string end curve meeting at the point considered are shifted slightly. The condition allowing to get rid of these derivatives reads as

$$J_{tu} = 0 \quad . \tag{9.4.12}$$

The condition states that there is no Kähler electric field component along string orbits so that the strings would behave like conductors. Note that this condition generalizes also to non-Abelian case (non-octonionic gamma matrices). Effective 3-dimensionality suggests that also  $\Phi_Q$  is constant along stringy curves.

With these optimistic assumptions the ansatz would reduce to

$$\Psi = (D_K + Q_K)\Psi_i = \left[ \frac{D_{K,2}R}{R} + \hat{\Gamma}^u(\lambda_1 + \lambda_2) \right] \Psi_i . \quad (9.4.13)$$

6. Continuing in the same optimistic spirit the modified Dirac equation reduces to

$$\begin{aligned} (D_K + Q_K)(D_K + Q_K)\Psi_i &= (D_K + Q_K) \left[ \frac{D_{K,2}R}{R} + \hat{\Gamma}^u(\lambda_1 + \lambda_2) \right] \Psi_i \\ &= \left[ \frac{D_{K,2}^2R}{R} + (\hat{\Gamma}^u)^2(\lambda_1 + \lambda_2)^2 + [D_K, \hat{\Gamma}^u](\lambda_1 + \lambda_2) \right] \Psi_i . \end{aligned} \quad (9.4.14)$$

Since  $R$  depends only on the two transversal coordinates, one obtains equation analogous to a 2-dimensional Schrödinger equation in 2-D magnetic field and quantization of  $\lambda_1 + \lambda_2$  is expected. In the octonionic picture the magnetic field is Abelian so that the analogy is rather concrete. If the region surrounding the wormhole throat has boundary, only finite number of eigen-modes are expected. If a string-like object is in question there is no boundary so that the number of eigenvalues can be infinite. This means homological non-triviality and Kähler magnetic charge so that a string carrying magnetic monopoles at its ends is in question.

7. The quantization of  $\lambda_i$  ought to have a description in terms of the analogy with the harmonic oscillator wave functions for a charged particle in an external Abelian magnetic field.  $\lambda_1 - \lambda_2$  could be determined by the boundary conditions.  $\lambda_1 = \lambda_2$  is suggested by the duality of the slicing defined by stringy curves and by string end curves.

To sum up, the solution ansatz is very simple for Kähler option provided that the induced Kähler form (more generally, induced electro-weak gauge field) vanishes in  $(u, v)$  planes and the generalized plane-waves  $\exp(i\Phi_Q)$  are constant along the stringy curves as the effective 3-dimensionality and light-likeness of these curves suggests. For the dual solution ansatz  $\exp(i\Phi_Q)$  would be constant along the string end curves. These ansätze are analogs of plane waves with opposite wave vectors but same frequency.

### 9.4.3 Could the notion of octo-twistor make sense?

The basic problem of the twistor program is how to overcome the difficulties caused by particle massivation and TGD framework suggests possible clues in this respect.

1. In TGD framework it is natural to regard particles as massless particles in 8-D sense and to introduce 8-D counterpart of twistors by relying on the geometric picture in which twistors correspond to a pair of spinors characterizing light-like momentum ray and a point of  $M^8$  through which the ray traverses. Twistors would consist of a pair of spinors and quark and lepton spinors define the natural candidate for the spinors in question.
2. In the case of ordinary Clifford algebra unit matrix and six-dimensional gamma matrices  $\gamma_i$ ,  $i = 1, \dots, 6$  and  $\gamma_7 = \prod_i \gamma_i$  would define the variant of Pauli sigma matrices as  $\sigma_0 = 1$ ,  $\sigma_k = \gamma_k$ ,  $k = 1, \dots, 7$ . The problem is that masslessness condition does not correspond to the vanishing of the determinant for the matrix  $p_k \sigma^k$ .
3. In the case of octo-twistors Pauli sigma matrices  $\sigma^k$  would correspond to hyper-octonion units  $\{\sigma_0, \sigma_k\} = \{1, ie^k\}$  and one could assign to  $p_k \sigma^k$  a matrix by the linear map defined by the multiplication with  $P = p_k \sigma^k$ . The matrix is of form  $P_{mn} = p^k f_{kmn}$ , where  $f_{kmn}$  are the structure constants characterizing multiplication by hyper-octonion. The norm squared for octonion is the fourth root for the determinant of this matrix. Since  $p_k \sigma^k$  maps its octonionic

conjugate to zero so that the determinant must vanish (as is easy to see directly by reducing the situation to that for hyper-complex numbers by considering the hyper-complex plane defined by  $P$ ).

4. The associativity of octo-twistors means that the momentum like quantity and the two spinors belong to the same complex quaternionic plane. This suggests that octo-twistor can be mapped to an ordinary twistor by mapping the basis of hyper-quaternions to Pauli sigma matrices. Quaternionization would also allow to assign to momentum to the spinors in standard manner.

One can consider two approaches to the notion of octo-twistor: global and local.

1. The global approach to the notion of octo-twistor starts from four-momentum and color charges combined to form an 8-vector. Associativity requires that both the momentum and the spinors defining the twistors are in the same quaternionic plane which suggests that 8-D twistors reduce to 4-D twistors. In the case of  $M^8$  and assuming 8-momenta, this difficulty can be overcome if fixed  $M^4 \subset M^8$  defines Minkowski momentum. In the case of  $M^4 \times CP_2$  one can assign to light-like geodesics light-like 8-momentum in terms of the tangent vector to a light-like geodesic line reducing to circle in  $CP_2$ . In quantum theory color isospin and hypercharge would be the counterparts of  $CP_2$  momentum. In this case the geometric condition assigning to the light-like ray a position assignable to light-cone boundary of  $M^8$  in second light-cone boundary of  $M^8$  requires  $M^8 - H$  duality. The objection against this approach is that it is stringy propagator which should fix the notion of twistor used.
2. The second approach is local and replaces 8-momentum with the charge vector  $Q_\alpha$  appearing in the stringy propagator belonging to the local hyper-quaternionic plane of the space-time surface by the associativity condition. Local twistorialization would be based on  $Q_\alpha$ , which together with the leptonic and quark-like spinors should belong to the local quaternionic sub-space. This means four complex components for both spinors and four components for real components for  $Q_\alpha$ . The defining equation would read in this case be

$$Q_{i\alpha} = \bar{\Psi}_i \hat{\Gamma}_\alpha \Psi_i . \tag{9.4.15}$$

Here  $i = q, L$  refers to leptonic/quark-like spinor. These conditions would hold true separately for quark-like and lepton like charge vectors since quark and lepton currents are separately conserved.

The experience with the ordinary twistors and the requirement that local octo-twistors can be mapped to ordinary twistors suggest that one should consider the condition

$$g_K^{\alpha\beta} Q_{i\alpha} Q_{i\beta} = 0 \tag{9.4.16}$$

as a generalization of the masslessness condition. Here  $g_K$  is the effective metric defined by the anti-commutator of the modified gamma matrices defined by C-S action or Kähler action. One can hope that this condition is consistent with the vanishing of the commutator  $[D_K, D_3]$  giving already 8 conditions. If the dynamics of Kähler action manages to make massive particles effectively massless, a local twistor description in essentially 4-dimensional sense would be possible by the effective metric defined by modified gamma matrices and the construction of local twistors would reduce to standard recipes.

## 9.5 SUSY algebra of fermionic oscillator operators and WCW local Clifford algebra elements as super-fields

Whether TGD allows space-time supersymmetry has been a long-standing question. Majorana spinors appear in  $N = 1$  super-symmetric QFTs- in particular minimally super-symmetric standard model

(MSSM). Majorana-Weyl spinors appear in M-theory and super string models. An undesirable consequence is chiral anomaly in the case that the numbers of left and right handed spinors are not same. For  $D = 11$  and  $D = 10$  these anomalies cancel which led to the breakthrough of string models and later to M-theory. The probable reason for considering these dimensions is that standard model does not predict right-handed neutrino (although neutrino mass suggests that right handed neutrino exists) so that the numbers of left and right handed Weyl-spinors are not the same.

In TGD framework the situation is different. Covariantly constant right-handed neutrino spinor acts as a super-symmetry in  $CP_2$ . One might think that right-handed neutrino in a well-defined sense disappears from the spectrum as a zero mode so that the number of right and left handed chiralities in  $M^4 \times CP_2$  would not be same. For light-like 3-surfaces covariantly constant right-handed neutrino does not however solve the counterpart of Dirac equation for a non-vanishing four-momentum and color quantum numbers of the physical state. Therefore it does not disappear from the spectrum anymore and one expects the same number of right and left handed chiralities.

In TGD framework the separate conservation of baryon and lepton numbers excludes Majorana spinors and also the the Minkowski signature of  $M^4 \times CP_2$  makes them impossible. The conclusion that TGD does not allow super-symmetry is however wrong. For  $\mathcal{N} = 2N$  Weyl spinors are indeed possible and if the number of right and left handed Weyl spinors is same super-symmetry is possible. In 8-D context right and left-handed fermions correspond to quarks and leptons and since color in TGD framework corresponds to  $CP_2$  partial waves rather than spin like quantum number, also the numbers of quark and lepton-like spinors are same.

The physical picture suggest a new kind of approach to super-symmetry in the sense that the anti-commutations of fermionic oscillator operators associated with the modes of the induced spinor fields define a structure analogous to SUSY algebra. This means that  $\mathcal{N} = 2N$  SUSY with large  $N$  is in question allowing spins higher than two and also large fermion numbers. Recall that  $\mathcal{N} \leq 32$  is implied by the absence of spins higher than two and the number of real spinor components is  $N = 32$  also in TGD. The situation clearly differs from that encountered in super-string models and SUSYs and the large value of  $N$  allows to expect very powerful constraints on dynamics irrespective of the fact that SUSY is broken. Right handed neutrino modes define a sub-algebra for which the SUSY is only slightly broken by the absence of weak interactions and one could also consider a theory containing a large number of  $\mathcal{N} = 2$  super-multiplets corresponding to the addition of right-handed neutrinos and antineutrinos at the wormhole throat.

Masslessness condition is essential for super-symmetry and at the fundamental level it could be formulated in terms of modified gamma matrices using octonionic representation and assuming that they span local quaternionic sub-algebra at each point of the space-time sheet. SUSY algebra has standard interpretation with respect to spin and isospin indices only at the partonic 2-surfaces so that the basic algebra should be formulated at these surfaces. Effective 2-dimensionality would require that partonic 2-surfaces can be taken to be ends of any light-like 3-surface  $Y_I^3$  in the slicing of the region surrounding a given wormhole throat.

### 9.5.1 Super-algebra associated with the modified gamma matrices

Anti-commutation relations for fermionic oscillator operators associated with the induced spinor fields are naturally formulated in terms of the modified gamma matrices. Super-conformal symmetry suggests that the anti-commutation relations for the fermionic oscillator operators at light-like 3-surfaces or at their ends are most naturally formulated as anti-commutation relations for SUSY algebra. The resulting anti-commutation relations would fix the quantum TGD. Lepton and quark like spinors are now the counterparts of right and left handed Weyl spinors. Spinors with dotted and un-dotted indices correspond to conjugate representations of  $SO(3, 1) \times SU(4)_L \times SU(2)_R$ . The anti-commutation relations make sense for sigma matrices identified as 6-dimensional matrices  $1_6, \gamma_7, \gamma_1, \dots, \gamma_6$  .

In leptonic sector one would have the anticommutation relations

$$\begin{aligned} \{a_{m\dot{\alpha}}^\dagger, a_\beta^n\} &= 2\delta_m^n D_{\dot{\alpha}\beta} \ , \\ D &= (p_\mu + \sum_a Q_\mu^a) \sigma^\mu \ . \end{aligned} \tag{9.5.1}$$

In quark sector  $\sigma^\mu$  is replaced with  $\bar{\sigma}^\mu$  obtained by changing the signs of space-like sigma matrices.  $p_\mu$  and  $Q_\mu^a$  are the projections of momentum and color charges in Cartan algebra to the space-time

surface. The action of these charges is on the position of the tip of  $CD$  and therefore purely algebraic as far as space-time coordinates are considered. The anti-commutation relations define a generalization of the ordinary equal-time anticommutation relations for fermionic oscillator operators to a manifestly covariant form. Extended SUSY algebra suggest that the anti-commutators could contain additional central charge term proportional to  $\delta_{\alpha\beta}$  but the 8-D chiral invariance excludes this term.

In the octonionic representation of the sigma matrices matrix indices cannot be present at the right handed side without additional conditions. Octonionic units however allow a representation as matrices defined by the structure constants failing only when products of more than two octonions are considered. For the quaternionic sub-algebra this does not occur. Both spinor modes and gamma matrices must belong to the local hyper-quaternionic sub-algebra. Octonionic representation reduces  $SO(7, 1)$  so  $G_2$  as a tangent space group. Similar reduction for 7-dimensional compact space takes place also M-theory.

One can consider basically two different options concerning the definition of the super-algebra. If the super-algebra is defined at the 3-D ends of the intersection of  $X^4$  with the boundaries of  $CD$ , the modified gamma matrices appearing in the operator  $D$  appearing in the anti-commutator are associated with Kähler action. If the generalized masslessness condition  $D^2 = 0$  holds true -as suggested already earlier- one can hope that no explicit breaking of super-symmetry takes place and elegant description of massive states as effectively massless states making also possible generalization of twistor is possible. One must however notice that also massive representatives of SUSY exist. SUSY algebra could be also defined at 2-D ends of light-like 3-surfaces. According to considerations of [28] these options are equivalent if the effective metric defined by the modified gamma matrices is degenerate so that space-time sheet is effectively 3-dimensional. In this case propagation takes place along 3-D light-like 3-surfaces. This condition fails for string like objects.

One can realize the local Clifford algebra in terms of super fields by introducing theta parameters in the standard manner and the expressing a collection of local Clifford algebra element with varying values of fermion numbers (function of  $CD$  and  $CP_2$  coordinates) as a chiral super-field. The definition of a chiral super field requires the introduction of super-covariant derivatives.

Standard form for the anti-commutators of super-covariant derivatives  $D_\alpha$  make sense only if the momentum and color charges do not act as differential operators acting on space-time coordinates and thus affecting the modified gamma matrices. This is achieved since  $p_k$  and  $Q_a$  act on the position of the tip of  $CD$  in  $M^4 \times CP_2$  (rather than internal coordinates of the space-time sheet).

### 9.5.2 Super-fields associated with WCW Clifford algebra

WCW local Clifford algebra elements possess definite fermion numbers and it is not physically sensible to super-pose local Clifford algebra elements with different fermion numbers. The extremely elegant formulation of super-symmetric theories in terms of super-fields encourages to ask whether the local Clifford algebra elements could allow expansion in terms of complex theta parameters assigned to various fermionic oscillator operator in order to obtain formal superposition of elements with different fermion numbers. One can also ask whether the notion of chiral super field might make sense.

The obvious question is whether it makes sense to assign super-fields with the modified gamma matrices.

1. As already noticed, modified gamma matrices are not covariantly constant but this is not a problem since the action of momentum generators and color generators space-time coordinates is purely algebraic.
2. One can define the notion of super-field also at the fundamental level. Chiral super-field would be continuation of the local Clifford algebra of associated with  $CD$  to a local Clifford algebra element associated with the union of  $CD$ s. This would allow elegant description of cm degrees of freedom, which are the most interesting as far as QFT limit is considered.
3. In particular, the Kähler function of WCW as a function of complex coordinates can be extended to a chiral super-field defined in quantum fluctuation degrees of freedom. It would depend on zero modes too. Does also the latter dependence allow super-space continuation? Coefficients of powers of theta would correspond to fermionic oscillator operators. Does this function define the propagators of various states associated with light-like 3-surface? Configuration space complex

coordinates would correspond to the modes of induced spinor field so that super-symmetry would be realized very concretely.

4. Quantum criticality implies infinite number of conserved super-currents assignable to zero modes and it seems that similar coding makes sense also for the dependence of Kähler function on zero modes.

The really elegant feature of the super-field concept is that it allows to code the Taylor polynomial of a function at given point -essentially non-local data- to a purely local data about super field. The coding of the Taylor expansion of WCW Kähler function at maximum would represent only one example of this expansion.

The obvious idea is that the exponent of the super-space Kähler function defines the vacuum functional of the theory determining all interaction vertices. In this interpretation the scalar components  $\phi_i$  of infinite-component chiral field would correspond to complex coordinates of WCW. Also zero modes might allow super-symmetrization by using the fermionic currents implied by quantum criticality.

It is not clear whether vector super-fields make sense in this framework or are needed.

1. Zero energy ontology and the identification of gauge bosons as wormhole contacts encourage the identification of both fermions and bosons as chiral super-fields. One could assign to fermions either the positive or negative energy variant of  $\mathcal{N}$  super-algebra having possibly infinite number of generators and to bosons the direct sum of these super-algebras so that one has positive and negative energy fermions  $F_+$  and  $F_-$  with  $\mathcal{N}$  super-symmetry and bosons  $B_{+-}$  with  $(\mathcal{N}, \mathcal{N})$  super-symmetry.  $B_{+-}$  would be anti-chiral with respect to  $\theta_+$  and chiral with respect to  $\theta_-$  and hermiticity condition can be considered as an additional condition with hermitian conjugation mapping  $\theta_+$  to  $\theta_-$ . The fundamental action would reduce to the integral over  $\theta_+$  and  $\theta_-$  and their conjugates in the product of  $\bar{F}_- B_{-+} F_+$ . Gauge symmetries are consistent with this guess if realized by regarding both  $B$  and  $F$  fields as chiral super-fields. Bosonic emergence would suggest that no kinetic term is needed for bosons.
2. One can consider also the possibility of Hermitian vector field  $V$  as local Clifford algebra element by using the same basic definition as used in super-symmetric quantum field theories. The c-number part of  $V$  could be interpreted in terms of the spinor connection of WCW: this part cannot be dynamical. It is not however clear whether the definition of corresponding chiral super-field is sensible in the infinite-dimensional context. Also one can ask whether this kind of field is needed at the fundamental level since bosons and their super-partners in TGD framework are identified as pairs of wormhole throats. Super-Kähler function  $K = K(\Phi^\dagger, \Phi)$  ( $K = K(\Phi^\dagger, \exp(-V)\Phi)$ ) would be a function of chiral super-field  $\Phi$ , its conjugate  $\Phi^\dagger$  (, and vector super-field  $V$ ). A profound generalization of the physics as geometry idea would be the outcome.

At QFT limit the super fields depend on the point of  $M^4$ . The dependence on the point  $h$  of  $M^4 \times CP_2$  makes sense also in WCW context since  $h$  can be interpreted as position of the either tip of  $CD$ . A given value of  $\Phi$  at given point  $h$  of  $H$  fixes the WCW coordinates characterizing the light-like 3-surface  $X_i^3$  inside  $CD$  with tip at  $h$ . Constant values of  $\Phi$  analogous to vacuum expectation of Higgs means that  $X_i^3$  is same for all  $CD$ s. The quantum field character of  $\Phi$  codes for the fact that one has actually quantum superposition of space-time surfaces. The functional integral around a given maximum of Kähler function replaces this superposition effectively with single space-time surface.

## 9.6 SUSY algebra at QFT limit

The first expectation is that QFT limit TGD corresponds to a situation in which space-time surfaces are representable as a graph for some map  $M^4 \rightarrow CP_2$ . This assumption is not actually needed in zero energy ontology since  $M^4$  labels the positions of either tip of  $CD$  rather than points of the space-time sheet. The position of the other tip of  $CD$  relative to the first one could be interpreted in terms of Robertson-Walker coordinates for quantum cosmology [65]. Second intuitively plausible idea is that particle space-time sheets are replaced with world-lines. Actually the replacement of partonic 2-surfaces with points is needed and even this assumption can be given up in one formulation

of QFT limit feeding information about partonic 2-surfaces to the theory. What is essential that only perturbations around single maximum of Kähler function are considered. If several maxima are important, one must include a weighting defined by the values of the exponent of Kähler function.

### 9.6.1 Minimum information about space-time sheet and particle quantum numbers needed to formulate SUSY algebra

The basic problem is how to feed just the essential information about quantum states and space-time surfaces to the definition of the QFT limit.

1. The information about quantum numbers of particles feeded to the measurement interaction must be feeded also to the QFT action. It is natural to start from the classical description of point like particles in  $H$  in terms of light-like curves of  $H$  reducing to light-like geodesic lines for free particles. Momentum and color charges serve as natural quantum numbers. The conserved color charges associated with  $CP_2$  geodesics need not correspond to the usual color charges since they correspond to center of mass rotational motion in  $CP_2$  degrees of freedom. Ordinary color charges correspond to the spinorial partial waves assignable to  $CP_2$  type extremals.
2. Should interpreted QFT limit as a QFT in  $X^4$  representable as a graph for a map  $M^4 \rightarrow CP_2$ , or in  $M^4$ , or perhaps in  $M^4 \times CP_2$ ? In zero energy ontology the proper interpretation is in terms of QFT in  $M^4$  labeling the tips of  $CD$ s so that no restrictions on space-time sheets need to be posed. Furthermore, by quantum classical correspondence the space-time sheet surrounding given wormhole throat depends on the four-momentum assigned so that Poincare invariant theory in  $M^4$  is the only logically consistent option. Minimal extension to  $M^4 \times CP_2$  is required in order to take into account the geodesic motion in  $CP_2$  degrees of freedom.
3. What information about space-time surface is needed?
  - (a) One can in principle feed all information about space-time sheet without losing Poincare invariance since momentum operators do not act on space-time coordinates. The description becomes however in-practical even if one restricts the consideration to the maxima of Kähler function.
  - (b) The minimal approach would use only cm degrees of freedom for the tip of the  $CD$  associated with the particle and feed minimum information about light-like 3-surface inside the  $CD$ .
  - (c) The information about partonic two-surfaces  $X^2$  defined as intersections of 3-D light-like wormhole throats with the boundary of  $CD$  characterizes elementary particles, and it would be natural to feed this information to the theory by replacing  $M^4$  gamma matrices with modified gamma matrices. This would feed in also the information about hyper-quaternionicity making possible to generalize the notion of twistor. This information would be coded by the partial derivatives of the imbedding space coordinates at  $X^2$ , and would be needed only at the partonic 2-surfaces  $X^2$  defining the generalized vertices.
  - (d) Some information about zero modes characterized by the induced Kähler form invariant under quantum fluctuations assignable to Hamiltonians of  $\delta M_{\pm}^4 \times CP_2$  at boundaries of  $CD$  is certainly needed: here the identification of Kähler potential as the Kähler function of WCW is highly attractive hypothesis.

### 9.6.2 The physical picture behind the realization of SUSY algebra at point like limit

The challenge is to deduce SUSY algebra in the approximation that partonic 2-surfaces are replaced by points. The basic physical constraint on the realization of the SUSY algebra come from the condition that one must be able to describe also massive particles as members of SUSY multiplets. This should make possible also twistorialization in terms of octonionic gamma matrices reducing to quaternionic ones using representation of octonion units in terms of the structure constants of the octonionic algebra. The general structure of modified Dirac action suggests how to proceed.  $p^k \gamma_k$  should be replaced with a simplified version of its 8-D variant in  $M^4 \times CP_2$  and the  $CP_2$  part of this operator should describe the massivation.

1. Since light-like 3-surfaces contract to light-like curves at point like limit and since only  $CP_2$  gamma matrices contribute to Chern-Simons Dirac action, it is natural to assume that the  $CP_2$  projection of the light-like curve describing the particle characterizes the situation. The interpretation of the curve is in terms of center of mass motion of the topologically condensed space-time sheet describing the particle. For particles which are massless in  $M^4$ , the  $CP_2$  projection must contract to a point. For massive particles the projection is a curve in  $CP_2$ .
2. The generalization of the Dirac operator appearing in commutation relations reads as

$$p^k \gamma_k \rightarrow D = p^k \gamma_k + Q \gamma_k \frac{ds^k}{ds} ,$$

$$s_{kl} \frac{ds^k}{dt} \frac{ds^l}{dt} = 1 . \quad (9.6.1)$$

Mass shell condition fixes the value of  $Q$

$$Q = \pm m . \quad (9.6.2)$$

For geodesic circle the angle coordinate to be angle parameterizing the geodesic circle is the natural variable and the gamma matrices can be taken to be just single constant gamma matrix along the geodesic circle.

3. Imbedding space spinors have anomalous color charge equal to -1 unit for lepton and 1/3 units for quarks. Mass shell condition is satisfied if  $Q$  is proportional to anomalous hyper-charge and mass of the particle in turn determined by p-adic thermodynamics.
4. The geometric interpretation would be that in topological condensation the color rotational degrees of freedom of the particle are reduced. If the light-like 3-surfaces contains the geodesic the geodesic circle  $S^1$ , color rotational degrees of freedom are not lost completely and color hyper-charge remains a good quantum number in these degrees of freedom. It is however important to notice that anomalous color hypercharge has nothing to do with ordinary color quantum numbers.
5. Particle mass  $m$  should relate closely to the frequencies characterizing general extremals. Quite generally, one can write in cylindrical coordinates the general expressions of  $CP_2$  angle variables  $\Psi$  and  $\Phi$  as  $(\Psi, \Phi) = (\omega_1 t + k_1 z + n_1 \phi \dots, \omega_2 t + k_2 z + n_2 \phi \dots)$ . Here ... denotes Fourier expansion [2] , [2] : this corresponds to Cartan algebra of Poincare group with energy, one momentum component and angular momentum defining the quantum numbers. One can say that the frequencies define a warping of  $M^4$  for  $(\Psi, \Phi) = (\omega_1 t, \omega_2 t)$ . The frequencies characterizing the warping of the canonically imbedded  $M^4$  should closely relate to the mass of the particle. This raises the question whether the replacement of  $S^1$  with  $S^1 \times S^1$  is appropriate.
6. Twistor description is also required. Generalization of ordinary twistors to octotwistor with quaternionicity condition as constraint allows to describe massive particles using almost-twistors. For massive particle the unit octonion corresponding to momentum in rest frame, the octonion defined by the polarization vector  $\epsilon_k \gamma_k$ , and the tangent vector  $\gamma_k ds^k / ds$  (analog of polarization vector in  $CP_2$ ) generate quaternionic sub-algebra. For massless particle momentum and polarization generate quaternion sub-algebra as  $M^4$  tangent space.

The SUSY algebra at QFT limit differs from the SUSY algebra defining the fundamental anti-commutators of the fermionic oscillator operators for the induced spinor fields since the modified gamma matrices defined by the Kähler action are replaced with ordinary gamma matrices. This is quite a dramatic difference and raises two questions. The first question "Why not replace the anti-commutation relations with those for the actual fermionic oscillator algebra?" has been already answered.

One can also wonder why not to replace Kähler action with the action defined by the 4-D volume in the induced metric? After all, apart from almost vacuum extremals 4-volume action has almost the same basic extremals ( $CP_2$  type extremals, restricted subset of massless extremals, string like objects). The modified gamma matrices for volume action are just induced gamma matrices reducing to  $M^4$  gamma matrices for canonically imbedded  $M^4$  so that the proposed form of the super-algebra in this framework can be seen as a well-motivated approximation. Also super-symmetry breaking induced by the mixing of  $M^4$  chiralities is expected to occur. There are however arguments in favor Kähler action.

1. Four-volume option has obvious shortcomings. Only very small space-time sheets are possible since vacuum functional decreases exponentially as a function of four-volume so that the Planck constant allowing space-time sheet with a given four-volume would scale like 1/four-volume. As a matter fact, also for Kähler action large value of Planck constant is required and this explains why string like objects correspond to a macroscopic quantum phase. Classical gauge fields would be completely absent from the space-time dynamics. The notion of effective 3-dimensionality would make no sense and the slicings by light-like 3-surfaces are not restricted to a finite volume surrounding the wormhole throat at QFT limit. Hence the value of  $\mathcal{N}$  is expected to be infinite and one can hope of obtaining the SUSY QFT limit with a finite value of  $\mathcal{N}$  only as an approximation.
2. For  $CP_2$  type extremals and string like objects the two actions are expected to give rise to a rather similar theory. Canonically imbedded  $M^4$  and its small deformations are an exception. The good news is that for the small deformations of  $M^4$  one can expect finite value of  $\mathcal{N}$  as an exact result rather than approximation.
3. The information about the zero modes - including vacuum degeneracy - is actually not lost as one replaces modified gamma matrices with the ordinary ones in anti-commutations since the Kähler potential defining the action principle (assuming bosonic emergence) carries information about zero modes. The Kähler potential carries also information about quantum fluctuating degrees of freedom coded by the super-potential at the maximum of Kähler function (with measurement interaction controllable by the experimenter included and affecting only the super-potential and thus the maximum of Kähler function but not WCW metric).
4. The quantum criticality of the Kähler action distinguishes Kähler action from four-volume. It predicts inclusion hierarchies of super-conformal algebras assignable to the zero modes. In each breaking of the super-conformal symmetry the rank of the WCW Kähler metric is reduced as quantum fluctuating degrees of freedom are transformed to zero modes. Some components of the inverse of the Kähler metric appearing in the Kähler potential diverge as a consequence and the corresponding complex coordinates of WCW transform to zero modes. This picture conforms with the view about SUSY breaking as a reduction of the rank of the Kähler metric defined by Kähler potential.

### 9.6.3 Explicit form of the SUSY algebra at QFT limit

The explicit form of the SUSY algebra follows from the proposed picture.

1. Spinor modes at  $X^2$  correspond to the generators of the algebra. Effective 2-D property implies that spinor modes at partonic 2-surface can be assumed to have well-defined weak isospin and spin and be proportional to constant spinors.
2. The anti-commutators of oscillator operators define SUSY algebra. In leptonic sector one has

$$\begin{aligned} \{a_{m\dot{\alpha}}^\dagger, a_\beta^n\} &= \delta_m^n D_{\dot{\alpha}\beta} \ , \\ D &= (p^k \sigma_k + Q^a \sigma_a) \ . \end{aligned} \tag{9.6.3}$$

$Q^a$  denote color charges. The notions are same as in the case of WCW Clifford algebra. In quark sector one has opposite chirality and  $\sigma$  is replaced with  $\hat{\sigma}$ . Both the ordinary and octonionic representations of sigma matrices are possible.

### 9.6.4 How the representations of SUSY in TGD differ from the standard representations?

The minimal super-sub-algebra generated by right-handed neutrino and antineutrino are the most interesting at low energies, and it is interesting to compare the naturally emerging representations of SUSY to the standard representations appearing in super-symmetric YM theories.

The basic new element is that it is possible to have short representations of SUSY algebra for massive states since particles are massless in 8-D sense. The mechanism causing the massivation remains open and p-adic thermodynamics can be responsible for it. Higgs mechanism could however induce small corrections to the masses.

The SUSY representations of SYM theories are constructed from  $J = 0$  ground state (chiral multiplet for  $\mathcal{N} = 1$  hyper-multiplet for  $\mathcal{N} = 2$ : more logical naming convention would be just scalar multiplet) and  $J = 1/2$  ground state for vector multiplet in both cases.  $\mathcal{N} = 2$  multiplet decomposes to vector and chiral multiplets of  $\mathcal{N} = 1$  SUSY. Hyper-multiplet decomposes into two chiral multiplets which are hermitian conjugates of each other. The group of R-symmetries is  $SU(2)_R \times U(1)_R$ . In TGD framework the situation is different for two reasons.

1. The counterparts of ordinary fermions are constructed from  $J = 1/2$  ground state with standard electro-weak quantum numbers associated with wormhole throat rather than  $J = 0$  ground state.
2. The counterparts of ordinary bosons are constructed from  $J = 0$  and  $J = 1$  ground states assigned to wormhole contacts with the electroweak quantum numbers of Higgs and electroweak gauge bosons. If one poses no restrictions on bound states, the value of  $\mathcal{N}$  is effectively doubled from that for representation associated with single wormhole throat.

These differences are allowed by general SUSY symmetry which allow the ground state to have arbitrary quantum numbers. Standard SYM theories however correspond to different representations so that the formalism used does not apply as such.

Consider first the states associated with single wormhole throat. The addition of righthanded neutrinos and their antineutrinos to a state with the constraint that  $p^k \gamma^k$  annihilates the state at partonic 2-surface  $X^2$  would mean that the helicities of the two super-symmetry generators are opposite. In this respect the situation is same as in the case of ordinary SUSY.

1. If one starts from  $J = 0$  ground state, which could correspond to a bosonic state generated by configuration space Hamiltonian and carrying  $SO(2) \times SU(3)_c$  quantum numbers one obtains the counterparts of chiral/hyper- multiplets. These states have however vanishing electro-weak quantum numbers and do not couple to ordinary quarks neither.
2. If one starts  $J = 1/2$  ground state one obtains the analog of the vector multiplet as in SYM but but belonging to a fundamental representation of rotation group and weak isospin group rather than to adjoint representation. For  $\mathcal{N} = 1$  one obtains the analog of vector chiral multiplet but containing spins  $J = 1/2$  and  $J = 1$ . For  $\mathcal{N} = 2$  one obtains two chiral multiplets with  $(J, F, R) = (1, 2, 1)$  and  $(J, F, R) = (1/2, 1, 0)$  and  $(J, F, R) = (0, 0, -1)$  and  $(-1/2, 1, 0) = (0, 0, 0)$ .
3. It is possible to have standard SUSY multiplet if one assumes that the added neutrino has always fermionic number opposite that the fermion in question. In this case one obtains  $\mathcal{N} = 1$  scalar multiplet. This option could be defended by stability arguments and by the fact that it does not put right-handed neutrino itself to a special role.

For the states associates with wormhole contact zero energy ontology allows to consider two non-equivalent options. The following argument supports the view that gauge bosons are obtained as wormhole throats only if the throats correspond to different signs of energy.

1. For the first option the both throats correspond to positive energies so that spin 1 bosons are obtained only if the fermion and antifermion associated with throats have opposite  $M^4$  chirality in the case that they are massless (this is important!). This looks somewhat strange but reflects the fact that  $J = 1$  states constructed from fermion and antifermion with same chirality and parallel 4-momenta have longitudinal polarization. If the ground state has longitudinal polarization the spin of the state is due to right-handed neutrinos alone: in this case however spin 1 states would have fermion number 2 and -2.

2. If the throats correspond to positive and negative energies the momenta are related by time reflection and physical polarizations for the negative energy antifermion correspond to non-physical polarizations of positive energy antifermion. In this case physical polarizations are obtained.

If one assumes that the signs of the energy are opposite for the wormhole throats, the following picture emerges.

1. If fermion and antifermion correspond to  $\mathcal{N} = 2$ -dimensional representation of super-symmetry, one expects  $2\mathcal{N} = 4$  gauge boson states obtained as a tensor product of two hyper-multiplets if bound states with all possible quantum number combinations are possible. Taking seriously the idea that only the bound states of fermion and antifermion are possible, one is led to consider the idea that the wormhole throats carry representations of  $\mathcal{N} = 1$  super-symmetry generated by  $M^4$  Weyl spinors with opposite chiralities at the two wormhole throats (right-handed neutrino and its antineutrino). This would give rise to a vector representation and eliminate a large number of exotic quantum number combinations such as the states with fermion number equal to two and also spin two states. This idea makes sense also for a general value of  $\mathcal{N}$ . Bosonic representation could be also seen as the analog of short representation for  $\mathcal{N} = 2N$  super-algebra reducing to a long representation  $\mathcal{N} = N$ . Short representations occur quite generally for the massive representations of SUSY and super-conformal algebras when  $2^r$  generators annihilate the states [23].

Note that in TGD framework the fermionic states of vector and hyper multiplets related by  $U(2)_R$   $R$ -symmetry differ by a  $\nu_R \bar{\nu}_R$  pair whose members are located at the opposite throats of the wormhole contact.

2. If no restrictions on the quantum numbers of the boson like representation are posed, zero energy ontology allows to consider also an alternative interpretation.  $\mathcal{N} = 4$  (or more generally,  $\mathcal{N} = 2N$ -) super-algebra could be interpreted as a direct sum of positive and negative energy super-algebras assigned to the opposite wormhole throats. Boson like multiplets could be interpreted as a long representation of the full algebra and fermionic representations as short representations with states annihilated either by the positive or negative energy part of the super-algebra. The central charges  $Z_{ij}$  must vanish in order to have a trivial representations with  $p^k = 0$ . This is expected since the representations are massless in the generalized sense.
3. Standard  $\mathcal{N} = 2$  multiplets are obtained if one assume that right-handed neutrino has always opposite fermion number than the fermion at the throat. The arguments in favor of this option have been already given.

## 9.7 Super-symmetric QFT limit of TGD

The definition of the SUSY QFT limit of TGD involves several challenges. A generalization of the super-space concept is needed to cope with  $\mathcal{N} > 1$  symmetry and the notions of chiral and vector super-fields must be defined precisely. The previous findings about the super-multiplets assignable to fermions and bosons suggest that standard formalism does not generalize as such. Accordingly, two lines of approach are studied in this section. The first one relies on the generalization of the standard definitions chiral and vector super-fields applied in TGD framework, and works in practice only for  $\mathcal{N} = (1, 0)$  and  $\mathcal{N} = (0, 1)$  in fermionic sector and  $\mathcal{N} = (1, 1)$  in bosonic sector (notation is motivated by zero energy ontology). Second approach relies on a new view about super fields forced by the condition that the formalism makes sense for  $\mathcal{N} = \infty$ .

### 9.7.1 Basic concepts and ideas

A brief overview about basic concepts and ideas to be discussed in this section is in order before going to the details.

#### The notion of super-space

1. Majorana spinors do not make sense in TGD framework but the use of Weyl spinors as spinors with definite H-chirality is possible. It is possible to use spinor of fixed chirality only since

leptons and charge conjugates of quarks can be regarded as having same H-chirality. By hyper-quaternionicity the octonionic gamma matrices allow a matrix representation in terms of octonionic structure constants so that also octonionic formulation makes sense. The pair  $\{a_m^\dagger, a_m\}$  of oscillator operators corresponds to the pair  $(\bar{\theta}_{m\dot{\alpha}}, \theta_m^\alpha)$ .

2. A non-trivial question relates to the identification of the super-space. The first candidate is  $M^{1,\mathcal{N}}$ ,  $M = M^4 \times S^1$ ,  $S^1$  a geodesic circle of  $CP_2$ . Since the gamma matrices of  $S^1$  must be expressed in terms of  $H$  gamma matrices one can however argue that effectively super-space corresponds induced from  $M^{1,\mathcal{N}}$ ,  $M = H$ . This and the condition of hyper-quaternionicity suggest the notion of induced super-symmetry suggests itself meaning that  $D = 4$  holds true effectively. The value of  $\mathcal{N}$  would be naturally  $\mathcal{N} = 2$  for fermions and  $\mathcal{N} = 4$  for bosons if one restricts the consideration to right-handed neutrino and antineutrino modes since  $CP_2$  spinor indices are effectively frozen in this case. If the numbers of quark and lepton like modes are different, one has  $\mathcal{N} = (\mathcal{N}_1, \mathcal{N}_2)$  super-symmetry, and the axial anomaly with respect to H-chirality is possible. The different couplings of lepton and quark fields to Kähler gauge potential should take care of the anomaly.

### Super-covariant derivatives

Consider next the definition of super-covariant derivatives.

1. The dotted and un-dotted indices  $D_{m,\alpha}$  *resp.*  $D_{m,\dot{\alpha}}$  label the spin and weak isospin indices of quark *resp.* lepton like spinors. The indices  $m$  label the spinor modes associated with quarks and leptons for the space-time sheet whose zero modes are coded by the induced  $CP_2$  Kähler form  $J_{\alpha\beta}$ . Also now leptons and antiquarks can be regarded as two induces spinor field with with same chirality so that one has  $\mathcal{N} = 2N$  super-symmetry.
2. Super-covariant derivatives can be defined by modifying the usual definitions in rather obvious manner.

$$D_{m,\alpha} = \frac{\partial}{\partial \theta_m^\alpha} - iQ_{\alpha\dot{\alpha}} \bar{\theta}_m^{\dot{\alpha}}, \quad \bar{D}_{m\dot{\alpha}} = -\frac{\partial}{\partial \bar{\theta}_m^{\dot{\alpha}}} + i\theta_m^\alpha Q_{\alpha\dot{\alpha}}, \quad Q = \sigma^A(p_A + Q_A). \quad (9.7.1)$$

3. The anti-commutations for given a H-chirality can be written as

$$\begin{aligned} \{D_{m\alpha}, D_{n\beta}\} &= 0, & \{\bar{D}_{m\dot{\alpha}}, \bar{D}_{n\dot{\beta}}\} &= 0, \\ \{D_{m\alpha}, \bar{D}_{n\dot{\beta}}\} &= \delta_m^n D_{\alpha\dot{\beta}}. \end{aligned} \quad (9.7.2)$$

### Identification of the super-fields: conventional approach

Also now super-field can be defined in terms of the Taylor expansion with respect to theta parameters. Chiral super-fields satisfy the usual conditions given by

$$D_{m\alpha} \Phi = 0, \quad \bar{D}_{m\dot{\alpha}} \Phi = 0. \quad (9.7.3)$$

The differences from standard SUSY are due to the fact that fermions have ground state which is not scalar but  $J = 1/2$  particle whereas bosons correspond to  $J = 1$  ground states and wormhole throats so that  $\mathcal{N}_B = 2\mathcal{N}_F$  holds true. This means that  $J = 0$  chiral field must be replaced with spin  $J = 1/2$  and  $\mathcal{N} = 2$  chiral superfield in the case of fermions and spin  $1/2$  vector field must be replaced with spin  $J = 1$   $\mathcal{N}_B = 4$  analog of vector super-field unless one poses additional conditions of the allowed bound states to reduce  $\mathcal{N}_B$  to  $\mathcal{N}_B = 2$ .

As found, the assumption that right handed neutrino has fermion number opposite to the fermion state assigned to the throat reduces the fermionic super-symmetry to  $\mathcal{N} = 1$  and bosonic super-symmetry to  $\mathcal{N} = 2$  and fermionic states can be regarded as short representations of  $\mathcal{N} = 2$  super-symmetry natural in zero energy ontology. With these assumptions standard formalism works as such.

1. The chiral super-field can be written as

$$\Phi = \Phi(\theta_m, H^k) , \quad H^k = h^k + i\bar{\theta}_m \bar{Q} \theta^m , \quad h^k \equiv (m^k, \phi) . \quad (9.7.4)$$

Here the sum is over both lepton and antiquark plus modes mode the induced spinor field.

2. Vector super-fields describe gauge bosons and their super-counterparts.  $V = V^\dagger$  is satisfied. The definition of vector super field is as usual. One starts from super field  $V$  and defines super gauge transformations as transformations  $V \rightarrow V + \Lambda + \Lambda^\dagger$ , where  $\Lambda$  is chiral spinor super-field.

$$W_{m\alpha} = X D_{m,\alpha} V , \quad \bar{W}_{m\alpha} = \bar{X} \bar{D}_{m,\alpha} V , \quad X = -\frac{1}{2^{\mathcal{N}}} \prod_{m,\alpha} \bar{D}_{m\alpha} . \quad (9.7.5)$$

defines a gauge invariant quantity analogous to gauge field. Chiral super-fields transform as  $\Phi \rightarrow \exp(\Lambda)\Phi$ ,  $\Phi^\dagger \rightarrow \Phi^\dagger \exp(\Lambda^\dagger)$ .

The quantity

$$L = \Phi^\dagger \exp(-V)\Phi . \quad (9.7.6)$$

is gauge invariant and defines a generalization of Dirac Lagrangian. This action can be regarded as a particular Kähler potential.

3. For ordinary SUSYs Kähler potential can be very general real function of super-fields and the space of super-fields defines Kähler manifold. Also super-potential which is sum of holomorphic function of chiral super-fields and its conjugate is possible and corresponds to the addition of real part of complex function to Kähler potential is possible. These terms are make possible breaking of super-symmetry by a generation of vacuum expectation values of some scalar fields.

**Identification of the super-fields: the approach inspired by  $\mathcal{N} = \infty$  case**

The standard approach does not work at all for  $\mathcal{N} = \infty$  and becomes highly questionable also for the values of  $\mathcal{N}$ , which are large. Zero energy ontology and the identification of fermions as wormhole throats and bosons as wormhole contacts inspires a new manner to see super fields. Positive energy chiral fields correspond to analytic functions of  $\theta$  alone with no dependence on  $\bar{\theta}$ . Negative energy chiral field is obtained as hermitian conjugate of this field. Hermitian conjugation maps  $\theta$  to  $\partial_\theta D$  in positive energy chiral super field and the resulting operator acts on the product  $X$  of all theta parameters. Note that the presence of  $D$  is essential for obtaining the generalization of Dirac action. Note that in this approach there is no need to introduce super-derivatives and  $\theta$ s and  $\partial_\theta D$ s define the representation of the space-time super-symmetry algebra. Super vector fields are defined as hermitian operators of form  $V_k = V_k(\theta, \partial_\theta)$  acting on chiral super-fields, and the generalization of chiral action with coupling to super vector fields is obtained by the minimal substitution  $D \rightarrow D + V$ .

**SUSY breaking**

The general vision about breaking of super-symmetry would be following.

1. The effective dimension of space-time as it appears in the anticommutators of super-generators in  $D = 5$ . Since the number of components of 5-D Weyl spinors is 4, the number  $\kappa$  of supergenerators is given by  $\kappa = 4\mathcal{N}$ .

2. One obtains a hierarchy of SUSY breakings. It is possible to decompose the full SUSY action to a sum of actions with a smaller value of  $\mathcal{N}$  by integrating over theta parameters associated with the higher modes of the induced spinor field. It is also possible to take into account only finite number of spinor modes. The presence of higher modes poses strong constraints on the coupling parameters of the SUSY action.
3. Taking into account only right-handed neutrino and its antineutrino, the number of real supercharges is  $\kappa = 8$  so that if  $D = 5$  is the effective space-time dimension  $\mathcal{N} = (1, 1)$  SUSY is obtained at the lowest level in good approximation due to the electro-weak inertness of right-handed neutrinos.

### 9.7.2 About super-field formalism in $\mathcal{N} = 2$ case

For SUSY limit of quantum TGD assuming that only right-handed neutrinos and antineutrinos appear as generators of super-symmetries and that the added righthanded neutrino has fermion number opposite that that of the fermion of the throat corresponds to  $\mathcal{N} = 2$  for gauge bosons and Higgs and to  $\mathcal{N} = 1$  equivalently  $\mathcal{N} = 2$  short representation for fermions. For this option super-field formalism guarantees also the conservation of fermion numbers automatically. With these assumptions it is of considerable interest to summarize the basic facts of  $\mathcal{N} = 2$  super-fields.

1.  $\mathcal{N} = 2$  super-multiplets are known as vector multiplet assigned to gauge bosons and their partners and hyper multiplet assigned with matter. Vector multiplet contains two Weyl fermions and vector boson and scalar in adjoint representations. The two fermionic states transform non-trivially under the R-symmetry group  $SU(2)_R \times U(1)_R$ . Vector multiplet decomposes under  $\mathcal{N} = 1$  supersymmetry to vector multiplet and chiral multiplet. Hyper-multiplet consists of two Weyl fermion and complex bosons and  $SU_R$  mixes the two fermions. Two  $\mathcal{N} = 1$  multiplets are in question.
2. A pedagogical representation for the generalization of  $\mathcal{N} = 1$  SYM action to  $\mathcal{N} = 2$  case can be found in the article of Adel Bilal [22] . This action includes only  $\mathcal{N} = 2$  super partners of gauge boson which are all in the adjoint representation of the gauge group.  $\mathcal{N} = 2$  vector multiplet decomposes to  $\mathcal{N} = 1$  vector multiplet and chiral multiplet and the  $\mathcal{N} = 1$  reduction of the action gives sum of  $\mathcal{N} = 1$  YM action and Kähler potential.  $\mathcal{N} = 2$  symmetry allows no super-potential for vector multiplet. The super YM action is determined by a holomorphic function known as pre-potential fixed completely by renormalizability to be quadratic function of  $\mathcal{N} = 2$  vector super-field  $\Psi$ .
3. The Lagrangian of  $\mathcal{N} = 2$  SUSY YM theory reduced to  $\mathcal{N} = 1$  notation reads as

$$L = \frac{1}{4\pi} \text{Im} \left[ \int d^4\theta \frac{\partial \mathcal{F}(A)}{\partial A} + \int d^2\theta \frac{1}{2} \frac{\partial^2 \mathcal{F}(A)}{\partial A^2} W_\alpha W^\alpha \right] . \quad (9.7.7)$$

$A$  denotes  $\mathcal{N} = 1$  chiral multiplet in  $\mathcal{N} = 2$  vector multiplet whose scalar component is denoted by  $a$ .

4.  $\mathcal{N} = 2$  supersymmetry implies that the Kähler potential and Kähler metric associated with the vector multiplet can be written in terms of single holomorphic function  $\mathcal{F}(A)$  known as prepotential as

$$\begin{aligned} K &= \text{Im} \left( \frac{\partial \mathcal{F}(A)}{\partial A} \bar{A} \right) , \\ ds^2 &= \text{Im} \left( \frac{\partial^2 \mathcal{F}(A)}{\partial^2 a^2} \right) da d\bar{a} . \end{aligned} \quad (9.7.8)$$

5. In the classical theory tree level Lagrangian allows to deduce  $\mathcal{F}(A)$  as

$$\mathcal{F}(A) = \frac{1}{2} \times \tau_{cl} A^2, \quad \tau_{cl} = \frac{\theta}{2\pi\hbar} + i \frac{4\pi}{g^2}. \quad (9.7.9)$$

Here  $\tau$  unifies gauge coupling strength and  $\theta$  parameter associated with the instanton term to single complex parameter and the holomorphy of  $\mathcal{F}(a)$  poses very powerful constraints on the theory.

The expression of the scalar potential associated with vector multiplet reads as

$$V(\phi) = \frac{1}{g^2} \text{Tr}(\phi, \phi^\dagger)^2. \quad (9.7.10)$$

Scalar potential vanishes in the sub-space defined by the Cartan algebra of gauge group so that scalar potential has  $r$ -dimensional sub-manifold of vanishing extrema, where  $r$  is the rank of the Cartan sub-algebra. Radiative corrections affect  $V$  so that the vacuum degeneracy disappears. Note that vacuum degeneracy is analogous to the vacuum degeneracy of Kähler action in TGD.

There are very strong constraints on the moduli space defined by scalars [9].

1. For  $D = 4$  and  $\mathcal{N} = 2$  the moduli space associated with the vector multiplet (so called Coulomb branch) contains one complex scalar defining so calling special Kähler manifold [67]. The moduli space associated with hyper-multiplet (so called Higgs branch) contains two scalars and is Hyper-Kähler manifold [20]. For  $\mathcal{N} > 2$  the moduli spaces are symmetric spaces. The article of Antoine van Proyen discusses vector multiplets in  $\mathcal{N} = 2$  supersymmetry and associated moduli spaces for the scalar fields appearing in the theory and fixed to a high degree by super-symmetry.
2. This picture conforms with the view that WCW is infinite-dimensional symmetric space with Hyper-Kähler structure and corresponds to the moduli space of hypermultiplet.

In TGD framework vector multiplets are associated with wormhole contacts. They do not represent fundamental degrees of freedom and describe at QFT limit phenomenologically bound states since it is the total momentum and color charge which appear in the modified Dirac equation in regions surrounding both wormhole throats. With above described assumptions about super-symmetry the bosonic multiplets are  $\mathcal{N} = 2$  multiplets whereas fermionic ones are short variants of them. Zero energy ontology plays an essential role.

### 9.7.3 Electric magnetic duality, monopole condensation and confinement from TGD point view

$\mathcal{N} = 2$  SYM theory was studied by Seiberg and Witten in their seminal paper *Electric-magnetic duality, monopole condensation, and confinement in  $\mathcal{N} = 2$  super-symmetric Yang-Mills theory* [65] and it is interesting to try to see the results of Seiberg and Witten from TGD point of view. Electric magnetic duality conjecture of Olive and Montonen was inspired by the observation about the upper bound form the masses of dyons deduced by Prasad and Somerfield and Bogomol'nyi (BPS) and reading as

$$M \geq \sqrt{|Z|}, \quad Z = v(n_e + i \frac{n_m}{\alpha}). \quad (9.7.11)$$

Here  $v$  denotes Higgs expectation value,  $\alpha = g^2/4\pi\hbar$  is gauge coupling strength, and  $n_e$  and  $n_m$  characterize the electric and magnetic charges of the dyon. States for which equality holds true in above formula are called BPS saturated and they correspond to massive representation of SUSY with the same number of states as appearing in massless representations. The observation inspiring the

duality conjecture was that the formula is symmetric under  $n_e \leftrightarrow n_m$ ,  $v \leftrightarrow v/\alpha$ , and  $\alpha \leftrightarrow 1/\alpha$ . Electric magnetic duality implies that the strong coupling phase for ordinary particles can be understood as a weak coupling phase for monopoles.

Witten demonstrated that in the original sense this duality can hold true for  $\mathcal{N} = 4$  theories since only in this case the electrons and monopoles have same quantum number spectrum but in the case of  $\mathcal{N} = 2$  theories it can hold true at the low energy Abelian limit of the theory and between particle and special class of dyons with vanishing electric charges (neutral magnetic monopoles). The duality of Montonen and Olive actually generalizes in the sense that all transformation of the group  $SL(2, Z)$  acting on the complex coupling strength

$$\tau = i \frac{4\pi\hbar}{g^2} + \frac{\theta}{2\pi}$$

transform different phases of the theory to each other. These transformations also transform dyons with charges  $(n_m, n_e)$  to each other.

An interesting question is whether electric magnetic duality and color confinement based on the condensate of magnetic monopoles could have counterparts in TGD framework.

1. The counterpart for the electric phase corresponds to wormhole throats surrounded by a slicing by light-like 3-surfaces with boundary so that momentum and color charges can be assigned to single wormhole throat and  $\mathcal{N}$  for the entire super-algebra is finite.
2. Also the counterpart of the magnetic phase exists. Topological magnetic monopoles make sense in TGD framework since the topology of  $CP_2$  allows wormhole throats carrying homological magnetic charges. Monopole phase could exist in the sense that the outer boundary of the space-time sheet carries the neutralizing magnetic charge or that the wormhole throats feed the magnetic fluxes to large space-time sheets. Also the deformations of string like objects  $X^2 \times Y^2 \subset M^4 \times CP_2$  carry naturally magnetic fluxes along them and could feed them to larger space-time sheets through magnetically charged wormhole throats defining bosonic super-multiplet. Also fermions with opposite magnetic charges can topologically condense at string like object and effectively serve as its ends. The same momentum and color charge would be associated with all wormhole throats associated with a given string like object having an interpretation as hadron-like object so that a color confined perturbative phase would be in question. The value of  $\mathcal{N}$  for the entire super-algebra is infinite for string like objects and the description in terms of super-conformal algebra seems to be more appropriate than QFT description. In this sense one would have genuinely non-perturbative phase.
3. As Witten shows, in  $\mathcal{N} = 2$  theory electric magnetic duality of Montonen and Olive fails in  $\mathcal{N} = 2$  SUSY because the number of states for electron multiplet is 4 and contains spin 1 state whereas monopole states have  $J \leq 1/2$ . In TGD framework the reduction of  $\mathcal{N} = 2$  symmetry to  $\mathcal{N} = 1$  symmetry for massless fermions changes the situation so that a natural conjecture is that electric magnetic duality actually holds true in TGD framework. If the conjecture is really true, it could be seen as a support for zero energy ontology as also for the identification of fermions as wormhole throats and bosons as wormhole contacts.
4. The mapping of the coupling constant to its inverse cannot apply to the Kähler coupling strength fixed by the quantum criticality but makes sense for the color coupling strength. If one accepts holography, then light-like 3-surfaces are fundamental objects and whether one can regard them as magnetic monopoles or not, depends on the space-time sheets assigned to them. This assignment could change in a phase transition transforming the space-time sheets surrounding the wormhole throats so that particles would transform to monopole like entities. More generally, the basic objects would be dyons and the phase transitions would be characterized by  $Sl(2, Z)$ .
5. One can of course, ask whether the inverse of Kähler coupling strength, which is analogous to the inverse of critical temperature and with CP breaking theta angle added to it as an imaginary part, could have a discrete spectrum of values identifiable as the orbit of  $Sl(2, Z)$ .

### 9.7.4 Interpretation of Kähler potential and super-potential terms in TGD framework

TGD suggests the interpretation of Kähler potential and superpotential in terms of WCW geometry.

1. The Kähler potential could be interpreted in terms of WCW Kähler function. If  $K$  is quadratic in chiral super-field only the dependence on zero modes is possible. This is what is required since integration over quantum fluctuating degrees of freedom is carried out at QFT limit. Maximum of configuration space Kähler function defines Kähler potential. Spinor modes more or less in 1-1 correspondence with coordinates of WCW. Could Kähler potential define the Kähler potential of WCW which would thus make itself directly visible at space-time level.
2. Super-potential term could be interpreted as counterpart for the addition of a real part of holomorphic function to Kähler function. This part would not affect WCW metric but would characterize different measurement interactions. Separate conservation of lepton and quark numbers require that super-potential is sum over lepton and quark contributions. R-parity conservation allows only quadratic super-potential. By quantum criticality the moduli space for the super-potential could correspond to the modifications of Kähler function not affecting Kähler metric but affecting the maximum of Kähler function and thus space-time sheet. This would be counterpart for the non-renormalization theorems of super-potential in SUSYs.

### 9.7.5 Generalization of bosonic emergence

Generalization of the bosonic emergence. The propagators for wormhole contacts carrying manyfermion states at wormhole throats are induced by propagators assignable to single throats as radiative corrections. Dirac action is replaced with  $K = \Phi^\dagger \exp(V) \Phi$ , where  $\Phi$  is chiral super field.

Different measurement interactions correspond to different super-potentials.

By previous arguments bosonic emergence would mean that the super-variant of the configuration space Kähler function defines the super-symmetric action principle at QFT limit so that one can say that the geometrization of quantum physics takes place in a very concrete sense also at QFT limit. This would be quite an elegant physical manifestation of the underlying infinite-dimensional geometry.

### 9.7.6 Is $\mathcal{N} > 8$ super-symmetry internally consistent?

The standard wisdom says that  $\mathcal{N} = 8$  is absolute upper bound for the super-symmetry (spins larger than 2 are not regarded as physical). In TGD  $\mathcal{N} = 8$  emerges naturally for space-time surfaces due to the dimension  $D = 8$  of imbedding space and the fact that imbedding space spinors with a given H-chirality (quarks and leptons which color appearing as partial waves in  $CP_2$  have 8 complex components. One obtains  $\mathcal{N} = 8$  without restrictions if one considers only the super-algebra defined by the oscillator operators associated with the lowest modes of these spinor fields at light-like 3-surfaces obtained as a solutions of the modified Dirac equation with measurement interaction term.

It is also possible to consider the super-symmetry generated by all modes of the induced spinor fields and thus with a quite large (even infinite for string like objects) number  $\mathcal{N}$  of super generators. This super-symmetry is broken as all super-symmetries in TGD framework. This means that rather high spins are present in the analogs of scalar and vector multiplets and the Kähler potential (expected to be closely related to the Kähler function of the world of the classical worlds (WCW)) describing interaction of chiral multiplet with a vector multiplet can be constructed also for any value of  $\mathcal{N}$  - at least formally. If one believes on the generalization of the bosonic emergence, one expects that bosonic part of the action is generated radiatively as one functionally integrates over the fields appearing in the chiral multiplet.

The standard wisdom says that it is not possible to construct interactions for higher spin fields. Is this really true? Why wouldn't the analogs of scalar (chiral/hyper) and vector multiplets make sense for higher values of  $\mathcal{N}$ ? Why would it be impossible to define a spin 1/2 chiral super-field associated with the vector multiplet and therefore the super-symmetric analog of YM action using standard formulas? Why the standard coupling to chiral multiplet would not make sense?

One objection against higher spins is of course the lack of the geometric interpretation. Spin 1 and Spin 2 fields allow it. Can one then imagine any geometric interpretation for higher spin components of super-fields? John Baez and others [37] are busily developing non-Abelian generalizations of group

theory, categories and geometry and speak about things that they call n-groups, n-categories, and n-geometries. Could the generalization of ordinary geometry to n-geometry in which parallel translations are performed for higher dimensional objects rather than points provide a natural interpretation for gauge fields assigned to higher spins? One would have natural hierarchy. Parallel translations of points would give rise curves, parallel translations of curves would give rise to surfaces, and so on. As as a special case the entire hierarchy of these parallel translations would be induced by ordinary parallel translation.

### 9.7.7 Super-fields in TGD framework

In the case of infinite-dimensional super-space the definition of the super-fields is not quite straightforward since the super-space integrals of finite polynomials of theta parameters always vanish so that the construction of super-symmetric action as an integral over super-space would give a trivial result. For chiral fields the integrals are formally non-vanishing but in the case that the super-field reduces to a finite polynomial of theta at  $y^\mu = 0$  the non-vanishing terms in real Lagrangian involve the action of an infinite number of operators  $\bar{D}_\alpha$  implying the proportionality to an infinite power of momentum which vanishes for massless states. It seems that one should be able to add in a natural manner terms which are obtained as theta derivatives of the product of all theta parameters and that the action should consist of the products of the terms associated with monomials of theta and monomials of derivatives with respect to theta parameters acting on the infinite product of theta parameters, call it  $X$ .

The fact that positive *resp.* negative energy vacuum is analogous to Dirac sea with negative *resp.* positive energy states filled suggests a remedy to the situation. This would mean that positive energy chiral field is just like its ordinary counterpart whereas negative energy chiral fields would be obtained by applying a polynomial of derivatives of theta to the product  $X = \prod \theta_{i\alpha}$  of all theta parameters. The theta integral of  $X$  is by definition equal to 1. In integral over theta parameters the monomials of theta associated with positive energy chiral field and negative energy chiral field would combine together and one would obtain desired action. In the following this approach is sketched. Devil lies in the details and detailed checks that everything works are not yet done.

#### TGD variants of chiral super fields

Consider first the construction of chiral super-fields and of the super-counterpart of Dirac action.

1. Wormhole throats carry a collection of *collinearly* moving fermions with momentum appearing in the measurement interaction term identified as the total momentum. This suggests that kinetic terms behave positive powers of Dirac operator with one power for each theta parameter.
2. One must be careful with dimensions. The counterpart of Dirac operator is  $D = \sigma^k(p_k + Q_k)/M$ . The mass parameter  $M$  must be included for dimensional reasons and changes only the normalization of the theta parameters from that used earlier and changes the anti-commutation relations of the super-algebra in an obvious manner. The value of  $M$  is determined by quantum criticality since it appears also in the measurement interaction term. The first guess for the value of  $M$  is of order  $CP_2$  mass defined as  $m(CP_2) = n\hbar_0/R$ , where  $R$  is the length of  $CP_2$  geodesic and  $n$  is a numerical constant. The proposal for a bi-local QFT limit describing gravitational interaction leads to the conclusion that gravitational constant is proportional to  $1/M^2$ .
3. In the case of single wormhole throat one can speak about positive and negative energy chiral fields. Positive energy chiral fields are constructed as polynomials, and more generally, as Taylor series whereas negative energy chiral fields are obtained by mapping positive energy chiral fields to an operator in which each theta parameter  $\theta$  is replaced with

$$\partial_\theta D = \partial_\theta \sigma^k \frac{(p_k + Q_k)}{M} . \quad (9.7.12)$$

This operator acts in the product  $X$  of all theta parameters to give the negative energy counterpart of chiral field. The inclusion of sigma-matrices is necessary in order to obtain chiral

symmetry at the level of  $H$ , in particular the counterpart of Dirac action. In the integral over all theta parameters defining the Lagrangian density the terms corresponding to monomials  $M(\theta, x)$  and their conjugates  $M(\partial_{\bar{\theta}} D^{-1}, x)$  are paired and theta integrals can be carried out easily. Here  $\rightarrow$  tells that the spatial derivatives appearing in  $D$  are applied to  $M$ .

4. There is an asymmetry between positive and negative energy states and the experience with the ordinary Dirac action  $\bar{\Psi} D \rightarrow \Psi - \bar{\Psi} D^{\leftarrow} \Psi$  suggests that one should add a term in which  $\theta$  parameters are replaced with  $-D\theta$  so that space-time derivatives act on the positive energy chiral field and partial derivative  $\partial_{\bar{\theta}}$  appear as such. The most plausible interpretation is that the negative energy chiral field is obtained by replacing  $\theta$ s in the positive energy chiral field with  $\partial_{\theta} X$  and allowing to act on  $X$ . The addition of  $D$  would thus give rise to the generalization of the kinetic term.
5. Chiral condition can be posed and one can express positive energy chiral field in as an infinite powers series containing all finite powers of theta parameters whereas negative energy chiral field contains only infinite powers of  $\theta$ . The interpretation is in terms of different Dirac vacuum. What one means which super-covariant derivatives is not quite clear.

(a) The usual definition of super covariant derivatives would be as

$$D_{i\alpha} = \partial_{i\alpha} + i(\bar{\theta} D)_{i\alpha} \quad , \quad \bar{D}_{i\dot{\alpha}} = \partial_{\theta_{i\dot{\alpha}}} + i(D\theta)_{i\dot{\alpha}} \quad . \quad (9.7.13)$$

(b) A definition giving rise to the same anti-commutators would be as

$$D_{i\alpha} = \partial_{i\alpha} \quad , \quad \bar{D}_{i\dot{\alpha}} = \partial_{i\dot{\alpha}} + 2i(D\theta)_{\dot{\alpha}} \quad (9.7.14)$$

In the recent case  $\bar{D}$  does not appear at all in the chiral action since for negative energy chiral field conjugation does not correspond to  $\theta \rightarrow \bar{\theta}$  but to  $\theta \rightarrow \partial_{\theta}$  and  $1 \rightarrow X$ . Hence the simplest theory would result using  $D_{\alpha} = \partial_{i\alpha}$ .

- (c) If one includes into the product of  $X$  of theta parameters only  $\theta$ s but not their conjugates, the two definitions are equivalent since the powers of  $\bar{\theta} D \theta$  give nothing in theta integration. This definition of  $X$  is possible using the definition of hermitian conjugation appropriate also for  $\mathcal{N} = \infty$ . This formalism of course works also for a finite value of  $\mathcal{N}$ .

Consider now the resulting action obtained by performing the theta integrations. The interesting question is what form of the super-covariant derivatives one should use. The following considerations suggests that the two alternatives give almost identical -if not identical- results but that the simpler definition  $D_{\alpha} = \partial_{i\alpha}$  is much more elegant.

1. For  $D_{\alpha} = \partial_{i\alpha}$  the propagators are just inverses of  $D^d$  where  $d$  is the number of theta parameters in the monomial defining the super-field component in question so that the Feynman rules for calculating bosonic propagators and vertices are very simple. Only the spinor and vector terms corresponding to degree  $d = 1$  and  $d = 2$  in theta parameters behave in the expected manner. This conforms with the collinearity. In particular, for spin 2 states the propagator would behave like  $p^{-4}$  for large momenta. This conforms with the prediction that graviton cannot correspond to singlet wormhole throat but to a string like object consisting of a superposition of pairs of wormhole contacts and of wormhole throats. If this expansion makes sense, higher spin propagators would behave as increasingly higher inverse powers of momentum and would not contribute much to the high energy physics. At energies much smaller than mass scale they would give rise to contact terms proportional to a negative power of mass dictated by the number of thetas.
2. For  $D_{\alpha} = \partial_{i\alpha} + i(\bar{\theta} D)_{\alpha}$  the situation is considerably more complex although the basic contribution to the propagators is same. The chiral field property using the standard definition means that propagator is multiplied by an infinite geometric series in  $D^2$  coming from the contractions of  $\bar{\theta} D \theta$  in positive energy chiral super-field as they are contracted with corresponding terms  $\partial_{\bar{\theta}} D \partial \theta$  appearing in negative energy chiral super-field acting on  $X$ . The summation can be done

by Feynman rules for a "free field theory" in which incoming particles correspond to  $\theta$  parameters and outgoing particles to partial derivatives with respect to theta parameters. The rule is that any theta parameter can be connected to any derivative with respect to theta parameter and any pair of theta parameters and its conjugate connected in this manner gives  $D^2/M^2$  as a result. For the  $N$ :th power of  $\bar{\theta}D\theta$  a given theta can be connected to  $\partial\theta$  in  $N!$  manner and same applies to its conjugate. Hence the  $1/N!$  factors coming from the expansion of plane wave  $\exp(ip \cdot m + i\bar{\theta}D\theta)$  cancel each other and one obtains geometric series.

- (a) These rules assign to the power series  $\exp(i\bar{\theta}D\theta)$  an over-all factor

$$Y = \mathcal{K}Y_1, \quad Y_1 = \frac{1 - \left(\frac{p^2 - m^2}{M^2}\right)^{K+1}}{1 - \frac{p^2 - m^2}{M^2}}. \quad (9.7.15)$$

The integer  $K$  results when one truncates the SUSY to a SUSY with finite value of  $\mathcal{N}$ . The value of  $K$  depends somewhat on the number of theta parameters associated with the field component but approaches infinite value for  $\mathcal{N} = \infty$ .

- (b) Propagator is inversely proportional to  $Y$ . This factor appears also in vertices and since the propagators and vertices defining the bosonic action involve always chiral loops with the same number of chiral field propagators and incoming vector super-fields the factors  $\mathcal{N}$  cancel out neatly.
- (c) For  $p^2 \ll M^2$  the factor  $Y_1$  equals to unity in good approximation. For  $|p^2 - m^2| \gg M^2$   $Y_1$  diverges at the limit  $\mathcal{K} \rightarrow \infty$  and propagator vanishes for  $|p^2 - m^2| \gg M^2$ , which raises the hope about dynamical cutoff guaranteeing UV finiteness. Vertices however contain a similar factor. Again the fact that the loops defining the bosonic vertices and propagators contain same number of vertices and propagators implies that these factors cancel each other.
- (d) The overall result seems to be a presence of infinite factors which however cancel completely in the expressions for bosonic vertices and propagators and introduce only a small effect at low energies. For  $D_\alpha = \partial_{i\alpha}$  all these complications are avoided. It should not be difficult to decide between these options.

### TGD variant of vector super field

Chiral super-fields are certainly not all that is needed. Also interactions must be included, and this raises the question about the TGD counterpart of the vector super-field.

1. The counterpart of the chiral action would be a generalization of the Dirac action coupled to a gauge potential obtained by adding the super counterpart of the vector potential to the proposed super counterpart of Dirac action. The generalization of the vector potential would be the TGD counterpart of the vector super field. Vector particle include  $M^4$  scalars since Higgs behaves as  $CP_2$  vector and  $H$ -scalars are excluded by chiral invariance.
2. Since bosons are bound states of positive and negative energy fermions at opposite wormhole throats it seems that vector super field must correspond to an operator slashed between positive and negative energy super-fields rather than ordinary vector super-field. The first guess is that vector super-field is an operator expressible as a Taylor series in which positive energy fermions correspond to the powers of  $\theta_\alpha$  and negative energy fermions correspond to the powers of derivatives  $\partial_{\theta_\alpha}$ . Naively,  $D$  in  $\partial_\theta D$  is replaced by  $D+V$ . Vector super-field must be hermitian ( $V = V^\dagger$ ) with hermitian conjugation defined so that it maps theta parameters to the partial derivatives  $\partial_\theta$  and performs complex conjugation. A better guess is that  $D$  appearing in the definition of the kinetic term is replaced with  $D+V$  where  $V$  is a hermitian super-field. This definition would be direct generalization of the minimal substitution rule.
3. It is important to notice that the gauge bosons appearing in the covariant derivatives have *same momentum* so that the interaction terms are local in momentum space rather than x-space. This conforms with the view that the  $N$  virtual bosons emitted in the  $N+2$  vertex propagate along single wormhole throat. For bosonic emergence these couplings give rise to exchanges of

$N$  collinear vector particles between two fermion lines behaving like  $(k^2 - m^2)^{-2N}$  and thus approaching rapidly to zero in UV and contact interaction in IR. For  $m = 0$  one obtains series of interactions corresponding to potentials of form  $V \propto r^{2n+1}$ . For massive case these interactions are screened by the Yukawa factor  $\exp(-mr/\hbar)$ . Confining linear interaction potential in QCD could result in this manner for  $m = 0$  and  $N = 2$ . If the coupling were local in  $x$ -space the exchange would involve  $N - 1$  free loop momenta giving loop integral diverging like  $\lambda^{2N-4}$  as a function of momentum cutoff. Already for  $d = 2$  one would obtain logarithmic divergence.

4. It is difficult to imagine how a kinetic term for the vector super-field could be defined. This supports the idea that bosonic propagators and vertices emerge as one performs functional integral over components of the chiral fields.
5. There is also the question about gauge invariance. The super-field generalization of the non-Abelian gauge transformation formula looks more like the generalization of Dirac action to its super-counterpart:  $D \rightarrow D + V$  everywhere. Here  $V$  is the contraction of sigma matrices with super-field  $V_k$ , which is vector field in  $M^4$  having also  $S^1$  component which does not depend on  $S^1$  coordinate. Positive energy chiral field would transform as  $\Phi_+ \rightarrow \exp(\Lambda)\Phi$ , where  $\lambda$  is a chiral field. The negative energy chiral field would transform as  $\Phi_- \rightarrow \Phi_- \exp(\Lambda^\dagger)$  with hermitian conjugation involving also the map of thetas to their derivatives. Each theta parameter would represent a fermion transforming under gauge symmetries in a manner dictated by its electro-weak quantum numbers (the inclusion of color quantum numbers is not quite trivial: probably they must be included as a label for quark modes). As in the case of Dirac action, the transformation formula for vector super-field would be dictated by the requirement that the derivatives of  $\Lambda$  coming from  $\exp(\Lambda)$  are canceled by the derivative terms in the transformation formula for the vector super field. The resulting transformation formulas are identical with standard ones formally since the only new thing is that both  $V_k$  and gauge group element  $g$  are super-fields.

### How to feed information about classical physics of space-time sheet to chiral and vector super-fields?

The new view about super fields need not be consistent with the geometric interpretation assigned to the chiral multiplets in the standard SUSY without some modifications.

1. The geometric interpretation of Kähler potential and super-potential are very attractive features of ordinary SUSY. The most general interpretation in TGD framework would be as the WCW Kähler function  $K$  and holomorphic function  $f$ , whose real part added to  $K$  does not affect its metric but changes the maxima of Kähler function.
2. In standard SUSYs the scalar parts of chiral fields give rise to Higgs expectation values and internal consistency arguments force the manifold of Higgs expectation values to be Kähler or even quaternionic Kähler manifold with coordinates interpreted as Higgs field. In TGD framework Higgs is  $CP_2$  vector which brings in additional constraint.  $CP_2$  is quaternionic Kähler manifold but  $CP_2$  coordinates do not allow interpretation as Higgs field.  $CP_2$  gamma matrices induced to  $S^1$  giving rise to a constant gamma matrix could be however identified as  $S^1$  component of vector potential identifiable as Higgs vacuum expectation contributing to the mass of a given particle besides the dominating contribution coming from p-adic thermodynamics.
3. In the model based on ordinary  $\mathcal{N} = 1$  SUSY each particle would correspond to its own  $\mathcal{N} = 1$  multiplet so that a Cartesian power of  $CP_2$ s would define the quaternionic manifold. This conforms with the geometric picture provided by the replacement of light-like 3-surfaces with braid strands in which a Cartesian power of  $\delta M_{\pm}^4 \times CP_2$  effectively replaces WCW.
4. The new view about super fields requires the replacement of the constant  $S^1$  component of the super gauge potential with a diagonal matrix whose eigenvalues depend on the mode of spinor field characterized by the theta parameter. Quite generally, super-symmetry breaking results from the replacement of the mass parameter  $m$  in  $D$  with a diagonal operator whose eigenvalues  $m_k$  give the masses assignable to the modes depending on the spinor mode. Mathematically the genuine  $S^1$  mass term determined by p-adic thermodynamics can be distinguished from a small Higgs expectation coded by  $S^1$  vector potential by comparing particles with different charges.

The induced Kähler form defining zero modes is so essential for quantum TGD at the fundamental level that the coding of at least part of this information to the chiral action is a highly desirable feature. This seems possible.

1. The overall renormalization factor of the chiral super field cannot carry the information about the geometry of the space-time sheet. The vector super-field vertices involving vector particles are obtained as chiral loops and the normalization factors from the vertices involving  $N$  vectors and 2 chiral particles cancel their inverses associated with the chiral propagators. Hence the possible renormalization of the generalized Dirac action has no physical implications. This is one of the nice outcomes of emergence concept.
2. One can however add to the induced gauge potentials associated with the space-time sheet to the super gauge potential as its classical parts. It is important to notice that  $X^4$  coordinates would appear as parameters constant with respect to  $p_k$  since  $p_k$  would correspond to  $M^4$  coordinate for the tip of  $CD$  rather than space-time coordinate. The standard interpretation would be as slowly varying background fields.
3. The information about vacuum degeneracy coded by the modified gamma matrices could be coded by replacing the operator  $D$  with that appearing in the modified Dirac action and assigned to the maximum of Kähler function. Note that this would bring in two color charges  $Q_i$ . The modified gamma matrices appearing in it would behave as constants with respect to  $p_k$  and  $Q_k$ . Somewhat surprisingly, zero energy ontology would make it possible to feed all information about the classical physics of the space-time sheet without losing Poincare invariance.

### 9.7.8 Could QFT limit be finite?

Could the resulting theory be finite without hyperbolic and mass scale cutoffs in UV region? Consider first general arguments without any resort to the proposed definition of TGD counterparts of super-fields.

1. Non-renormalization theorems allow to expect that a cancelation of quadratic infinities takes place as a consequence of super-symmetry. Cancelation of quadratic divergences in the bosonic propagators means that there is no need to assume that hyperbolic cutoffs are different for time-like and space-like momenta.
2. There are arguments suggesting that  $N = 8$  SUGRA is UV finite. Since the number of super-symmetries in quantum TGD is even higher than in  $N = 8$  super-gravity, the theory might be also UV finite. If infinities cancel, the theory without UV cutoff for the mass scale and hyperbolic angle could provide an excellent approximation to the theory. Also the standard prescription for calculating loop integrals might make sense if this is the case. Geometric arguments support the presence of the cutoffs but one must remain critical.
3. Super-symmetry alone does not guarantee finiteness since it is possible to define extremely general SUSY actions in terms of integrals of functions of super-space integrated over super-space. Chiral action should have some additional symmetries not possessed by super-symmetric counter-terms. Chiral action is quadratic in chiral super-field meaning the absence of self couplings of the chiral super field. Linear superposition of the solutions is certainly a very special symmetry and very essential for the perturbation theory. QFT limit is obtained by integrating over the quantum fluctuations in WCW degrees of freedom for a maximum of Kähler function. Therefore Kähler potential naturally corresponds to WCW Kähler potential at its maximum and depends only on zero modes. This would conform with the fact that only second derivatives of Kähler potential (Kähler metric) appear in the Kähler potential. Also R-parity arguments favor this form.
4. Also for the proposed TGD inspired identifications of super-fields, the cancelation of UV divergences should be essentially algebraic and due to the cancelation of chiral contributions from the loops contributing to the vector super-field propagators and vertices. Also for the emerging bosonic effective action same mechanism should be at work. The renormalization theorems state that the only renormalizations in SUSYs are wave function renormalizations. In the case

of bosonic propagators loops therefore mean only the renormalization of the propagator. In the recent case only the chiral loops are included so that the situation is analogous to Abelian YM theory or  $\mathcal{N} = 4$  super YM theory, where the beta functions for gauge couplings vanish. Hence one might hope that also now wave function renormalization is the only effect so that the radiatively generated contribution should be proportional to the standard form of the vector propagator. The worst that can occur is logarithmically diverging renormalization of the propagator which occur in many SUSYs. The challenge is to show that logarithmic divergences possibly coming from the  $\theta^d$ ,  $d = 1, 2$ , parts of the chiral super-field cancel. The condition for this cancellation is purely algebraic since the coupling to  $k = 2$  part is gradient coupling so that the leading divergences have same form.

5. It could happen that the contributions from  $d \leq 2$  cancel exactly as they do in SUSYs but the contributions from the field components with  $d > 2$  give a non-vanishing and certainly finite contribution. If this were the case then the exotic chiral field components with propagators behaving like  $1/p^d$ ,  $d > 2, \dots$  would make possible the propagation for the components of the vector super-field.

### 9.7.9 Can one understand p-adic coupling constant evolution as a prediction of QFT limit?

The precise formulation of the p-adic coupling constant evolution is one the basic challenges of quantum TGD. The best that one can hope is the deduction of p-adic thermodynamics and p-adic length scale hypothesis as well as p-adic coupling constant evolution from QFT limit alone.

For the simple form of the QFT limit involving  $M^4 \times S^1$  gamma matrices in the definition of  $D$ , p-adic length scale could make itself visible via the mass parameters and the contribution of the Higgs field appearing as  $S^1$  part of the gauge potential. This is of course just feeding in the results of p-adic thermodynamics. Gauge couplings predicted by the emergence would depend on these parameters but the coupling constant evolution would reflect only the effects of mass parameters on it.

4-D spin glass analogy is one of the basic visions about the physics of quantum TGD. In the theory of spin glasses ultrametric topology possessed also by p-adic number fields emerges as a topology of the energy landscape consisting of the minima of free energy. In TGD framework the space for the maxima of Kähler function could obey ultrametric topology with the value of prime  $p$  fixed by the scale of  $CD$  in question and given by a power of 2. Therefore one has good hopes that for small enough sub- $CD$ s of a given  $CD$  the failure of the strict non-determinism implies p-adic coupling constant evolution. p-Adic thermodynamics determining particle masses cannot of course follow from QFT limit since it relates to the space-like space-time regions (locally  $CP_2$  type vacuum extremals) defining the generalized Feynman diagrams. By combining this vision and the QFT limit with maximal information feed about the space-time sheet gives hopes about achieving more ambitious goals.

1. If one replaces  $D$  with the actual measurement interaction term, all information about the space-time sheet within a given  $CD$  is feeded via modified gamma matrices  $\hat{\Gamma}^\alpha = \Gamma^k \partial L_K / \partial_\alpha h^k$  in as effective slowly varying background fields. The propagators reflect directly the local space-time dynamics, and one obtains a distribution of scattering amplitudes as a function of the point of the space-time sheet within a given  $CD$ . A 4-D distribution for the values of gauge coupling constants is predicted whereas 1-D evolution or even discrete p-adic evolution would be quite enough.
2. Space-time surfaces decompose into connected Minkowskian regions surrounding wormhole throats (basins for the local slicings by light-like 3-surfaces parallel to the throats) and these regions naturally correspond to coherence regions at QFT limit. A space-time integral defining a quantum superposition of the amplitudes associated with various points of the coherence region looks like a physically natural mathematical object to consider. Only the kinetic terms for vector super-field would involve the weighting over the coherence region. Ideal weighting depends on zero modes only and therefore cannot depend on the induced metric.
  - (a) If the weighting is defined by Kähler action density, normalization is not required and would lead to difficulties when the Kähler action vanishes. This implies the proportionality of emerging bosonic kinetic terms to  $1/g_K^2$  so that propagators and also gauge coupling

strengths included by definition to the propagators are proportional to  $g_K^2$ . The basic property of emergence is that the dependence of Feynman diagrams on  $1/g_K^2$  coming from the modified gamma matrices cancels out in perturbation theory. This is a nice feature consistent with the idea that the propagator for the small deformations of 3-surfaces corresponds to the WCW contravariant Kähler metric proportional to  $g_K^2$  [17]. The counterparts of the gauge couplings identified in terms of the inverses of propagators for the vector super-field components obtained in this manner would depend on the p-adic length scale  $L_p \propto \sqrt{p}$ ,  $p \simeq 2^k$ , for the smallest  $CD$  containing the coherence region. One can criticize this weighting scheme. The ideal weighting scheme should depend on zero modes ( $J_{\alpha\beta}$ ) only but this weighting scheme depends on the induced metric. Huge amount of information is needed and a concrete connection with the view about generalized Feynman graphs is lacking. Note also that the properties of elementary particles reflecting themselves at the level of propagators would depend on the macroscopic field patterns of Kähler electric field.

- (b) The idea that light-like 3-surfaces meet at partonic two-surfaces  $X^2$  identified as their intersections of wormhole throats with the light-like boundaries of  $CD$ s would suggest only 2-D weighting over partonic 2-surfaces with Kähler action replaced by magnetic flux density  $\frac{1}{g_K} J \sqrt{g_2}$ ,  $J = J^{\alpha\beta} \epsilon_{\alpha\beta}$ . The dependence on the induced metric is only apparent.  $1/g_K$  factor must be included to get dimensions correctly. This weighting depends on zero modes only. The dependence of the coupling constants on the p-adic size scale of  $CD$  comes out naturally, and only the information from the scales relevant to elementary particles affect propagators and couplings. As in the previous case, non-trivial interference effects are possible since the sign of  $J$  varies. The only information about the preferred extremals of Kähler action is about the derivatives  $\partial_\alpha h^k$  at  $X^2$  appearing in  $\hat{\Gamma}^\alpha$ . In the calculation of the super-vector field propagators the information about the modified gamma matrices at *both* ends of  $X_l^3$  is needed and the weighting would be over the both ends.
- (c) One must decide whether to perform the weighting for the kinetic term of vector super-field action or for the loop integrals defining the corresponding propagators. Spin glass analogy would suggest the first option. The weighting the kinetic term would be proportional to  $x^2/g_K^2$ , where  $x$  is a numerical parameter characterizing the net result of the weighting. The emerging propagators would be proportional to  $g_K^2/x^2$  and  $g_K^2$  proportionality is indeed what one expects. For the latter option propagator would be proportional to  $x^2/g_K^2$ , which does not make sense unless one considers the rather remote possibility that electric-magnetic duality relates the two weightings. The value of  $x$  is expected to be smallest for homologically trivial partonic 2-surfaces (Kähler magnetic charge vanishes). Gauge coupling strengths would be therefore smallest for magnetic monopoles, which looks somewhat counter-intuitive if one thinks in terms of electric-magnetic duality. On the other hand, since the propagator for the deformations of 3-surface is contravariant Kähler metric of WCW becoming singular near vacuum extremals and since the kinetic term of Kähler action approaches zero near vacuum extremals, one expects gauge couplings to grow large near vacuum extremals since they are inversely proportional to the scale of the kinetic term. Also asymptotic freedom conforms with this result since in very short length scales magnetically charged string like objects are expected to replace space-time sheets as basic objects whereas long length scales correspond to nearly vacuum extremals.

A cautious conclusion is that the weighting scheme based on Kähler magnetic magnetic flux is the correct choice.

3. p-Adic coupling constant evolution for the propagator is obtained in a manner consistent with what has been discussed in [56]. If virtual boson momenta in a given half octave of masses labeled by integer  $k$  correspond to  $CD$  labeled by this integer. Since the coherence region surrounding the propagating wormhole throat is contained inside a  $CD$  characterized by this size scale, the scale of  $CD$  indeed defines the p-adic length scale in question. Since the propagator by definition is proportional to the coupling strength also coupling constant evolution is coded in this manner. The difference to earlier picture is that  $\alpha_K$  proportionality means that the loops defining propagator must be of order one or larger. In the model based on hyperbolic cutoff the cutoff guaranteed the desired value.

4. The failure of the strict determinism for Kähler action suggests that for the practical purposes the coherence regions must be replaced with an ensemble of local preferred extremals of Kähler action. The dependence of the modified gamma matrices defined by the Kähler action on the space-time point is analogous to a similar dependence of the coupling constant parameters of the spin glass Hamiltonian. The vacuum functional  $\exp(K)$  for the coherence region defines the counterpart for the real square root of the density matrix and the sum over the preferred extremals weighted by  $\exp(K)$  for the coherence region defines the analog of statistical average.

### 9.7.10 Is the QFT type description of gravitational interactions possible?

In TGD Universe graviton is necessarily a bi-local object and the emission and absorption of graviton are bi-local processes involving two wormhole contacts: a pair of particles rather than single particle emits graviton. This is definitely something new and defies a description in terms of QFT limit using point like particles. Graviton like states would be entangled states of vector bosons at both ends of string so that gravitation could be regarded as a square of YM interactions in rather concrete sense. The notion of emergence would suggest that graviton propagator is defined by a bosonic loop. Since bosonic loop is dimensionless, IR cutoff defined by the largest  $CD$  present must be actively involved.

The connection with strings is via the assignment of wormhole contacts at the ends of a stringy curve. Stringy diagrams would not however describe graviton emission. Rather, a generalization of the vertex of Feynman diagram would be in question in the sense that three string world sheets would be glued together along their 1-dimensional ends in the vertex. This generalizes similar description for gauge interactions using Feynman diagrams. In the microscopic description point like particles are replaced with 2-D partonic surfaces so that in gravitational case one has stringy 3-surfaces at vertices.

At QFT limit one can hope a description as a bi-local process using a bi-local generalization of the QFT limit so that stringy degrees of freedom need not be described explicitly. There are hopes about success, since these degrees of freedom have been taken into account in the spectrum of modes of the induced spinor field and reflect themselves as quantum numbers labeling fermionic oscillator operators. Also modified gamma matrices feed information about space-time surface to the theory.

#### What one really means with strings?

Before continuing is it is good take critical attitude to the proposed picture. What one really means with string is the first question.

1. Stringy curves appear in in the slicing of the space-time sheet around wormhole throat to light-like 3-surfaces labeled by the points of string. Hamilton-Jacobi coordinates [8] suggest that the  $M^4$  projections of these curves light-like so that the curves would be space-like.
2. For string like objects obtained as deformations of cosmic strings  $X^2 \times Y^2 \subset M^4 \times CP_2$  one can assign Kähler magnetic flux flowing along the stringy curves. These curves should define a special class of stringy curves.
3. If the basin for the slicing by light-like 3-surfaces for a given wormhole throat has an outer boundary at which induced Kähler form vanishes (it is not obvious that this can be the case), one can ask whether stringy curves effectively end at the boundary of the basin or what happens? Magnetic flux conservation does not allow to assign magnetic flux to the stringy curves now. The analogy with field lines gravitational scalar potential suggests a possible answer. All wormhole throats would act as sources for these lines identifiable as field lines of a gradient vector field. Basins would not actually have any boundaries since the extrema of the potential would consist in the generic case of a discrete set of points. Whether stringy curves really have something to do with field lines of a gradient of gravitational potential must be however left an open question.
4. Despite the emergence of stringy picture, string model as such does not seem to help much since the graviton emission vertex is completely different from that in string models.

A physically attractive realization of the braids - and more generally- of slicings of space-time surface by 3-surfaces and string world sheets, is discussed in [36] by starting from the observation that TGD defines an almost topological QFT of braids, braid cobordisms, and 2-knots. The boundaries of

the string world sheets at the space-like 3-surfaces at boundaries of  $CD$ s and wormhole throats would define space-like and time-like braids uniquely.

The idea relies on a rather direct translation of the notions of singular surfaces and surface operators used in gauge theory approach to knots [129] to TGD framework. It leads to the identification of slicing by three-surfaces as that induced by the inverse images of  $r = \text{constant}$  surfaces of  $CP_2$ , where  $r$  is  $U(2)$  invariant radial coordinate of  $CP_2$  playing the role of Higgs field vacuum expectation value in gauge theories.  $r = \infty$  surfaces correspond to geodesic spheres and define analogs of fractionally magnetically charged Dirac strings identifiable as preferred string world sheets. The union of these sheets labelled by subgroups  $U(2) \subset SU(3)$  would define the slicing of space-time surface by string world sheets. The choice of  $U(2)$  relates directly to the choice of quantization axes for color quantum numbers characterizing  $CD$  and would have the choice of braids and string world sheets as a space-time correlate.

### What one really means with gravitons?

One can also ask what one really means with graviton. The identification of graviton is indeed far from obvious.

1. Wormhole throats and contacts allow  $J = 2$  states but they couple only to states which corresponds to  $d \geq 2$  monomials of theta so that couplings to the fermions are absent.
2. TGD predicts a hierarchy of string like objects of all possible sizes and these are good candidates for graviton like states. The hierarchy of Planck constants and the huge values of gravitational Planck constant suggests that gigantic gravitons identifiable as stringy curves connecting particles at astrophysical distances are possible. The emission of dark graviton would be bi-local process in astrophysical length scales and would look locally like an emission of gauge boson.
3. One can of course argue it is not clear whether stringy gravitons represent hadron like objects responsible for strong gravitation below relevant p-adic length scale rather than genuine gravitons. For instance, the identification of elementary particles in terms of  $CP_2$  type extremals forces to ask whether gravitons could correspond to pieces of  $CP_2$  type extremals connecting positive and negative energy space-time sheets with a wormhole contact having two pairs of wormhole throats so that spin two states would become possible. If this generalization is accepted, one must also accept the possibility of wormhole contacts with arbitrary number of throat pairs. One can also wonder what is the origin of Planck length which is roughly  $10^4$  times shorter than  $CP_2$  length. For instance, could it have purely geometric interaction characterizing the distance between these wormhole contacts?

With this identification graviton emission at elementary particle level could be seen as a creation of a virtual wormhole throat pair inside wormhole contact formed by fermion and anti-fermion and making possible emission of graviton. One can also consider a distribution of wormhole throat pairs inside wormhole created in this manner in which case  $1/G_N$  would characterize the probability for the appearance of wormhole throat pair.

4. Graviton must be generalized to a super-field and bi-locality suggests that this field is a bi-local composite of super gauge fields in some sense. Ordinary graviton would be only single component of this field.

To sum up, it is far from clear what graviton precisely is and gauge-theory-gravitation correspondence suggests that there is a rich spectrum of graviton like states. Despite this one can characterize rather precisely what the description of gravitational interaction at QFT limit must be by using general symmetry principles and basic structure of quantum TGD.

### Could bi-local QFT allow to describe gravitation as a square of gauge interactions?

The key question is whether one can generalize the formalism of QFT limit to describe also gravitational interactions. The first guess is that in some sense gravitation is a square of YM interactions. This statement has a precise content in some string theories. Also the scattering amplitudes of  $N = 8$  super-gravity allow a construction in terms of  $N = 4$  SYM amplitudes. In the recent case gravitation as a square of YM theory would mean that graviton propagator emerges from vector super-field

propagators assignable at the ends of the gravitonic string. Vector propagators would in turn emerge from chiral super-field propagators.

The bi-local character of the basic process suggests that a bi-local generalization of QFT limit is needed to describe gravitation. In fact, at the long length scale limit of the theory the appearance of second derivatives in the curvature scalar could be seen as a signature of bi-locality at fundamental level. Bi-locality brings in the notion of distance and the metric description of gravitation indeed assumes that distances are dynamical. Note that also the typical experimental arrangements for detecting gravitons are bi-local (typically the variation of the distance between the ends of a metal bar is measured).

1. Bi-locality would suggest that one has a pairing of the chiral actions to a bi-local action. Whether the vector bosons at the ends of graviton string move collinearly or not is a non-trivial question. Experimentation with the candidates for the bilinear gravitational action shows that the simplest theory results when collinearity assumption is given up. It is also far from clear whether collinearity assumption allows any internally consistent mathematical realization: the problem is that by collinearity graviton propagator becomes proportional to  $1/p^4$  and one should somehow eliminate one  $1/p^2$  factor. If one gives up collinearity, one obtains a bosonic loop integral with vector boson momenta  $p - k$  and  $k$ . Graviton kinetic term emerges from a loop of two bosons and is therefore dimensionless so that IR cutoff  $L$  is necessary in order to obtain  $p^2 L^2$  type kinetic term and finiteness. The IR cutoff comes naturally as the size scale  $L$  of the largest  $CD$  involved and appears also as scaling factor of the action by purely dimensional reasons and disappears naturally from the interaction vertices.
2. Graviton would correspond to a bi-local composite of super gauge fields acting as operators  $V(\theta_i, \partial_{\theta_i})$ ,  $i = 1, 2$ , on the chiral super-fields at the ends of the string and graviton propagation should reduce to vector boson propagation just as vector boson propagation reduces to fermion pair propagation. General gauge invariance at the level of space-time sheet is not a problem. At the level of  $M^4$ , whose coordinates label the positions for the tips of  $CD$  the possibility to choose preferred  $M^4$  coordinates guarantees general coordinate invariance trivially. The elimination of non-physical graviton polarizations for massless gravitons is achieved by the ordinary gauge invariance. In this conceptual framework elimination of non-physical graviton polarization does not have obvious connection with general coordinate invariance. The properties of the slicings by light-like 3-surfaces suggest this connection.
3. At the point like limit the emission of gravitons is described by an interaction term of form  $T^{\alpha\beta} \delta g_{\alpha\beta}$ . This expression should have a bi-local gauge invariant generalization. The energy momentum tensor for Dirac action suggests the following remarkably simple expression for the interaction action  $L_{gr}$  in super space.

$$L_{gr} = K \bar{\Psi} D^A \Psi \times \bar{\Psi} D_A \Psi . \quad (9.7.16)$$

A summation over the contracted index pairs is understood in the formula. The theta parameters associated with the two actions are regarded as independent Grassmann variables.

4. If the vector boson momenta at the ends of graviton string vary freely apart from the constraint that they sum up to the momentum of the virtual graviton,  $K$  must be of form  $K = kL^2$  to compensate the dimension  $1/L^2$  coming from the two  $D_{AS}$ .  $L$  naturally corresponds to IR cutoff defined by the size of the largest  $CD$  involved. The bosonic loop giving graviton propagator at the IR limit is dimensionless so that the resulting propagator must be proportional to  $1/(p^2 L^2)$  so that the powers of  $L$  cancel each other in the propagators.  $D_A = p_A + Q_A + V_A$  is the covariant derivative corresponding to a particular momentum component. Note that also color charge (color hyper charge or isospin) is included and is present for massive particles. Since only covariant derivatives appear, the expression is manifestly super gauge invariant.
5. The integration over the theta parameters gives factors  $D = \hat{\Gamma}^A D_A / M$  for each integrated pair of theta parameters. Here  $M$  is a parameter with dimensions of mass to make  $D$  dimensionless and

$CP_2$  is the most natural guess for its value. The resulting action for graviton has the following form

$$\begin{aligned}
L_{gr} &= \frac{K}{M^2} \bar{\Psi} O^A \Psi \times \bar{\Psi} O_A \Psi , \\
O^A &= \frac{D^{\rightarrow} D^{A\rightarrow} - D^{\leftarrow} D^{A\leftarrow}}{M} , \\
D^{\leftarrow} &= \frac{D_A^{\leftarrow} \hat{\Gamma}^A}{M} , \quad D^{\rightarrow} = \frac{\hat{\Gamma}^A D_A^{\rightarrow}}{M} , \quad D = \frac{\hat{\Gamma}^A D_A}{M} .
\end{aligned}
\tag{9.7.17}$$

The  $1/p^2 L^2$  from the IR cutoff for the loop integral defining the emergent graviton propagator given by a dimensionless bosonic loop cancels  $L^2$  from factor  $kL^2/M^2$  and  $kM^2$  should be proportional to  $G_N$ .

6. The tensor structure of the graviton vertex resulting from  $DD^A$  in the lowest order seems to be correct.  $\hat{\Gamma}^A D^{B\rightarrow}$  *resp.*  $\hat{\Gamma}^A D^{B\leftarrow}$  is the analog of energy momentum tensor and in the lowest order gives rise to the desired proportionality of the gravitational coupling to momentum. Since graviton is emitted by a pair of particles the proportionality to the momenta of both particles is natural. Note that only the momenta associated with the vector bosons defining the emitted graviton-like particle are collinear, not the momenta of the emitting particles at the ends of the string. The bilinear  $D_B \otimes D_C$  is the counterpart of  $\delta g_{\alpha\beta}$  and polarization tensor of graviton. Both  $D_B$  and  $D_C$  are contracted with the analog of the energy momentum tensor.
7. Ordinary graviton must correspond to electro-weak  $U(1)$  for which coupling is to fermion number. The mixing of  $U(1)_Y$  and  $U(1) \subset SU(2)$  should be completely absent for gravitons. In other words, the corresponding value of Weinberg angle must vanish:  $\sin^2(\theta_{W,gr}) = 0$  implying  $m_Z = m_W$  in gravitonic propagation. The graviton analogs formed from massless gluons would have a finite interaction range by confinement and weak gravitons would be massive so that no dramatic new effects are predicted.

When one feeds the information about space-time surface into the theory additional complications arise since the modified gamma matrices  $\hat{\Gamma}^\alpha(x) = \Gamma^k \partial L_K / \partial_\alpha h^k$  would replace the  $M^4 \times S^1$  gamma matrices and one must integrate over the points  $x$ . As found, the condition that weighting scheme depends on zero modes only (is symplectic invariant at the level of WCW) fixes it uniquely to a weighting by magnetic flux at the intersections of light-like wormhole throats with the light-like boundaries of  $CD$  relevant for the  $p$ -adic length scale defined by the virtual momentum squared.

1. Bi-locality suggests that both ends of string correspond to their own partonic 2-surfaces so that both ends involve weighting by the Kähler magnetic flux  $J\sqrt{g}/g_K$ .  $J = J^{\alpha\beta} \epsilon_{\alpha\beta}$ . Since  $J$  vanishes for vacuum regions and since also its sign varies, this is expected to bring in four identical reduction factors -call them  $x$ - to the kinetic term of graviton.
2. The defining property of the emergence is that the variation of the scale of  $\hat{\Gamma}^A$  is compensated by the variation of the scale of the propagator so that the proportionality of  $\hat{\Gamma}^A$  to  $1/g_K^2$  is not seen in scattering amplitudes.
3. Again one must decide whether the weighting is performed for the calculation of the propagator or whether one uses the bosonic propagators already calculated with corresponding weightings at the ends of lines. Only the latter option conforms with the idea about gravitation as square of gauge interactions predicting  $\alpha_K^2$ -proportionality for the graviton propagator. From the general proportionality of bosonic propagators to  $g_K^2/x^2 \propto \alpha_K$  one has the order of magnitude estimate

$$16\pi G_N \sim \frac{kg_K^4}{x^4 M^2} \sim \frac{k\alpha_K^2}{M^2} .
\tag{9.7.18}$$

$16\pi G$  comes from the fact that it appears in the linearized Einstein's equations as the coefficient of energy momentum tensor. If  $k$  does not depend on  $\hbar$  then  $\alpha_K \propto 1/\hbar$  and  $M \propto \hbar/R$  correctly predicts that  $G_N$  does not depend on  $\hbar$ . Using  $\alpha_K \simeq 1/137$  and  $M = m(CP_2) = .2437 \times 10^{-3} m_{Pl}$  [41] one obtains the very rough estimate  $k = (m(CP_2)/\alpha_K m_{Pl})^2 = .056$ .

4. Note that the solutions of field equations in the static limit when the situation resembles formally electrostatics, gravitational coupling strength is estimated classically to be of order  $CP_2$  length squared [8]. Since the value of  $CP_2$  mass (and thus length) is firmly fixed by elementary particle mass calculations [41], this results could be seen as a serious objection against TGD. One could say that the weighting provides a "screening mechanism" reducing the naive value of the gravitational coupling strength.

This picture allows to interpret the cutoff for  $\mathcal{N}$  as a cutoff for the maximal number of points of the partonic 2-surface carrying fermionic quantum numbers: essentially a cutoff in measurement resolution is in question. The super-symmetric excitations of graviton can be interpreted microscopically as multi-string states but looking like a single string in the spatial measurement resolution provided by single partonic 2-surface.

### Could one apply the formalism at fundamental level?

There are good motivations for asking whether this formalism - when appropriately generalized- could apply to the basic quantum TGD.

1. Only the data about partonic 2-surfaces are feeded into the vertices so that the assumption that space-time sheets are representable as graphs for maps from  $M^4$  to  $CP_2$  is not actually needed. The information about the interior topology of the space-time sheet is un-necessary and the effective 2-dimensionality simplifies the situation enormously. Note however that the initial values of derivatives of  $H$ -coordinates at partonic 2-surfaces are needed.
2. The cutoff for  $\mathcal{N}$  has interpretation as a cutoff for the maximal number of points of the partonic 2-surface carrying fermionic quantum numbers: essentially a cutoff in measurement resolution is in question. Already  $\mathcal{N} = 2$  cutoff is expected to be a good approximation since higher theta monomials give rise to short range forces.
3. The super-symmetric excitations of graviton can be interpreted microscopically as multi-string states but looking like a single string in the spatial measurement resolution provided by single partonic 2-surface. Therefore strings split to space-like braids at fundamental level. The duality between these space-like braids and light-like braids at light-like 3-surfaces might be important.
4. The generalization should take into account the fact theta parameters correspond to different points of  $X^2$  and that the wormhole throats associated with the bosonic wormhole contacts are not one and same thing. These effects are expected to be small unless the size of the wormhole is very large as it is for anyon-like wormhole throats with macroscopic size containing states with a high fermion number [57]. Also global data such as the moduli characterizing the conformal equivalence class of partonic 2-surface are needed in order to describe family replication phenomenon at the fundamental level. The description of color quantum numbers at fundamental level introduces additional complications. The functional integral over WCW must be performed and gives rise to non-perturbative effects when a large number of maxima of Kähler function must be included.

## 9.8 A more detailed summary of Feynman diagrammatics for emergence

In the following the Feynman diagrammatics for Dirac action coupled to gauge potential is sketched briefly and some comments on generalization to the super-symmetric case are made.

### 9.8.1 Emergence in absence of super-symmetry

The resulting Feynman diagrammatics deserves some more detailed comments.

1. Consider first the exponent of the action  $\exp(iS_c)$  resulting in fermionic path integral. The exponent

$$\exp\left[i \int d^4x d^4y \bar{\xi}(x) G_F(x-y) \xi(y)\right] = \exp\left[i \int d^4k \bar{\xi}(-k) G_F(k) \xi(k)\right]$$

is combinatorially equivalent with the sum over  $n$ -point functions of a theory representing free fermions constructed using Wick's rules that is by connecting  $n$  Grassmann spinors and their conjugates in all possible ways by the fermion propagator  $G_F$ .

2. The action of

$$\exp\left[i \int d^4x \frac{\delta}{\delta \bar{\xi}(x)} \gamma \cdot A(x) \frac{\delta}{\delta \xi(x)}\right] = \exp\left[i \int d^4k d^4k_1 \frac{\delta}{\delta \bar{\xi}(k-k_1)} \gamma \cdot A(-k) \frac{\delta}{\delta \xi(k_1)}\right]$$

on diagrams consisting of  $n$  free fermion lines gives sum over all diagrams obtained by connecting fermion and anti-fermion ends of two fermion lines and inserting to the resulting vertex  $A(-k)$  such that momentum is conserved. This gives sum over all closed and open fermion lines containing  $n \geq 2$  boson insertions. The diagram with single gauge boson insertion gives a term proportional to  $A_\mu(k=0) \cdot \int d^4k k^\mu k^{-2}$ , which vanishes.

3.  $S_c$  as obtained in the fermionic path integral is the generating functional for connected many-fermion diagrams in an external gauge boson field and represented as sum over diagrams in which one has either closed fermion loop or open fermion line with  $n \geq 2$  bosons attached to it. The two parts of  $S_c$  have interpretation as the counterparts of YM action for gauge bosons and Dirac action for fermions involving arbitrary high gauge invariant  $n$ -boson couplings besides the standard coupling. An expansion in powers of  $\gamma^\mu D_\mu$  is suggestive. Arbitrary number of gauge bosons can appear in the bosonic vertices defined by the closed fermion loops and gauge invariance must pose strong constraints on the bosonic part of the action if expressible in terms of bosonic gauge invariants. The closed fermion loop with  $n = 2$  gauge boson insertions defines the bosonic kinetic term and bosonic propagator. The sign of the kinetic terms comes out correctly thanks to the minus sign assigned to the fermion loop.
4. Feynman diagrammatics is constructed for  $S_c$  using standard Feynman rules. In ordinary YM theory ghosts are needed for gauge fixing and this seems to be the case also now.
5. One can consider also the presence of Higgs bosons. Also the Higgs propagator would be generated radiatively and would be massless for massless fermions as the study of the fermionic self energy diagram shows. Higgs would be necessary  $CP_2$  vector in  $M^4 \times CP_2$  picture and  $E^4$  vector in  $M^8 = M^4 \times E^4$  picture. It is not clear whether one can describe Higgs simply as an  $M^4$  scalar. Note that TGD allows in principle Higgs boson but - according to the recent view - it does not play a role in particle massivation.

### 9.8.2 Some differences from standard Feynman diagrammatics

The diagrammatics differs from the Feynman diagrammatics of standard gauge theories in some respects.

1. 1-P irreducible self energy insertions involve always at least one gauge boson line since the simplest fermionic loop has become the inverse of the bosonic propagator. Fermionic self energy loops in gauge theories tends to spoil asymptotic freedom in gauge theories. In the recent case the lowest order self-energy corrections to the propagators of non-abelian gauge bosons correspond to bosonic loops since fermionic loops define propagators. Hence asymptotic freedom is suggestive.

2. The only fundamental vertex is  $AF\bar{F}$  vertex. As already found, there seems no point in attaching to the vertex an explicit gauge coupling constant  $g$ . If this is however done  $n$ -boson vertices defined by loops are proportional to  $g^n$ . In gauge theories  $n$ -boson vertices are proportional to  $g^{n-2}$  so that a formal consistency with the gauge theory picture is achieved for  $g = 1$ . In each internal boson line the  $g^2$  factor coming from the ends of the bosonic propagator line is canceled by the  $g^{-2}$  factor associated with the bosonic propagator. In S-matrix the division of the bosonic propagator from the external boson lines implies  $g^n$  proportionality of an  $n$ -point function involving  $n$  gauge bosons. This means asymmetry between fermions and bosons unless one has  $g = 1$ .  $g = 1$  above means  $g = \sqrt{\hbar_0}$ . Since fermionic propagator is proportional to  $\hbar_0^0$  and since loop integral involves the factor  $1/\hbar_0$ , the dimensions of bosonic propagator and radiatively generated vertices come out correctly. The counterparts of gauge coupling constants could be identified from the amplitudes for 2-fermion scattering by comparison with the predictions of standard gauge theories. The small value of effective gauge coupling  $g$  obtained in this manner would correspond to a large deviation of the normalization factor of the radiatively generated boson propagator from its standard value.
3. Furry's theorem holding true for Abelian gauge theories implies that all closed loops with an odd number of Abelian gauge boson insertions vanish. This conforms with the expectation that 3-vertices involving Abelian gauge bosons must vanish by gauge invariance. In the non-abelian case Furry's theorem does not hold true so that non-Abelian 3-boson vertices are obtained.

### 9.8.3 Generalization of the formalism to the super-symmetric case

In principle the generalization of the formula of generalized Feynmann diagrammatics to super-symmetric case at QFT limit of TGD is straightforward.

1. Consider first the standard formalism making sense only for  $\mathcal{N} = 1$  case in TGD framework. In this case the Kähler potential  $K(\Phi^\dagger, \exp(-V)\Phi)$  replaces Dirac action coupled to gauge potentials and the functional integral at the first step is over super-fields assigned to the fermions. Theta integrations gives the Lagrangian as function of components of super-fields and the free-field functional integral over the fields appearing in  $\Phi$  and  $\Phi^\dagger$  gives the action as a functional of gauge boson fields and their super-partners appearing in  $V$ . All vertices and propagators are expressible in terms of loops of fermions and their super-partners and gauge couplings and their evolution follow as predictions.
2. For the option based on TGD inspired generalization of super-fields the fundamental action is the generalization of Dirac action. As already found the propagators for chiral field components with  $d$  theta parameters behave as  $k^{-d}$  so that they do not induce divergences in fermionic loops. Also bosonic propagators for field components involving  $d$  thetas behave in similar manner. The possible divergences in the bosonic propagators would vanish by the same mechanism as in ordinary super-symmetry.

In the earlier approach the elimination of UV divergences required the introduction of cutoffs in mass squared and hyperbolic angle characterizing velocity of virtual fermion in the rest system of the virtual boson. The requirement that quadratic divergences are absent in the inverses of the propagators forced the hyperbolic cutoffs to be different for time-like and space-like momenta. The justification for hyperbolic cutoff was in terms of a geometric argument: the causal diamond ( $CD$ ) characterizing virtual fermion must remain inside the  $CD$  defining the IR cutoff. Super-symmetry could imply this cutoff in a smooth manner by the cancelation of the divergences associated with particles and their super-partners as already noticed.

## Chapter 10

# Generalized Feynman Graphs as Generalized Braids

### 10.1 Introduction

Ulla send me a link to an article by Sam Nelson about very interesting new-to-me notion known as algebraic knots [101, 57], which has initiated a revolution in knot theory. This notion was introduced 1996 by Louis Kauffman [95] so that it is already 15 year old concept. While reading the article I realized that this notion fits perfectly the needs of TGD and leads to a progress in attempts to articulate more precisely what generalized Feynman diagrams are. It should be added that the knots and braids are not anything new in TGD framework and I have considered knot theory from TGD point of view already earlier [?].

The basic challenge of quantum TGD is to give a precise content to the notion of generalization Feynman diagram and the reduction to braids of some kind is very attractive possibility inspired by zero energy ontology. The point is that no  $n > 2$ -vertices at the level of braid strands are needed if bosonic emergence holds true. In the following I will summarize briefly the vision about generalized Feynman diagrams, introduce the notion of algebraic knot, and after than discuss in more detail how the notion of algebraic knot could be applied to generalized Feynman diagrams.

1. The algebraic structures kei, quandle, rack, and biquandle and their algebraic modifications as such are not enough. The lines of Feynman graphs are replaced by braids and in vertices braid strands redistribute. This poses several challenges: the crossing associated with braiding and crossing occurring in non-planar Feynman diagrams should be integrated to a more general notion; braids are replaced with sub-manifold braids; braids of braids ...of braids are possible; the redistribution of braid strands in vertices should be algebraized. In the following I try to abstract the basic operations which should be algebraized in the case of generalized Feynman diagrams.
2. One should be also able to concretely identify braids and 2-braids (string world sheets) as well as partonic 2-surfaces and I have discussed several identifications during last years. Legendrian braids turn out to be very natural candidates for braids and their duals for the partonic 2-surfaces. String world sheets in turn could correspond to the analogs of Lagrangian sub-manifolds or to minimal surfaces of space-time surface satisfying the weak form of electric-magnetic duality. The latter option turns out to be more plausible. Finite measurement resolution would be realized as symplectic invariance with respect to the subgroup of the symplectic group leaving the end points of braid strands invariant. In accordance with the general vision TGD as almost topological QFT would mean symplectic QFT. The identification of braids, partonic 2-surfaces and string world sheets - if correct - would solve quantum TGD explicitly at string world sheet level in other words in finite measurement resolution.
3. Irrespective of whether the algebraic knots are needed, the natural question is what generalized Feynman diagrams are. It seems that the basic building bricks can be identified so that one can write rather explicit Feynman rules already now. Of course, the rules are still far from

something to be burned into the spine of the first year graduate student. A brief summary of generalized Feynman rules in zero energy ontology is proposed. This requires the identification of vertices, propagators, and prescription for integrating over all 3-surfaces. It turns out that the basic building blocks of generalized Feynman diagrams are well-defined.

4. The notion of generalized Feynman diagram leads to a beautiful duality between the descriptions of hadronic reactions in terms of hadrons and partons analogous to gauge-gravity duality and AdS/CFT duality but requiring no additional assumptions. The model of quark gluon plasma as a strongly interacting phase is proposed. Color magnetic flux tubes are responsible for the long range correlations making the plasma phase more like a very large hadron rather than a gas of partons. One also ends up with a simple estimate for the viscosity/entropy ratio using black-hole analogy.

## 10.2 Algebraic braids, sub-manifold braid theory, and generalized Feynman diagrams

Ulla send me a link to an article by Sam Nelson about very interesting new-to-me notion known as algebraic knots [101, 57], which has initiated a revolution in knot theory. This notion was introduced 1996 by Louis Kauffman [95] so that it is already 15 year old concept. While reading the article I realized that this notion fits perfectly the needs of TGD and leads to a progress in attempts to articulate more precisely what generalized Feynman diagrams are.

In the following I will summarize briefly the vision about generalized Feynman diagrams, introduce the notion of algebraic knot, and after that discuss in more detail how the notion of algebraic knot could be applied to generalized Feynman diagrams. The algebraic structures *kei*, *quandle*, *rack*, and *biquandle* and their algebraic modifications as such are not enough. The lines of Feynman graphs are replaced by braids and in vertices braid strands redistribute. This poses several challenges: the crossing associated with braiding and crossing occurring in non-planar Feynman diagrams should be integrated to a more general notion; braids are replaced with sub-manifold braids; braids of braids ...of braids are possible; the redistribution of braid strands in vertices should be algebraized. In the following I try to abstract the basic operations which should be algebraized in the case of generalized Feynman diagrams.

One should be also able to concretely identify braids and 2-braids (string world sheets) as well as partonic 2-surfaces and I have discussed several identifications during last years. Legendrian braids turn out to be very natural candidates for braids and their duals for the partonic 2-surfaces. String world sheets in turn could correspond to the analogs of Lagrangian sub-manifolds or to minimal surfaces of space-time surface satisfying the weak form of electric-magnetic duality. The latter option turns out to be more plausible. Finite measurement resolution would be realized as symplectic invariance with respect to the subgroup of the symplectic group leaving the end points of braid strands invariant. In accordance with the general vision TGD as almost topological QFT would mean symplectic QFT. The identification of braids, partonic 2-surfaces and string world sheets - if correct - would solve quantum TGD explicitly at string world sheet level in other words in finite measurement resolution.

Irrespective of whether the algebraic knots are needed, the natural question is what generalized Feynman diagrams are. It seems that the basic building bricks can be identified so that one can write rather explicit Feynman rules already now. Of course, the rules are still far from something to be burned into the spine of the first year graduate student.

### 10.2.1 Generalized Feynman diagrams, Feynman diagrams, and braid diagrams

**How knots and braids à la TGD differ from standard knots and braids?**

TGD approach to knots and braids differs from the knot and braid theories in given abstract 3-manifold (4-manifold in case of 2-knots and 2-braids) is that space-time is in TGD framework identified as 4-D surface in  $M^4 \times CP_2$  and preferred 3-surfaces correspond to light-like 3-surfaces defined by wormhole throats and space-like 3-surfaces defined by the ends of space-time sheets at the two light-like boundaries of causal diamond  $CD$ .

The notion of finite measurement resolution effectively replaces 3-surfaces of both kinds with braids and space-time surface with string world sheets having braid strands as their ends. The 4-dimensionality of space-time implies that string world sheets can be knotted and intersect at discrete points (counterpart of linking for ordinary knots). Also space-time surface can have self-intersections consisting of discrete points.

The ordinary knot theory in  $E^3$  involves projection to a preferred 2-plane  $E^2$  and one assigns to the crossing points of the projection an index distinguishing between two cases which are transformed to each other by violently taking the first piece of strand through another piece of strand. In TGD one must identify some physically preferred 2-dimensional manifold in imbedding space to which the braid strands are projected. There are many possibilities even when one requires maximal symmetries. An obvious requirement is however that this 2-manifold is large enough.

1. For the braids at the ends of space-time surface the 2-manifold could be large enough sphere  $S^2$  of light-cone boundary in coordinates in which the line connecting the tips of  $CD$  defines a preferred time direction and therefore unique light-like radial coordinate. In very small knots it could be also the geodesic sphere of  $CP_2$  (apart from the action of isometries there are two geodesic spheres in  $CP_2$ ).
2. For light-like braids the preferred plane would be naturally  $M^2$  for which time direction corresponds to the line connecting the tips of  $CD$  and spatial direction to the quantization axis of spin. Note that these axes are fixed uniquely and the choices of  $M^2$  are labelled by the points of projective sphere  $P^2$  telling the direction of space-like axis. Preferred plane  $M^2$  emerges naturally also from number theoretic vision and corresponds in octonionic pictures to hyper-complex plane of hyper-octonions. It is also forced by the condition that the choice of quantization axes has a geometric correlate both at the level of imbedding space geometry and the geometry of the "world of classical worlds".

The braid theory in TGD framework could be called sub-manifold braid theory and certainly differs from the standard one.

1. If the first homology group of the 3-surface is non-trivial as it when the light-like 3-surfaces represents an orbit of partonic 2-surface with genus larger than zero, the winding of the braid strand (wrapping of branes in M-theory) meaning that it represents a homologically non-trivial curve brings in new effects not described by the ordinary knot theory. A typical new situation is the one in which 3-surface is locally a product of higher genus 2-surface and line segment so that knot strand can wind around the 2-surface. This gives rise to what are called non-planar braid diagrams for which the projection to plane produces non-standard crossings.
2. In the case of 2-knots similar exotic effects could be due to the non-trivial 2-homology of space-time surface. Wormhole throats assigned with elementary particle wormhole throats are homologically non-trivial 2-surfaces and might make this kind of effects possible for 2-knots if they are possible.

The challenge is to find a generalization of the usual knot and braid theories so that they apply in the case of braids (2-braids) imbedded in 3-D (4-D) surfaces with preferred highly symmetry sub-manifold of  $M^4 \times CP_2$  defining the analog of plane to which the knots are projected. A proper description of exotic crossings due to non-trivial homology of 3-surface (4-surface) is needed.

### Basic questions

The questions are following.

1. How the mathematical framework of standard knot theory should be modified in order to cope with the situation encountered in TGD? To my surprise I found that this kind of mathematical framework exists: so called algebraic knots [101, 57] define a generalization of knot theory very probably able to cope with this kind of situation.
2. Second question is whether the generalized Feynman diagrams could be regarded as braid diagrams in generalized sense. Generalized Feynman diagrams are generalizations of ordinary

Feynman diagrams. The lines of generalized Feynman diagrams correspond to the orbits of wormhole throats and of wormhole contacts with throats carrying elementary particle quantum numbers.

The lines meet at vertices which are partonic 2-surfaces. Single wormhole throat can describe fermion whereas bosons have wormhole contacts with fermion and antifermion at the opposite throats as building bricks. It seems however that all fermions carry Kähler magnetic charge so that physical particles are string like objects with magnetic charges at their ends.

The short range of weak interactions results from the screening of the axial isospin by neutrinos at the other end of string like object and also color confinement could be understood in this manner. One cannot exclude the possibility that the length of magnetic flux tube is of order Compton length.

3. Vertices of the generalized Feynman diagrams correspond to the partonic 2-surfaces along which light-like 3-surfaces meet and this is certainly a challenge for the required generalization of braid theory. The basic objection against the reduction to algebraic braid diagrams is that reaction vertices for particles cannot be described by ordinary braid theory: the splitting of braid strands is needed.

The notion of bosonic emergence [56] however suggests that 3-vertex and possible higher vertices correspond to the splitting of braids rather than braid strands. By allowing braids which come from both past and future and identifying free fermions as wormhole throats and bosons as wormhole contacts consisting of a pair of wormhole throats carrying fermion and antifermion number, one can understand boson exchanges as recombinations without any need to have splitting of braid strands. Strictly and technically speaking, one would have tangles like objects instead of braids. This would be an enormous simplification since  $n > 2$ -vertices which are the source of divergences in QFT:s would be absent.

4. Non-planar Feynman diagrams are the curse of the twistor approach and I have already earlier proposed that the generalized Feynman amplitudes and perhaps even twistorial amplitudes could be constructed as analogs of knot invariants by recursively transforming non-planar Feynman diagrams to planar ones for which one can write twistor amplitudes. This forces to answer two questions.
  - (a) Does the non-nonplanarity of Feynman diagrams - completely combinatorial objects identified as diagrams in plane - have anything to do with the non-planarity of algebraic knot diagrams and with the non-planarity of generalized Feynman diagrams which are purely geometric objects?
  - (b) Could these two kind of non-planarities be fused to together by identifying the projection 2-plane as preferred  $M^2 \subset M^4$ . This would mean that non-planarity in QFT sense is defined for entire braids: braid A can have virtual crossing with B. Non-planarity in the sense of knot theory would be defined for braid strands inside the braids. At vertices braid strands are redistributed between incoming lines and the analog of virtual crossing be identifiable as an exchange of braid strand between braids. Several kinds of non-planarities would be present and the idea about gradual unknotting of a non-planar diagram so that a planar diagram results as the final outcome might make sense and allow to generalize the recursion recipe for the twistorial amplitudes.
  - (c) One might consider the possibility that inside orbits of wormhole throats defining the lines of Feynman diagrams the  $R$ -matrix for integrable QFT in  $M^2$  (only permutations of momenta are allowed) describes the dynamics so that one obtains just a permutation of momenta assigned to the braid strands. Ordinary braiding would be described by existing braid theories. The core problem would be the representation of the exchange of a strand between braids algebraically.

### 10.2.2 Brief summary of algebraic knot theory

#### Basic ideas of algebraic knot theory

In ordinary knot theory one takes as a starting point the representation of knots of  $E^3$  by their plane plane projections to which one attach a "color" to each crossing telling whether the strand goes over

or under the strand it crosses in planar projection. These numbers are fixed uniquely as one traverses through the entire knot in given direction.

The so called Reidemeister moves are the fundamental modifications of knot leaving its isotopy equivalence class unchanged and correspond to continuous deformations of the knot. Any algebraic invariant assignable to the knot must remain unaffected under these moves. Reidemeister moves as such look completely trivial and the non-trivial point is that they represent the minimum number of independent moves which are represented algebraically.

In algebraic knot theory topological knots are replaced by typographical knots resulting as planar projections. This mapping of topology to algebra and this is always fascinating. It turns out that the existing knot invariants generalize and ordinary knot theory can be seen as a special case of the algebraic knot theory. In a loose sense one can say that the algebraic knots are to the classical knot theory what algebraic numbers are to rational numbers.

Virtual crossing is the key notion of the algebraic knot theory. Virtual crossing and their rules of interaction were introduced 1996 by Louis Kauffman as basic notions [5]. For instance, a strand with only virtual crossings should be replaceable by any strand with the same number of virtual crossings and same end points. Reidemeister moves generalize to virtual moves. One can say that in this case crossing is self-intersection rather than going under or above. I cannot be eliminated by a small deformation of the knot. There are actually several kinds of non-standard crossings: examples listed in figure 7 of [101]) are virtual, flat, singular, and twist bar crossings.

Algebraic knots have a concrete geometric interpretation.

1. Virtual knots are obtained if one replaces  $E^3$  as imbedding space with a space which has non-trivial first homology group. This implies that knot can represent a homologically non-trivial curve giving an additional flavor to the unknottedness since homologically non-trivial curve cannot be transformed to a curve which is homologically non-trivial by any continuous deformation.
2. The violent projection to plane leads to the emergence of virtual crossings. The product  $(S^1 \times S^1) \times D$ , where  $(S^1 \times S^1)$  is torus  $D$  is finite line segment, provides the simplest example. Torus can be identified as a rectangle with opposite sides identified and homologically non-trivial knots correspond to curves winding  $n_1$  times around the first  $S^1$  and  $n_2$  times around the second  $S^1$ . These curves are not continuous in the representation where  $S^1 \times S^1$  is rectangle in plane.
3. A simple geometric visualization of virtual crossing is obtained by adding to the plane a handle along which the second strand traverses and in this manner avoids intersection. This visualization allows to understand the geometric motivation for the the virtual moves.

This geometric interpretation is natural in TGD framework where the plane to which the projection occurs corresponds to  $M^2 \subset M^4$  or is replaced with the sphere at the boundary of  $S^2$  and 3-surfaces can have arbitrary topology and partonic 2-surfaces defining as their orbits light-like 3-surfaces can have arbitrary genus.

In TGD framework the situation is however more general than represented by sub-manifold braid theory. Single braid represents the line of generalized Feynman diagram. Vertices represent something new: in the vertex the lines meet and the braid strands are redistributed but do not disappear or pop up from anywhere. That the braid strands can come both from the future and past is also an important generalization. There are physical arguments suggesting that there are only 3-vertices for braids but not higher ones [18]. The challenge is to represent algebraically the vertices of generalized Feynman diagrams.

### Algebraic knots

The basic idea in the algebraization of knots is rather simple. If  $x$  and  $y$  are the crossing portions of knot, the basic algebraic operation is binary operation giving "the result of  $x$  going under  $y$ ", call it  $x \triangleright y$  telling what happens to  $x$ . "Portion of knot" means the piece of knot between two crossings and  $x \triangleright y$  denotes the portion of knot next to  $x$ . The definition is asymmetrical in  $x$  and  $y$  and the dual of the operation would be  $y \triangleleft x$  would be "the result of  $y$  going above  $x$ ". One can of course ask, why not to define the outcome of the operation as a pair  $(x \triangleleft y, y \triangleright x)$ . This operation would be bi-local in a well-defined sense. One can of course do this: in this case one has binary operation from  $X \times X \rightarrow X \times X$  mapping pairs of portions to pairs of portions. In the first case one has binary operation  $X \times X \rightarrow X$ .

The idea is to abstract this basic idea and replace  $X$  with a set endowed with operation  $\triangleright$  or  $\triangleleft$  or both and formulate the Reidemeister conditions given as conditions satisfied by the algebra. One ends up to four basic algebraic structures kei, quandle, rack, and biquandle.

1. In the case of non-oriented knots the kei is the algebraic structure. Kei - or inventory quandle-is a set  $X$  with a map  $X \times X \rightarrow X$  satisfying the conditions

- (a)  $x \triangleright x = x$  (idempotency, one of the Reidemeister moves)
- (b)  $(x \triangleright y) \triangleright y = x$  (operation is its own right inverse having also interpretation as Reidemeister move)
- (c)  $(x \triangleright y) \triangleright z = (x \triangleright z) \triangleright (y \triangleright z)$  (self-distributivity)

$Z[t]/(t^2)$  module with  $x \triangleright y = tx + (1 - t)y$  is a kei.

2. For orientable knot diagram there is preferred direction of travel along knot and one can distinguish between  $\triangleright$  and its right inverse  $\triangleright^{-1}$ . This gives quandle satisfying the axioms

- (a)  $x \triangleright x = x$
- (b)  $(x \triangleright y) \triangleright^{-1} y = (x \triangleright^{-1} y) \triangleright y = x$
- (c)  $(x \triangleright y) \triangleright z = (x \triangleright z) \triangleright (y \triangleright z)$

$Z[t^{\pm 1}]$  module with  $x \triangleright y = tx + (1 - t)y$  is a quandle.

3. One can also introduce framed knots: intuitively one attaches to a knot very near to it. More precise formulation in terms of a section of normal bundle of the knot. This makes possible to speak about self-linking. Reidemeister moves must be modified appropriately. In this case rack is the appropriate structure. It satisfies the axioms of quandle except the first axiom since corresponding operation is not a move anymore. Rack axioms are equivalent with the requirement that functions  $f_y : X \rightarrow X$  defined by  $f_y(x) = x \triangleright y$  are automorphisms of the structure. Therefore the elements of rack represent its morphisms. The modules over  $Z[t^{\pm 1}, s]/s(t + s - 1)$  are racks. Coxeter racks are inner product spaces with  $x \triangleright y$  obtained by reflecting  $x$  across  $y$ .
4. Biquandle consists of arcs connecting the subsequent crossings (both under- and over-) of oriented knot diagram. Biquandle operation is a map  $B : X \times X \rightarrow X \times X$  of order pairs satisfying certain invertibility conditions together with set theoretic Yang-Baxter equation:

$$(B \times I)(I \times B)(B \times I) = (I \times B)(B \times I)(I \times B) .$$

Here  $I : X \rightarrow X$  is the identity map. The three conditions to which Yang-Baxter equation decomposes gives the counterparts of the above discussed axioms. Alexander biquandle is the module  $Z[t^{\pm 1}, s^{\pm 1}]$  with  $B(x, y) = (ty + (1 - ts)x, sx)$  where one has  $s \neq 1$ . If one includes virtual, flat and singular crossings one obtains virtual/singular aundles and semiquandles.

### 10.2.3 Generalized Feynman diagrams as generalized braid diagrams?

Zero energy ontology suggests the interpretation of the generalized Feynman diagrams as generalized braid diagrams so that there would be no need for vertices at the fundamental braid strand level. The notion of algebraic braid (or tangle) might allow to formulate this idea more precisely.

#### Could one fuse the notions of braid diagram and Feynman diagram?

The challenge is to fuse the notions of braid diagram and Feynman diagram having quite different origin.

1. All generalized Feynman diagrams are reduced to sub-manifold braid diagrams at microscopic level by bosonic emergence (bosons as pairs of fermionic wormhole throats). Three-vertices appear only for entire braids and are purely topological whereas braid strands carrying quantum numbers are just re-distributed in vertices. No 3-vertices at the really microscopic level! This is an additional nail to the coffin of divergences in TGD Universe.

2. By projecting the braid strands of generalized Feynman diagrams to preferred plane  $M^2 \subset M^4$  (or rather 2-D causal diamond), one could achieve a unified description of non-planar Feynman diagrams and braid diagrams. For Feynman diagrams the intersections have a purely combinatorial origin coming from representations as 2-D diagrams.

For braid diagrams the intersections have different origin and non-planarity has different meaning. The crossings of entire braids analogous to those appearing in non-planar Feynman diagrams should define one particular exotic crossing besides virtual crossings of braid strands due to non-trivial first homology of 3-surfaces.

3. The necessity to choose preferred plane  $M^2$  looks strange from QFT point of view. In TGD framework it is forced by the number theoretic vision in which  $M^2$  represents hyper-complex plane of sub-space of hyper-octonions which is subspace of complexified octonions. The choice of  $M^2$  is also forced by the condition that the choice of quantization axes has a geometric correlate both at the level of imbedding space geometry and the geometry of the "world of classical worlds".
4. Also 2-braid diagrams defined as projections of string world sheets are suggestive and would be defined by a projections to the 3-D boundary of  $CD$  or to  $M^3 \subset M^4$ . They would provide a more concrete stringy illustration about generalized Feynman diagram as analog of string diagram. Another attractive illustration is in terms of dance metaphor with the boundary of  $CD$  defining the 3-D space-like parquette. The duality between space-like and light-like braids is expected to be of importance.

The obvious conjecture is that Feynman amplitudes are analogous to knot invariants constructible by gradually reducing non-planar Feynman diagrams to planar ones after which the already existing twistor theoretical machinery of  $\mathcal{N} = 4$  SYMs would apply [82].

### Does 2-D integrable QFT dictate the scattering inside the lines of generalized Feynman diagrams

The preferred plane  $M^2$  (more precisely, 2-D causal diamond having also interpretation as Penrose diagram) plays a key role as also the preferred sphere  $S^2$  at the boundary of  $CD$ . It is perhaps not accident that a generalization of braiding was discovered in integrable quantum field theories in  $M^2$ . The S-matrix of this theory is rather trivial looking: particle moving with different velocities cross each other and suffer a phase lag and permutation of 2-momenta which has physical effects only in the case of non-identical particles. The  $R$ -matrix describing this process reduces to the  $R$ -matrix describing the basic braiding operation in braid theories at the static limit.

I have already earlier conjectured that this kind of integrable QFT is part of quantum TGD [20]. The natural guess is that it describes what happens for the projections of 4-momenta in  $M^2$  in scattering process inside lines of generalized Feynman diagrams. If integrable theories in  $M^2$  control this scattering, it would cause only phase changes and permutation of the  $M^2$  projections of the 4-momenta. The most plausible guess is that  $M^2$  QFT characterized by  $R$ -matrix describes what happens to the braid momenta during the free propagation and the remaining challenge would be to understand what happens in the vertices defined by 2-D partonic surfaces at which re-distribution of braid strands takes place.

### How quantum TGD as almost topological QFT differs from topological QFT for braids and 3-manifolds

One must distinguish between two topological QFTs. These correspond to topological QFT defining braid invariants and invariants of 3-manifolds respectively. The reason is that knots are an essential element in the procedure yielding 3-manifolds. Both 3-manifold invariants and knot invariants would be defined as Wilson loops involving path integral over gauge connections for a given 3-manifold with exponent of non-Abelian Chern-Simons action defining the weight.

1. In TGD framework the topological QFT producing braid invariants for a given 3-manifold is replaced with sub-manifold braid theory. Kähler action reduces Chern-Simons terms for preferred extremals and only these contribute to the functional integral. What is the counterpart of

topological invariance in this framework? Are general isotopies allowed or should one allow only sub-group of symplectic group of  $CD$  boundary leaving the end points of braids invariant? For this option Reidemeister moves are undetectable in the finite measurement resolution defined by the subgroup of the symplectic group. Symplectic transformations would not affect 3-surfaces as the analogs of abstract contact manifold since induced Kähler form would not be affected and only the imbedding would be changed.

In the approach based on inclusions of HFFs gauge invariance or its generalizations would represent finite measurement resolution (the action of included algebra would generate states not distinguishable from the original one).

2. There is also ordinary topological QFT allowing to construct topological invariants for 3-manifold. In TGD framework the analog of topological QFT is defined by Chern-Simons-Kähler action in the space of preferred 3-surfaces. Now one sums over small deformations of 3-surface instead of gauge potentials. If extremals of Chern-Simons-Kähler action are in question, symplectic invariance is the most that one can hope for and this might be the situation quite generally. If all light-like 3-surfaces are allowed so that only weak form of electric-magnetic duality at them would bring metric into the theory, it might be possible to have topological invariance at 3-D level but not at 4-D level. It however seems that symplectic invariance with respect to subgroup leaving end points of braids invariant is the realistic expectation.

### Could the allowed braids define Legendrian sub-manifolds of contact manifolds?

The basic questions concern the identification of braids and 2-braids. In quantum TGD they cannot be arbitrary but determined by dynamics providing space-time correlates for quantum dynamics. The deformations of braids should mean also deformations of 3-surfaces which as topological manifolds would however remain as such. Therefore topological QFT for given 3-manifold with path integral over gauge connections would in TGD correspond to functional integral of 3-surfaces corresponding to same topology even symplectic structure. The quantum fluctuating degrees of freedom indeed correspond to symplectic group divided by its subgroup defining measurement resolution.

What is the dynamics defining the braids strands? What selects them? I have considered this problem several times. Just two examples is enough here.

1. Could they be some special light-like curves? Could the condition that the end points of the curves correspond to rational points in some preferred coordinates allow to select these light-like curves? But what about light-like curves associated with the ends of the space-time surface?
2. The solutions of modified Dirac equation [28] are localized to curves by using the analog of periodic boundary conditions: the length of the curve is quantized in the effective metric defined by the modified gamma matrices. Here one however introduced a coordinate along light-like 3-surface and it is not clear how one should fix this preferred coordinate.

#### 1. Legendrian and Lagrangian sub-manifolds

A hint about what is missing comes from the observation that a non-vanishing Chern-Simons-Kähler form  $A$  defines a contact structure [8] at light-like 3-surfaces if one has  $A \wedge dA \neq 0$ . This condition states complete non-integrability of the distribution of 2-planes defined by the condition  $A_\mu t^\mu = 0$ , where  $t$  is tangent vector in the tangent bundle of light-like 3-surface. It also states that the flow lines of  $A$  do *not* define global coordinate varying along them.

1. It is however possible to have 1-dimensional curves for which  $A_\mu t^\mu = 0$  holds true at each point. These curves are known as Legendrian sub-manifolds to be distinguished from Lagrangian manifolds for which the projection of symplectic form expressible locally as  $J = dA$  vanishes. The set of this curves is discrete so that one obtains braids. Legendrian knots are the simplest example of Legendrian sub-manifolds and the question is whether braid strands could be identified as Legendrian knots. For Legendrian braids symplectic invariance replaces topological invariance and Legendrian knots and braids can be trivial in topological sense. In some situations the property of being Legendrian implies un-knottedness.

2. For Legendrian braid strands the Kähler gauge potential vanishes. Since the solutions of the modified Dirac equation are localized to braid strands, this means that the coupling to Kähler gauge potential vanishes. From physics point of view a generalization of Legendre braid strand by allowing gauge transformations  $A \rightarrow A + d\Phi$  looks natural since it means that the coupling of induced spinors is pure gauge terms and can be eliminated by a gauge transformation.

2. 2-D duals of Legendrian sub-manifolds

One can consider also what might be called 2-dimensional duals of Legendrian sub-manifolds.

1. Also the one-form obtained from the dual of Kähler magnetic field defined as  $B^\mu = \epsilon^{\mu\nu\gamma} J_{\nu\gamma}$  defines a distribution of 2-planes. This vector field is ill-defined for light-like surfaces since contravariant metric is ill-defined. One can however multiply  $B$  with the square root of metric determining formally so that metric would disappear completely just as it disappears from Chern-Simons action. This looks however somewhat tricky mathematically. At the 3-D space-like ends of space-time sheets at boundaries of  $CD$   $B^\mu$  is however well-defined as such.
2. The distribution of 2-planes is integrable if one has  $B \wedge dB = 0$  stating that one has Beltrami field: physically the conditions states that the current  $dB$  feels no Lorentz force. The geometric content is that  $B$  defines a global coordinate varying along its flow lines. For the preferred extremals of Kähler action Beltrami condition is satisfied by isometry currents and Kähler current in the interior of space-time sheets. If this condition holds at 3-surfaces, one would have an global time coordinate and integrable distribution of 2-planes defining a slicing of the 2-surface. This would realize the conjecture that space-time surface has a slicing by partonic 2-surfaces. One could say that the 2-surfaces defined by the distribution are orthogonal to  $B$ . This need not however mean that the projection of  $J$  to these 2-surfaces vanishes. The condition  $B \wedge dB = 0$  on the space-like 3-surfaces could be interpreted in terms of effective 2-dimensionality. The simplest option posing no additional conditions would allow two types of braids at space-like 3-surfaces and only Legendrian braids at light-like 3-surfaces.

These observations inspire a question. Could it be that the conjectured dual slicings of space-time sheets by space-like partonic 2-surfaces and by string world sheets are defined by  $A_\mu$  and  $B^\mu$  respectively associated with slicings by light-like 3-surfaces and space-like 3-surfaces? Could partonic 2-surfaces be identified as 2-D duals of 1-D Legendrian sub-manifolds?

The identification of braids as Legendrian braids for light-like 3-surfaces and with Legendrian braids or their duals for space-like 3-surfaces would in turn imply that topological braid theory is replaced with a symplectic braid theory in accordance with the view about TGD as almost topological QFT. If finite measurement resolution corresponds to the replacement of symplectic group with the coset space obtained by dividing by a subgroup, symplectic subgroup would take the role of isotopies in knot theory. This symplectic subgroup could be simply the symplectic group leaving the end points of braids invariant.

**An attempt to identify the constraints on the braid algebra**

The basic problems in understanding of quantum TGD are conceptual. One must proceed by trying to define various concepts precisely to remove the many possible sources of confusion. With this in mind I try collect essential points about generalized Feynman diagrams and their relation to braid diagrams and Feynman diagrams and discuss also the most obvious constraints on algebraization.

Let us first summarize what generalized Feynman diagrams are.

1. Generalized Feynman diagrams are 3-D (or 4-D, depends on taste) objects inside  $CD \times CP_2$ . Ordinary Feynman diagrams are in plane. If finite measurement resolution has as a space-time correlate discretization at the level of partonic 2-surfaces, both space-like and light-like 3-surfaces reduce to braids and the lines of generalized Feynman diagrams correspond to braids. It is possible to obtain the analogs of ordinary Feynman diagrams by projection to  $M^2 \subset M^4$  defined uniquely for given  $CD$ . The resulting apparent intersections would represent ne particular kind of exotic intersection.

2. Light-like 3-surfaces define the lines of generalized Feynman diagrams and the braiding results naturally. Non-trivial first homology for the orbits of partonic 2-surfaces with genus  $g > 0$  could be called homological virtual intersections.
3. It zero energy ontology braids must be characterized by time orientation. Also it seems that one must distinguish in zero energy ontology between on mass shell braids and off mass shell braid pairs which decompose to pairs of braids with positive and negative energy massless on mass shell states. In order to avoid confusion one should perhaps speak about tangles inside  $CD$  rather than braids. The operations of the algebra are same except that the braids can end either to the upper or lower light-like boundary of  $CD$ . The projection to  $M^2$  effectively reduces the  $CD$  to a 2-dimensional causal diamond.
4. The vertices of generalized Feynman diagrams are partonic 2-surfaces at which the light-like 3-surfaces meet. This is a new element. If the notion of bosonic emergence is accepted no  $n > 2$ -vertices are needed so that braid strands are redistributed in the reaction vertices. The redistribution of braid strands in vertices must be introduced as an additional operation somewhat analogous to  $\triangleright$  and the challenge is to reduce this operation to something simple. Perhaps the basic operation reduces to an exchange of braid strand between braids. The process can be seen as a decay of of braid with the conservation of braid strands with strands from future and past having opposite strand numbers. Also for this operation the analogs of Reidemeister moves should be identified. In dance metaphor this operation corresponds to a situation in which the dancer leaves the group to which it belongs and goes to a new one.
5. A fusion of Feynman diagrammatic non-planarity and braid theoretic non-planarity is needed and the projection to  $M^2$  could provide this fusion when at least two kinds of virtual crossings are allowed. The choice of  $M^2$  could be global. An open question is whether the choice of  $M^2$  could characterize separately each line of generalized Feynman diagram characterized by the four-momentum associated with it in the rest system defined by the tips of  $CD$ . Somehow the theory should be able to fuse the braiding matrix for integrable QFT in  $M^2$  applying to entire braids with the braiding matrix for braid theory applying at the level of single braid.

Both integral QFTs in  $M^2$  and braid theories suggest that biquandle structure is the structure that one should try to generalized.

1. The representations of resulting bi-quandle like structure could allow abstract interesting information about generalized Feynman diagrams themselves but the dream is to construct generalized Feynman diagrams as analogs of knot invariants by a recursive procedure analogous to un-knotting of a knot.
2. The analog of bi-quandle algebra should have a hierarchical structure containing braid strands at the lowest level, braids at next level, and braids of braids...of braids at higher levels. The notion of operad would be ideal for formulating this hierarchy and I have already proposed that this notion must be essential for the generalized Feynman diagrammatics. An essential element is the vanishing of total strand number in the vertex (completely analogous to conserved charged such as fermion number). Again a convenient visualization is in terms of dancers forming dynamical groups, forming groups of groups forming .....

I have already earlier suggested [20] that the notion of operad [23] relying on permutation group and its subgroups acting in tensor products of linear spaces is central for understanding generalized Feynman diagrams.  $n \rightarrow n_1 + n_2$  decay vertex for  $n$ -braid would correspond to "symmetry breaking"  $S_n \rightarrow S_{n_1} \times S_{n_2}$ . Braid group represents the covering of permutation group so that braid group and its subgroups permuting braids would suggest itself as the basic group theoretical notion. One could assign to each strand of  $n$ -braid decaying to  $n_1$  and  $n_2$  braids a two-valued color telling whether it becomes a strand of  $n_1$ -braid or  $n_2$ -braid. Could also this "color" be interpreted as a particular kind of exotic crossing?

3. What could be the analogs of Reidemeister moves for braid strands?
  - (a) If the braid strands are dynamically determined, arbitrary deformations are not possible. If however all isotopy classes are allowed, the interpretation would be that a kind of gauge

choice selecting one preferred representation of strand among all possible ones obtained by continuous deformations is in question.

- (b) Second option is that braid strands are dynamically determined within finite measurement resolution so that one would have braid theory in given length scale resolution.
  - (c) Third option is that topological QFT is replaced with symplectic QFT: this option is suggested by the possibility to identify braid strands as Legendrian knots or their duals. Subgroup of the symplectic group leaving the end points of braids invariant would act as the analog of continuous transformations and play also the role of gauge group. The new element is that symplectic transformations affect partonic 2-surfaces and space-time surfaces except at the end points of braid.
4. Also 2-braids and perhaps also 2-knots could be useful and would provide string theory like approach to TGD. In this case the projections could be performed to the ends of  $CD$  or to  $M^3$ , which can be identified uniquely for a given  $CD$ .
  5. There are of course many additional subtleties involved. One should not forget loop corrections, which naturally correspond to sub- $CD$ s. The hierarchy of Planck constants and number theoretical universality bring in additional complexities.

All this looks perhaps hopelessly complex but the Universe around is complex even if the basic principles could be very simple.

#### 10.2.4 About string world sheets, partonic 2-surfaces, and two-knots

String world sheets and partonic 2-surfaces provide a beautiful visualization of generalized Feynman diagrams as braids and also support for the duality of string world sheets and partonic 2-surfaces as duality of light-like and space-like braids. Dance metaphor is very helpful here.

1. The projection of string world sheets and partonic 2-surfaces to 3-D space replaces knot projection. In TGD context this 3-D of space could correspond to the 3-D light-like boundary of  $CD$  and 2-knot projection would correspond to the projection of the braids associated with the lines of generalized Feynman diagram. Another identification would be as  $M^1 \times E^2$ , where  $M^1$  is the line connecting the tips of  $CD$  and  $E^2$  the orthogonal complement of  $M^2$ .
2. Using dance metaphor for light-like braiding, braids assignable to the lines of generalized Feynman diagrams would correspond to groups of dancers. At vertices the dancing groups would exchange members and completely new groups would be formed by the dancers. The number of dancers (negative for those dancing in the reverse time direction) would be conserved. Dancers would be connected by threads representing strings having braid points at their ends. During the dance the light-like braiding would induce space-like braiding as the threads connecting the dancers would get entangled. This would suggest that the light-like braids and space-like braidings are equivalent in accordance with the conjectured duality between string-world sheets and partonic 2-surfaces. The presence of genuine 2-knottedness could spoil this equivalence unless it is completely local.

Can string world sheets and partonic 2-surfaces get knotted?

1. Since partonic 2-surfaces (wormhole throats) are imbedded in light-cone boundary, the preferred 3-D manifolds to which one can project them is light-cone boundary (boundary of  $CD$ ). Since the projection reduces to inclusion these surfaces cannot get knotted. Only if the partonic 2-surfaces contains in its interior the tip of the light-cone something non-trivial identifiable as virtual 2-knottedness is obtained.
2. One might argue that the conjectured duality between the descriptions provided by partonic 2-surfaces and string world sheets requires that also string world sheets represent trivial 2-braids. I have shown earlier that nontrivial local knots glued to the string world sheet require that  $M^4$  time coordinate has a local maximum. Does this mean that 2-knots are excluded? This is not obvious: TGD allows also regions of space-time surface with Euclidian signature and generalized Feynman graphs as 4-D space-time regions are indeed Euclidian. In these regions string world sheets could get knotted.

What happens for knot diagrams when the dimension of knot is increased to two? According to the articles of Nelson [101] and Carter [57] the crossings for the projections of braid strands are replaced with more complex singularities for the projections of 2-knots. One can decompose the 2-knots to regions surrounded by boxes. Box can contain just single piece of 2-D surface; it can contain two intersection pieces of 2-surfaces as the counterpart of intersecting knot strands and one can tell which of them is above which; the box can contain also a discrete point in the intersection of projections of three disjoint regions of knot which consists of discrete points; and there is also a box containing so called cone point. Unfortunately, I failed to understand the meaning of the cone point.

For 2-knots Reidemeister moves are replaced with Roseman moves. The generalization would allow virtual self intersections for the projection and induced by the non-trivial second homology of 4-D imbedding space. In TGD framework elementary particles have homologically non-trivial partonic 2-surfaces (magnetic monopoles) as their building bricks so that even if 2-knotting in standard sense might be not allowed, virtual 2-knotting would be possible. In TGD framework one works with a subgroup of symplectic transformations defining measurement resolution instead of isotopies and this might reduce the number of allowed mov

### The dynamics of string world sheets and the expression for Kähler action

The dynamics of string world sheets is an open question. Effective 2-dimensionality suggests that Kähler action for the preferred extremal should be expressible using 2-D data but there are several guesses for what the explicit expression could be, and one can only make only guesses at this moment and apply internal consistency conditions in attempts to kill various options.

#### 1. *Could weak form of electric-magnetic duality hold true for string world sheets?*

If one believes on duality between string world sheets and partonic 2-surfaces, one can argue that string world sheets are most naturally 2-surfaces at which the weak form of electric magnetic duality holds true. One can even consider the possibility that the weak form of electric-magnetic duality holds true only at the the string world sheets and partonic 2-surfaces but not at the preferred 3-surfaces.

1. The weak form of electric magnetic duality would mean that induced Kähler form is non-vanishing at them and Kähler magnetic flux over string world sheet is proportional to Kähler electric flux.
2. The flux of the induced Kähler form of  $CP_2$  over string world sheet would define a dimensionless "area". Could Kähler action for preferred extremals reduces to this flux apart from a proportionality constant. This "area" would have trivially extremum with respect to symplectic variations if the braid strands are Legendrian sub-manifolds since in this case the projection of Kähler gauge potential on them vanishes. This is a highly non-trivial point and favors weak form of electric-magnetic duality and the identification of Kähler action as Kähler magnetic flux. This option is also in spirit with the vision about TGD as almost topological QFT meaning that induced metric appears in the theory only via electric-magnetic duality.
3. Kähler magnetic flux over string world sheet has a continuous spectrum so that the identification as Kähler action could make sense. For partonic 2-surfaces the magnetic flux would be quantized and give constant term to the action perhaps identifiable as the contribution of  $CP_2$  type vacuum extremals giving this kind of contribution.

The change of space-time orientation by changing the sign of permutation symbol would change the sign in electric-magnetic duality condition and would not be a symmetry. For a given magnetic charge the sign of electric charge changes when orientation is changed. The value of Kähler action does not depend on space-time orientation but weak form of electric-magnetic duality as boundary condition implies dependence of the Kähler action on space-time orientation. The change of the sign of Kähler electric charge suggests the interpretation of orientation change as one aspect of charge conjugation. Could this orientation dependence be responsible for matter antimatter asymmetry?

#### 2. *Could string world sheets be Lagrangian sub-manifolds in generalized sense?*

Legendrian sub-manifolds can be lifted to Lagrangian sub-manifolds [8] Could one generalize this by replacing Lagrangian sub-manifold with 2-D sub-manifold of space-times surface for which the projection of the induced Kähler form vanishes? Could string world sheets be Lagrangian sub-manifolds?

I have also proposed that the inverse image of homologically non-trivial sphere of  $CP_2$  under imbedding map could define counterparts of string world sheets or partonic 2-surfaces. This conjecture does not work as such for cosmic strings, massless extremals having 2-D projection since the inverse image is in this case 4-dimensional. The option based on homologically non-trivial geodesic sphere is not consistent with the identification as analog of Lagrangian manifold but the identification as the inverse image of homologically trivial geodesic sphere is.

The most general option suggested is that string world sheet is mapped to 2-D Lagrangian sub-manifold of  $CP_2$  in the imbedding map. This would mean that theory is exactly solvable at string world sheet level. Vacuum extremals with a vanishing induced Kähler form would be exceptional in this framework since they would be mapped as a whole to Lagrangian sub-manifolds of  $CP_2$ . The boundary condition would be that the boundaries of string world sheets defined by braids at preferred 3-surfaces are Legendrian sub-manifolds. The generalization would mean that Legendrian braid strands could be continued to Lagrangian string world sheets for which induced Kähler form vanishes. The physical interpretation would be that if particle moves along this kind of string world sheet, it feels no covariant Lorentz-Kähler force and contra variant Lorentz forces is orthogonal to the string world sheet.

There are however serious objections.

1. This proposal does not respect the proposed duality between string world sheets and partonic 2-surfaces which as carries of Kähler magnetic charges cannot be Lagrangian 2-manifolds.
2. One loses the elegant identification of Kähler action as Kähler magnetic flux since Kähler magnetic flux vanishes. Apart from proportionality constant Kähler electric flux

$$\int_{Y^2} *J$$

is as a dimensionless scaling invariant a natural candidate for Kähler action but need not be extremum if braids are Legendrian sub-manifolds whereas for Kähler magnetic flux this is the case. There is however an explicit dependence on metric which does not conform with the idea that almost topological QFT is symplectic QFT.

3. The sign factor of the dual flux which depends on the orientation of the string world sheet and thus changes sign when the orientation of space-time sheet is changed by changing that of the string world sheet. This is in conflict with the independence of Kähler action on orientation. One can however argue that the orientation makes itself actually physically visible via the weak form of electric-magnetic duality. If the above discussed duality holds true, the net contribution to Kähler action would vanish as the total Kähler magnetic flux for partonic 2-surfaces. Therefore the duality cannot hold true if Kähler action reduces to dual flux.
4. There is also a purely formal counter argument. The inverse images of Lagrangian sub-manifolds of  $CP_2$  can be 4-dimensional (cosmic strings and massless extremals) whereas string world sheets are 2-dimensional.

### String world sheets as minimal surfaces

Effective 2-dimensionality suggests a reduction of Kähler action to Chern-Simons terms to the area of minimal surfaces defined by string world sheets holds true [35]. Skeptic could argue that the expressibility of Kähler action involving no dimensional parameters except  $CP_2$  scaled does not favor this proposal. The connection of minimal surface property with holomorphy and conformal invariance however forces to take the proposal seriously and it is easy to imagine how string tension emerges since the size scale of  $CP_2$  appears in the induced metric [35].

One can ask whether the minimal surface property conforms with the proposal that string worlds sheets obey the weak form of electric-magnetic duality and with the proposal that they are generalized Lagrangian sub-manifolds.

1. The basic answer is simple: minimal surface property and possible additional conditions (Lagrangian sub-manifold property or the weak form of electric magnetic duality) poses only additional conditions forcing the space-time sheet to be such that the imbedded string world sheet is

a minimal surface of space-time surface: minimal surface property is a condition on space-time sheet rather than string world sheet. The weak form of electric-magnetic duality is favored because it poses conditions on the first derivatives in the normal direction unlike Lagrangian sub-manifold property.

2. Any proposal for 2-D expression of Kähler action should be consistent with the proposed real-octonion analytic solution ansatz for the preferred extremals [8]. The ansatz is based on real-octonion analytic map of imbedding space to itself obtained by algebraically continuing real-complex analytic map of 2-D sub-manifold of imbedding space to another such 2-D sub-manifold. Space-time surface is obtained by requiring that the "imaginary" part of the map vanishes so that image point is hyper-quaternion valued. Wick rotation allows to formulate the conditions using octonions and quaternions. Minimal surfaces (of space-time surface) are indeed objects for which the imbedding maps are holomorphic and the real-octonion analyticity could be perhaps seen as algebraic continuation of this property.
3. Does Kähler action for the preferred extremals reduce to the area of the string world sheet or to Kähler magnetic flux or are the representations equivalent so that the induced Kähler form would effectively define area form? If the Kähler form associated with the induced metric on string world sheet is proportional to the induced Kähler form the Kähler magnetic flux is proportional to the area and Kähler action reduces to genuine area. Could one pose this condition as an additional constraint on string world sheets? For Lagrangian sub-manifolds Kähler electric field should be proportional to the area form and the condition involves information about space-time surface and is therefore more complex and does not look plausible.

### Explicit conditions expressing the minimal surface property of the string world sheet

It is instructive to write explicitly the condition for the minimal surface property of the string world sheet and for the reduction of the area Kähler form to the induced Kähler form. For string world sheets with Minkowskian signature of the induced metric Kähler structure must be replaced by its hyper-complex analog involving hyper-complex unit  $e$  satisfying  $e^2 = 1$  but replaced with real unit at the level hyper-complex coordinates.  $e$  can be represented as antisymmetric Kähler form  $J_g$  associated with the induced metric but now one has  $J_g^2 = g$  instead of  $J_g^2 = -g$ . The condition that the signed area reduces to Kähler electric flux means that  $J_g$  must be proportional to the induced Kähler form:  $J_g = kJ$ ,  $k = \text{constant}$  in a given space-time region.

One should make an educated guess for the imbedding of the string world sheet into a preferred extremal of Kähler action. To achieve this it is natural to interpret the minimal surface property as a condition for the preferred Kähler extremal in the vicinity of the string world sheet guaranteeing that the sheet is a minimal surface satisfying  $J_g = kJ$ . By the weak form of electric-magnetic duality partonic 2-surfaces represent both electric and magnetic monopoles. The weak form of electric-magnetic duality requires for string world sheets that the Kähler magnetic field at string world sheet is proportional to the component of the Kähler electric field parallel to the string world sheet. Kähler electric field is assumed to have component only in the direction of string world sheet.

#### 1. Minkowskian string world sheets

Let us try to formulate explicitly the conditions for the reduction of the signed area to Kähler electric flux in the case of Minkowskian string world sheets.

1. Let us assume that the space-time surface in Minkowskian regions has coordinates  $(u, v, w, \bar{w})$  [8]. The pair  $(u, v)$  defines light-like coordinates at the string world sheet having identification as hyper-complex coordinates with hyper-complex unit satisfying  $e = 1$ .  $u$  and  $v$  need not - nor cannot as it turns out - be light-like with respect to the metric of the space-time surface. One can use  $(u, v)$  as coordinates for string world sheet and assume that  $w = x^1 + ix^2$  and  $\bar{w}$  are constant for the string world sheet. Without a loss of generality one can assume  $w = \bar{w} = 0$  at string world sheet.
2. The induced Kähler structure must be consistent with the metric. This implies that the induced metric satisfies the conditions

$$g_{uu} = g_{vv} = 0 . \quad (10.2.1)$$

The analogs of these conditions in regions with Euclidian signature would be  $g_{zz} = g_{\bar{z}\bar{z}} = 0$ .

3. Assume that the imbedding map for space-time surface has the form

$$s^m = s^m(u, v) + f^m(u, v, x^m)_{kl} x^k x^l , \quad (10.2.2)$$

so that the conditions

$$\partial_l k s^m = 0 , \quad \partial_k \partial_u s^m = 0 , \quad \partial_k \partial_v s^m = 0 \quad (10.2.3)$$

are satisfied at string world sheet. These conditions imply that the only non-vanishing components of the induced  $CP_2$  Kähler form at string world sheet are  $J_{uv}$  and  $J_{w\bar{w}}$ . Same applies to the induced metric if the metric of  $M^4$  satisfies these conditions (no non-vanishing components of form  $m_{uk}$  or  $m_{vk}$ ).

4. Also the following conditions hold true for the induced metric of the space-time surface

$$\partial_k g_{uv} = 0 , \quad \partial_u g_{kv} = 0 , \quad \partial_v g_{ku} = 0 . \quad (10.2.4)$$

at string world sheet as is easy to see by using the ansatz.

Consider now the minimal surface conditions stating that the trace of the four components of the second fundamental form whose components are labelled by the coordinates  $\{x^\alpha\} \equiv (u, v, w, \bar{w})$  vanish for string world sheet.

1. Since only  $g_{uv}$  is non-vanishing, only the components  $H_{uv}^k$  of the second fundamental form appear in the minimal surface equations. They are given by the general formula

$$\begin{aligned} H_{uv}^\alpha &= H^\gamma P_\gamma^\alpha , \\ H^\alpha &= (\partial_u \partial_v x^\alpha + (\beta \gamma)^\alpha \partial_u x^\beta \partial_v x^\gamma) . \end{aligned} \quad (10.2.5)$$

Here  $P_\gamma^\alpha$  is the projector to the normal space of the string world sheet. Formula contains also Christoffel symbols  $(\beta \gamma)^\alpha$ .

2. Since the imbedding map is simply  $(u, v) \rightarrow (u, v, 0, 0)$  all second derivatives in the formula vanish. Also  $H^k = 0, k \in \{w, \bar{w}\}$  holds true. One has also  $\partial_u x^\alpha = \delta_u^\alpha$  and  $\partial_v x^\beta = \delta_v^\beta$ . This gives

$$H^\alpha = (u \alpha v) . \quad (10.2.6)$$

All these Christoffel symbols however vanish if the assumption  $g_{uu} = g_{vv} = 0$  and the assumptions about imbedding ansatz hold true. Hence a minimal surface is in question.

Consider now the conditions on the induced metric of the string world sheet

1. The conditions reduce to

$$g_{uu} = g_{vv} = 0 . \quad (10.2.7)$$

The conditions on the diagonal components of the metric are the analogs of Virasoro conditions fixing the coordinate choices in string models. The conditions state that the coordinate lines for  $u$  and  $v$  are light-like curves in the induced metric.

2. The conditions can be expressed directly in terms of the induced metric and read

$$\begin{aligned} m_{uu} + s_{kl} \partial_u s^k \partial_u s^l &= 0 , \\ m_{vv} + s_{kl} \partial_v s^k \partial_v s^l &= 0 . \end{aligned} \quad (10.2.8)$$

The  $CP_2$  contribution is negative for both equations. The conditions make sense only for  $(m_{uu} > 0, m_{vv} > 0)$ . Note that the determinant condition  $m_{uu}m_{vv} - m_{uv}m_{vu} < 0$  expresses the Minkowskian signature of the  $(u, v)$  coordinate plane in  $M^4$ .

The additional condition states

$$J_{uv}^g = kJ_{uv} . \quad (10.2.9)$$

It reduces signed area to Kähler electric flux. If the weak form of electric-magnetic duality holds true one can interpret the area as magnetic flux defined as the flux of the dual of induced Kähler form over space-like surface and defining electric charge. A further condition is that the boundary of string world sheet is Legendrean manifold so that the flux and thus area is extremized also at the boundaries.

### 2. Conditions for the Euclidian string world sheets

One can do the same calculation for string world sheet with Euclidian signature. The only difference is that  $(u, v)$  is replaced with  $(z, \bar{z})$ . The imbedding map has the same form assuming that space-time sheet with Euclidian signature allows coordinates  $(z, \bar{z}, w, \bar{w})$  and the local conditions on the imbedding are a direct generalization of the above described conditions. In this case the vanishing for the diagonal components of the string world sheet metric reads as

$$\begin{aligned} h_{kl} \partial_z s^k \partial_z s^l &= 0 , \\ h_{kl} \partial_{\bar{z}} s^k \partial_{\bar{z}} s^l &= 0 . \end{aligned} \quad (10.2.10)$$

The natural ansatz is that complex  $CP_2$  coordinates are holomorphic functions of the complex coordinates of the space-time sheet.

### 3. Wick rotation for Minkowskian string world sheets leads to a more detailed solution ansatz

Wick rotation is a standard trick used in string models to map Minkowskian string world sheets to Euclidian ones. Wick rotation indeed allows to define what one means with real-octonion analyticity. Could one identify string world sheets in Minkowskian regions by using Wick rotation and does this give the same result as the direct approach?

Wick rotation transforms space-time surfaces in  $M^4 \times CP_2$  to those in  $E^4 \times CP_2$ . In  $E^4 \times CP_2$  octonion real-analyticity is a well-defined notion and one can identify the space-time surfaces at which the imaginary part of octonion real-analytic function vanishes: imaginary part is defined via the decomposition of octonion to two quaternions as  $o = q_1 + Iq_2$  where  $I$  is a preferred octonion unit. The reverse of the Wick rotation maps the quaternionic surfaces to what might be called hyper-quaternionic surfaces in  $M^4 \times CP_2$ .

In this picture string world sheets would be hyper-complex surfaces defined as inverse images of complex surfaces of quaternionic space-time surface obtained by the inverse of Wick rotation. For this

approach to be equivalent with the above one it seems necessary to require that the the treatment of the conditions on metric should be equivalent to that for which hyper-complex unit  $e$  is not put equal to 1. This would mean that the conditions reduce to independent conditions for the real and imaginary parts of the real number formally represented as hyper-complex number with  $e = 1$ .

Wick rotation allows to guess the form of the ansatz for  $CP_2$  coordinates as functions of space-time coordinates In Euclidian context holomorphich functions of space-time coordinates are the natural ansatz. Therefore the natural guess is that one can map the hypercomplex number  $t \pm ez$  to complex coordinate  $t \pm iz$  by the analog of Wick rotation and assume that  $CP_2$  complex coordinates are analytic functions of the complex space-time coordinates obtained in this manner.

The resulting induced metric could be obtained directly using real coordinates  $(t, z)$  for string world sheet or by calculating the induced metric in complex coordinates  $t \pm iz$  and by mapping the expressions to hyper-complex numbers by Wick rotation (by replacing  $i$  with  $e = 1$ ). If the diagonal components of the induced metric vanish for  $t \pm iz$  they vanish also for hyper-complex coordinates so that this approach seem to make sense.

**Electric-magnetic duality for flux Hamiltonians and the existence of Wilson sheets**

One must distinguish between two conjectured dualities. The weak form of electric-magnetic duality and the duality between string world sheets and partonic 2-surfaces. Could the first duality imply equivalence of not only electric and magnetic flux Hamiltonians but also electric and magnetic Wilson sheets? Could the latter duality allow two different representations of flux Hamiltonians?

1. For electric-magnetic duality holding true at string world sheets one would have non-vanishing Kähler form and the fluxes would be non-vanishing. The Hamiltonian fluxes

$$Q_{m,A} = \int_{X^2} JH_A dx^1 dx^2 = \int_{X^2} H_A J_{\alpha\beta} dx^\alpha \wedge dx^\beta \tag{10.2.11}$$

for partonic 2-surfaces  $X^2$  define WCW Hamiltonians playing a key role in the definition of WCW Kähler geometry. They have also interpretation as a generalization of Wilson loops to Wilson 2-surfaces.

2. Weak form of electric magnetic duality would imply both at partonic 2-surfaces and string world sheets the proportionality

$$Q_{m,A} = \int_{X^2} JH_A dx^1 \wedge dx^2 \propto Q_{m,A}^* = \int_{X^2} H_A * J_{\alpha\beta} dx^\alpha \wedge dx^\beta . \tag{10.2.12}$$

Therefore the electric-magnetic duality would have a concrete meaning also at the level of WCW geometry.

3. If string world sheets are Lagrangian sub-manifolds Hamiltonian fluxes would vanish identically so that the identification as Wilson sheets does not make sense. One would lose electric-magnetic duality for flux sheets. The dual fluxes

$$*Q_A = \int_{Y^2} *JH_A dx^1 \wedge dx^2 = \int_{Y^2} \epsilon_{\alpha\beta}{}^{\gamma\delta} J_{\gamma\delta} = \int_{Y^2} \frac{\sqrt{\det(g_A)}}{\det(g_2^\perp)} J_{34}^\perp dx^1 \wedge dx^2$$

for string world sheets  $Y^2$  are however non-vanishing. Unlike fluxes, the dual fluxes depend on the induced metric although they are scaling invariant.

Under what conditions the conjectured duality between partonic 2-surface and string world sheets hold true at the level of WCW Hamiltonians?

1. For the weak form of electric-magnetic duality at string world sheets the duality would mean that the sum of the fluxes for partonic 2-surfaces and sum of the fluxes for string world sheets are identical apart from a proportionality constant:

$$\sum_i Q_A(X_i^2) \propto \sum_i Q_A(Y_i^2) . \quad (10.2.13)$$

Note that in zero ontology it seems necessary to sum over all the partonic surfaces (at both ends of the space-time sheet) and over all string world sheets.

2. For Lagrangian sub-manifold option the duality can hold true only in the form

$$\sum_i Q_A(X_i^2) \propto \sum_i Q_A^*(Y_i^2) . \quad (10.2.14)$$

Obviously this option is less symmetric and elegant.

### Summary

There are several arguments favoring weak form of electric-magnetic duality for both string world sheets and partonic 2-surfaces. Legendrian sub-manifold property for braid strands follows from the assumption that Kähler action for preferred extremals is proportional to the Kähler magnetic flux associated with preferred 2-surfaces and is stationary with respect to the variations of the boundary. What is especially nice is that Legendrian sub-manifold property implies automatically unique braids. The minimal option favored by the idea that 3-surfaces are basic dynamical objects is the one for which weak form of electric-magnetic duality holds true only at partonic 2-surfaces and string world sheets. A stronger option assumes it at preferred 3-surfaces. Duality between string world sheets and partonic 2-surfaces suggests that WCW Hamiltonians can be defined as sums of Kähler magnetic fluxes for either partonic 2-surfaces or string world sheets.

### 10.2.5 What generalized Feynman rules could be?

After all these explanations the skeptic reader might ask whether this lengthy discussion gives any idea about what the generalized Feynman rules might look like. The attempt to answer this question is a good manner to make a map about what is understood and what is not understood. The basic questions are simple. What constraints does zero energy ontology (ZEO) pose? What does the necessity to project the four-momenta to a preferred plane  $M^2$  mean? What mathematical expressions one should assign to the propagator lines and vertices? How does one perform the functional integral over 3-surfaces in finite measurement resolution? The following represents tentative answers to these questions but does not say much about exact role of algebraic knots.

#### Zero energy ontology

ZEO poses very powerful constraints on generalized Feynman diagrams and gives hopes that both UV and IR divergences cancel.

1. ZEO predicts that the fermions assigned with braid strands associated with the virtual particles are on mass shell massless particles for which the sign of energy can be also negative: in the case of wormhole throats this can give rise to a tachyonic exchange.
2. The on mass shell conditions for each wormhole throat in the diagram involving loops are very stringent and expected to eliminate very large classes of diagrams. If however given diagonal diagram leading from n-particle state to the same n-particle state -completely analogous to self energy diagram- is possible then the ladders form by these diagrams are also possible and one obtains infinite of this kind of diagrams as generalized self energy correction and is excellent hopes that geometric series gives a closed algebraic function.

3. IR divergences plaguing massless theories are cancelled if the incoming and outgoing particles are massive bound states of massless on mass shell particles. In the simplest manner this is achieved when the 3-momenta are in opposite direction. For internal lines the massive on-mass shell-condition is not needed at all. Therefore there is an almost complete separation of the problem how bound state masses are determined from the problem of constructing the scattering amplitudes.
4. What looks like a problematic aspect ZEO is that the massless on-mass-shell propagators would diverge for wormhole throats. The solution comes from the projection of 4-momenta to  $M^2$ . In the generic the projection is time-like and one avoids the singularity. The study of solutions of the modified Dirac equation [28] and number theoretic vision [70] indeed suggests that the four-momenta are obtained by rotating massless  $M^2$  momenta and their projections to  $M^2$  are in general integer multiples of hyper-complex primes or light-like. The light-like momenta would be treated like in the case of ordinary Feynman diagrams using  $i\epsilon$ -prescription of the propagator and would also give a finite contributions corresponding to integral over physical on mass shell states. This guarantees also the vanishing of the possible IR divergences coming from the summation over different  $M^2$  momenta.

There is a strong temptation to identify - or at least relate - the  $M^2$  momenta labeling the solutions of the modified Dirac equation with the region momenta of twistor approach [84]. The reduction of the region momenta to  $M^2$  momenta could dramatically simplify the twistorial description. It does not seem however plausible that  $\mathcal{N} = 4$  super-symmetric gauge theory could allow the identification of  $M^2$  projections of 4-momenta as region momenta. On the other hand, there is no reason to expect the reduction of TGD certainly to a gauge theory containing QCD as part. For instance, color magnetic flux tubes in many-sheeted space-time are central for understanding jets, quark gluon plasma, hadronization and fragmentation [11] but cannot be deduced from QCD. Note also that the splitting of parton momenta to their  $M^2$  projections and transversal parts is an ad hoc assumption motivated by parton model rather than first principle implication of QCD: in TGD framework this splitting would emerge from first principles.

5. Zero energy ontology strongly suggests that all particles (including photons, gluons, and gravitons) have mass which can be arbitrarily small and can be see as being due to the fact that particle "eats" Higgs like states giving it the otherwise lacking polarization states. This would mean a generalization of the notion of Higgs particle to a Higgs like particle with spin. It would also mean rearrangement of massless states at wormhole throat level to massive physical states.

The projection of the momenta to  $M^2$  is consistent with this vision. The natural generalization of the gauge condition  $p \cdot \epsilon = 0$  is obtained by replacing  $p$  with the projection of the total momentum of the boson to  $M^2$  and  $\epsilon$  with its polarization so that one has  $p_{||} \cdot \epsilon$ . If the projection to  $M^2$  is light-like, three polarization states are possible in the generic case, so that massivation is required by internal consistency. Note that if intermediate states in the unitary condition were states with light-like  $M^2$ -momentum one could have a problematic situation.

6. A further natural assumption is that the  $M^2$  projections of all momenta assignable to braid strands are parallel. Only the projections of the momenta to the orthogonal complement  $E^2$  of  $M^2$  can be non-parallel and for massive wormhole throats they must be non-parallel. This assumption does not break Lorentz invariance since in the full amplitude one must integrate over possible choices of  $M^2$ . It also interpret the gauge conditions either at the level of braid strands or of partons. Quantum classical correspondence in strong form would actually suggests that quantum 4-momenta should co-incide with the classical ones. The restriction to  $M^2$  projections is however necessary and seems also natural. For instance, for massless extremals only  $M^2$  projection of wave-vector can be well-defined: in transversal degrees of freedom there is a superposition over Fourier components with different transversal wave-vectors. Also the partonic description of hadrons gives for the  $M^2$  projections of the parton momenta a preferred role. It is highly encouraging that this picture emerged first from the modified Dirac equation and purely number theoretic vision based on the identification of  $M^2$  momenta in terms of hyper-complex primes.

The number theoretical approach also suggests a number theoretical quantization of the transversal parts of the momenta [70]: four-momenta would be obtained by rotating massless  $M^2$  mo-

menta in  $M^4$  in such a manner that the components of the resulting 3-momenta are integer valued. This leads to a classical problem of number theory which is to deduce the number of 3-vectors of fixed length with integer valued components. One encounters the n-dimensional generalization of this problem in the construction of discrete analogs of quantum groups (these "classical" groups are analogous to Bohr orbits) and emerge in quantum arithmetics [86], which is a deformation of ordinary arithmetics characterized by p-adic prime and giving rigorous justification for the notion of canonical identification mapping p-adic numbers to reals.

7. The real beauty of Feynman rules is that they guarantee unitarity automatically. In fact, unitarity reduces to Cutkosky rules which can be formulated in terms of cut obtained by putting certain subset of internal lines on mass shell so that it represents on mass shell state. Cut analyticity implies the usual  $iDisc(T) = TT^\dagger$ . In the recent context the cutting of the internal lines by putting them on-mass-shell requires a generalization.
  - (a) The first guess is that on mass shell property means that  $M^2$  projection for the momenta is light-like. This would mean that also these momenta contribute to the amplitude but the contribution is finite just like in the usual case. In this formulation the real particles would be the massless wormhole throats.
  - (b) Second possibility is that the internal lines on on mass shell states corresponding to massive on mass-shell-particles. This would correspond to the experimental meaning of the unitary conditions if real particles are the massive on mass shell particles. Mathematically it seems possible to pick up from the amplitude the states which correspond to massive on mass shell states but one should understand why the discontinuity should be associated with physical net masses for wormhole contacts or many-particle states formed by them. General connection with unitarity and analyticity might allow to understand this.
8.  $CD$ s are labelled by various moduli and one must integrate over them. Once the tips of the  $CD$  and therefore a preferred  $M^1$  is selected, the choice of angular momentum quantization axis orthogonal to  $M^1$  remains: this choice means fixing  $M^2$ . These choices are parameterized by sphere  $S^2$ . It seems that an integration over different choices of  $M^2$  is needed to achieve Poincare invariance.

### How the propagators are determined?

In accordance with previous sections it will be assumed that the braid are Legendrian braids and therefore completely well-defined. One should assign propagator to the braid. A good guess is that the propagator reduces to a product of three terms.

1. A multi-particle propagator which is a product of collinear massless propagators for braid strands with fermion number  $F = 0, 1 - 1$ . The constraint on the momenta is  $p_i = \lambda_i p$  with  $\sum_i \lambda_i = 1$ . So that the fermionic propagator is  $\frac{1}{\prod_i \lambda_i} p^k \gamma_k$ . If one gas  $p = nP$ , where  $P$  is hyper-complex prime, one must sum over combinations of  $\lambda_i = n_i$  satisfying  $\sum_i n_i = n$ .
2. A unitary  $S$ -matrix for integrable QFT in  $M^2$  in which the velocities of particles assignable to braid strands appear for which fixed by  $R$ -matrix defines the basic 2-vertex representing the process in which a particle passes through another one. For this  $S$ -matrix braids are the basic units. To each crossing appearing in non-planar Feynman diagram one would have an  $R$ -matrix representing the effect of a reconnection the ends of the lines coming to the crossing point. In this manner one could gradually transform the non-planar diagram to a planar diagram. One can ask whether a formulation in terms of a suitable  $R$ -matrix could allow to generalize twistor program to apply in the case of non-planar diagrams.
3. An  $S$ -matrix predicted by topological QFT for a given braid. This  $S$ -matrix should be constructible in terms of Chern-Simons term defining a symplectic QFT.

There are several questions about quantum numbers assignable to the braid strands.

1. Can braid strands be only fermionic or can they also carry purely bosonic quantum numbers corresponding to WCW Hamiltonians and therefore to Hamiltonians of  $\delta M_{\pm}^4 \times CP_2$ ? Nothing is lost if one assumes that both purely bosonic and purely fermionic lines are possible and looks whether this leads to inconsistencies. If virtual fermions correspond to single wormhole throat they can have only time-like  $M^2$ -momenta. If virtual fermions correspond to pairs of wormhole throats with second throat carrying purely bosonic quantum numbers, also fermionic can have space-like net momenta. The interpretation would be in terms of topological condensation. This is however not possible if all strands are fermionic. Situation changes if one identifies physical fermions wormhole throats at the ends of Kähler magnetic flux tube as one indeed does: in this case virtual net momentum can be space-like if the sign of energy is opposite for the ends of the flux tube.
2. Are the 3-momenta associated with the wormholes of wormhole contact parallel so that only the sign of energy could distinguish between them for space-like total momentum and  $M^2$  mass squared would be the same? This assumption simplifies the situation but is not absolutely necessary.
3. What about the momentum components orthogonal to  $M^2$ ? Are they restricted only by the massless mass shell conditions on internal lines and quantization of the  $M^2$  projection of 4-momentum?
4. What braids do elementary particles correspond? The braids assigned to the wormhole throat lines can have arbitrary number  $n$  of strands and for  $n = 1, 2$  the treatment of braiding is almost trivial. A natural assumption is that propagator is simply a product of massless collinear propagators for  $M^2$  projection of momentum [29]. Collinearity means that propagator is product of a multifermion propagator  $\frac{1}{\lambda_i p_k \gamma_k}$ , and multiboson propagator  $\frac{1}{\mu_i p_k \gamma_k}$ ,  $\sum \lambda_i + \sum \mu_i = 1$ . There are also quantization conditions on  $M^2$  projections of momenta from modified Dirac equation implying that multiplies of hyper-complex prime are in question in suitable units. Note however that it is not clear whether purely bosonic strands are present.
5. For ordinary elementary particles with propagators behaving like  $\prod_i \lambda_i^{-1} p^{-n}$ , only  $n \leq 2$  is possible. The topologically really interesting states with more than two braid strands are something else than what we have used to call elementary particles. The proposed interpretation is in terms of anyonic states [57]. One important implication is that  $\mathcal{N} = 1$  SUSY generated by right-handed neutrino or its antineutrino is SUSY for which all members of the multiplet assigned to a wormhole throat have braid number smaller than 3. For  $\mathcal{N} = 2$  SUSY generated by right-handed neutrino and its antiparticle the states containing fermion and neutrino-antineutrino pair have three braid strands and SUSY breaking is expected to be strong.

### Vertices

Conformal invariance raises the hope that vertices can be deduced from super-conformal invariance as  $n$ -point functions. Therefore lines would come from integrable QFT in  $M^2$  and topological braid theory and vertices from conformal field theory: both theories are integrable.

The basic question is how the vertices are defined by the 2-D partonic surfaces at which the ends of lines meet. Finite measurement resolution reduces the lines to braids so that the vertices reduce to the intersection of braid strands with the partonic 2-surface.

1. Conformal invariance is the basic symmetry of quantum TGD. Does this mean that the vertices can be identified as  $n$ -point functions for points of the partonic 2-surface defined by the incoming and outgoing braid strands? How strong constraints can one pose on this conformal field theory? Is this field theory free and fixed by anticommutation relations of induced spinor fields so that correlation function would reduce to product of fermionic two points functions with standard operator in the vertices represented by strand ends. If purely bosonic vertices are present, their correlation functions must result from the functional integral over WCW.
2. For the fermionic fields associated with each incoming braid the anticommutators of fermions and antifermions are trivial just as the usual equal time anticommutation relations. This means that the vertex reduces to sum of products of fermionic correlation functions with arguments belonging to different incoming and outgoing lines. How can one calculate the correlators?

- (a) Should one perform standard second quantization of fermions at light-like 3-surface allowing infinite number of spinor modes, apply a finite measurement resolution to obtain braids, for each partonic 2-surface, and use the full fermion fields to calculate the correlators? In this case braid strands would be discontinuous in vertices. A possible problem might be that the cutoff in spinor modes seems to come from the theory itself: finite measurement resolution is a property of quantum state itself.
  - (b) Could finite measurement resolution allow to approximate the braid strands with continuous ones so that the correlators between strands belonging to different lines are given by anticommutation relations? This would simplify enormously the situation and would conform with the idea of finite measurement resolution and the vision that interaction vertices reduce to braids. This vision is encouraged by the previous considerations and would mean that replication of braid strands analogous to replication of DNA strands can be seen as a fundamental process of Nature. This of course represents an important deviation from the standard picture.
3. Suppose that one accepts the latter option. What can happen in the vertex, where line goes from one braid to another one?
- (a) Can the direction of momentum changed as visual intuition suggests? Is the total braid momentum conservation the only constraint so that the velocities assignable braid strands in each line would be constrained by the total momentum of the line.
  - (b) What kind of operators appear in the vertex? To get some idea about this one can look for the simplest possible vertex, namely FFB vertex which could in fact be the only fundamental vertex as the arguments of [18] suggest. The propagator of spin one boson decomposes to product of a projection operator to the polarization states divided by  $p^2$  factor. The projection operator sum over products  $\epsilon_i^k \gamma_k$  at both ends where  $\gamma_k$  acts in the spinor space defined by fermions. Also fermion lines have spinor and its conjugate at their ends. This gives rise to  $p^k \gamma_k / p^2$ .  $p^k \gamma_k$  is the analog of the bosonic polarization tensor factorizing into a sum over products of fermionic spinors and their conjugates. This gives the BFF vertex  $\epsilon_i^k \gamma_k$  slashed between the fermionic propagators which are effectively 2-dimensional.
  - (c) Note that if H-chiralities are same at the throats of the wormhole contact, only spin one states are possible. Scalars would be leptiquarks in accordance with general view about lepton and quark number conservation. One particular implication is that Higgs in the standard sense is not possible in TGD framework. It can appear only as a state with a polarization which is in  $CP_2$  direction. In any case, Higgs like states would be eaten by massless state so that all particles would have at least a small mass.

### Functional integral over 3-surfaces

The basic question is how one can functionally integrate over light-like 3-surfaces or space-like 3-surfaces.

1. Does effective 2-dimensionality allow to reduce the functional integration to that over partonic 2-surfaces assigned with space-time sheet inside  $CD$  plus radiative corrections from the hierarchy of sub- $CD$ s?
2. Does finite measurement resolution reduce the functional integral to an ordinary integral over the positions of the end points of braids and could this integral reduce to a sum? Symplectic group of  $\delta M_{\pm}^4 \times CP_2$  basically parametrizes the quantum fluctuating degrees of freedom in WCW. Could finite measurement resolution reduce the symplectic group of  $\delta M_{\pm}^4 \times CP_2$  to a coset space obtained by dividing with symplectic transformations leaving the end points invariant and could the outcome be a discrete group as proposed? Functional integral would reduce to sum.
3. If Kähler action reduces to Chern-Simons-Kähler terms to surface area terms in the proposed manner, the integration over WCW would be very much analogous to a functional integral over string world sheets and the wisdom gained in string models might be of considerable help.

### Summary

What can one conclude from these argument? To my view the situation gives rise to a considerable optimism. I believe that on basis of the proposed picture it should be possible to build a concrete mathematical models for the generalized Feynman graphics and the idea about reduction to generalized braid diagrams having algebraic representations could pose additional powerful constraints on the construction. Braid invariants could also be building bricks of the generalized Feynman diagrams. In particular, the treatment of the non-planarity of Feynman diagrams in terms of  $M^2$  braiding matrix would be something new.

## 10.3 Duality between low energy and high energy descriptions of hadron physics

I found the talk of Matthew Schwartz titled *The Emergence of Jets at the Large Hadron Collider* [18] belonging to the Monday Colloquium Series at Harvard. The talk told about the history of the notion of jet and how it is applied at LHC. The notion of jet is something between perturbative and non-perturbative QCD and therefore not a precisely defined concept as one approaches small mass limit for jets.

The talk inspired some questions relating to QCD and hadron physics in general. I am of course not competent to say anything interesting about jet algorithms. Hadronization process is however not well understood in the framework of QCD and uses phenomenological fragmentation functions. The description of jet formation in turn uses phenomenological quark distribution functions. TGD leads to a rather detailed fresh ideas about what quarks, gluons, and hadrons are and stringy and QFT like descriptions emerge as excellent candidates for low and high energy descriptions of hadrons. Low energies are the weakness of QCD and one can well ask whether QCD fails as a physical theory at infrared. Could TGD do better in this respect?

Only a minor fraction of the rest energy of proton is in the form of quarks and gluons. In TGD framework these degrees of freedom would naturally correspond to color magnetic flux tubes carrying color magnetic energy and in proton-proton collisions the color magnetic energy of p-p system in cm system is gigantic. The natural question is therefore about what happens to the "color magnetic bodies" of the colliding protons and of quarks in proton-proton collision.

In the sequel I will develop a simple argument leading to a very concrete duality between two descriptions of hadron reactions manifest at the level of generalized Feynman graphs. The first description is in terms of meson exchanges and applies naturally in long scales. Second one is terms of perturbative QCD applying in short scales. The basic ingredients of the argument are the weak form of electric-magnetic duality [28] and bosonic emergence [56] leading to a rather concrete view about physical particles, generalized Feynman diagrams reducing to generalized braid diagrams in the framework of zero energy ontology (ZEO), and reconnection of Kähler magnetic flux tubes having interpretation in terms of string diagrams providing the mechanism of hadronization. Basically the prediction follows from the dual interpretations of generalized Feynman diagrams either as stringy diagrams (low energies) or as Feynman diagrams (high energies).

It must be emphasized that this duality is something completely new and a simple prediction of the notion of generalized Feynman diagram. The result is exact: no limits (such as large  $N$  limit) are needed.

### 10.3.1 Weak form of electric magnetic duality and bosonic emergence

The weak form of electric magnetic duality allows the identification of quark wormhole throats as Kähler magnetic monopoles with non-vanishing magnetic charges  $Q_m$ . The closely related bosonic emergence [56] effectively eliminates the fundamental BFF vertices from the theory.

1. Elementary fermion corresponds to single wormhole throat with Kähler magnetic charge. In topological condensation a wormhole throat is formed and the working hypothesis is that the second throat is Kähler magnetically neutral. The throats created in topological condensation (formation of topological sum) are always homologically trivial since purely local process is in question.

2. In absence of topological condensation physical leptons correspond to string like objects with opposite Kähler magnetic charges at the ends. Topologically condensed lepton carries also neutralizing weak isospin carried by neutrino pair at the throats of the neutralizing wormhole contact. Wormhole contact itself carries no Kähler magnetic flux. The neutralization scale for  $Q_m$  and weak isospin could be either weak length scale for both fermions and bosons. The alternative option is Compton length quite generally - this even for fermions since it is enough that the weak isospin of weak bosons is neutralized in the weak scale. The alert reader have of course asked whether the weak isospin of fermion must be neutralized at all if this is the case. Whether this really happens is not relevant for the following arguments.
3. Whether a given quark is accompanied by a wormhole contact neutralizing its weak isospin is not quite clear: this need not be the case since the Compton length of weak bosons defines the range of weak interactions. Therefore one can consider the possibility that physical quarks have non-vanishing  $Q_m$  and that only hadrons have  $Q_m = 0$ . Now the Kähler magnetic flux tubes would connect valence quarks. In the case of proton one would have three of them. About 31 year old proposal is that color hyper charge is proportional to Kähler magnetic charge. If so then color confinement would require Kähler magnetic confinement.
4. By bosonic emergence bosons correspond to wormhole contacts or pairs of them. Now wormhole throats have opposite values of  $Q_m$  but the contact itself carries vanishing Kähler magnetic flux. Fermion and anti-fermion are accompanied by neutralizing Kähler magnetic charge at the ends of their flux tubes and neutrino pair at its throats neutralizes the weak charge of the boson.

### 10.3.2 The dual interpretations of generalized Feynman diagrams in terms of hadronic and partonic reaction vertices

Generalized Feynman diagrams are defined in the framework of zero energy ontology (ZEO). Bosonic emergence eliminates fundamental BFF vertices and reduces generalized Feynman diagrams to generalized braid diagrams. This is essential for the dual interpretation of the qgg vertex as a meson emission vertex for hadron. The key idea is following.

1. Topologically condensed hadron - say proton- corresponds to a double sheeted structure: let us label the sheets by letters A and B. Suppose that the sheet A contains wormhole throats of quarks carrying magnetic charges. These wormhole throats are connected by magnetically neutral wormhole contact to sheet B for which wormhole throats carry vanishing magnetic charges.
2. What happens when hadronic quark emits a gluon is easiest to understand by considering first the annihilation of topologically non-condensed charged lepton and antilepton to photon - that is  $L + \bar{L} \rightarrow \gamma$  vertex. Lepton and antilepton are accompanied by flux tubes at different space-time sheets A and B and each has single wormhole throat: one can speak of a pair of topologically condensed deformations of  $CP_2$  type vacuum extremals as a correlate for single wormhole throat. At both ends of the flux tubes deformations of  $CP_2$  type vacuum extremals fuse via topological sum to form a pair of photon wormhole contacts carrying no Kähler magnetic flux. The condition that the resulting structure has the size of weak gauge boson suggests that weak scale defines also the size of leptons and quarks as magnetic flux tubes. Quarks can however carry net Kähler magnetic charge (the ends of flux tube do not have opposite values of Kähler magnetic charge).
3. With some mental gymnastics the annihilation vertex  $L + \bar{L} \rightarrow \gamma$  can be deformed to describe photon emission vertex  $L \rightarrow L + \gamma$ : The negative energy antilepton arrives from future and positive energy lepton from the past and they fuse to a virtual photon in the manner discussed.
4. qgg vertex requires further mental gymnastics but locally nothing is changed since the protonic quark emitting the gluon is connected by a color magnetic flux tube to another protonic quark in the case of incoming proton (and possibly to neutrino carrying wormhole contact with size given by the weak length scale). What happens is therefore essentially the same as above. The protonic quark has become part of gluon at space-time sheet A but has still flux tube connection to proton. Besides this there appears wormhole throat at space-time sheet B carrying quark quantum numbers: this quark would in the usual picture correspond to the quark after gluon

emission and antiquark at the same space-time sheet associated with the gluon. Therefore one has proton with one quark moving away inside gluon at sheet A and a meson like entity at sheet B. The dual interpretation as the emission of meson by proton makes sense. This vertex does not correspond to the stringy vertex  $AB + CD \rightarrow AD + BC$  in which strings touch at some point of the interior and recombine but is something totally new and made possible by many-sheeted space-time. For gauge boson magnetically charge throats are at different space-time sheets, for meson they are at the same space-time sheet and connected by Kähler magnetic flux tube.

5. Obviously the interpretation as an emission of meson like entity makes sense for any hadron like entity for which quark or antiquark emits gluon. This is what the duality of hadronic and parton descriptions would mean. Note that bosonic emergence is absolutely essential element of this duality. In QCD it is not possible to understand this duality at the level of Feynman diagrams.

### 10.3.3 Reconnection of color magnetic flux tubes

The reconnection of color magnetic flux tubes is the key mechanism of hadronization and a slow process as compared to quark gluon emission.

1. Reconnection vertices have interpretation in terms of stringy vertices  $AB + CD \rightarrow AD + BC$  for which interiors of strings serving as representatives of flux tubes touch. The first guess is that reconnection is responsible for the low energy dynamics of hadronic collisions.
2. Reconnection process takes place for both the hadronic color magnetic flux tubes and those of quarks and gluons. For ordinary hadron physics hadrons are characterized by Mersenne prime  $M_{107}$ . For  $M_{89}$  hadron physics reconnection process takes place in much shorter scales for hadronic flux tubes.
3. Each quark is characterized by p-adic length scales: in fact this scale characterizes the length scale of the magnetic bodies of the quark. Therefore Reconnection at the level of the magnetic bodies of quarks take places in several time and length scales. For top quark the size scale of magnetic body is very small as is also the reconnection time scale. In the case of u and d quarks with mass in MeV range the size scale of the magnetic body would be of the order of electron Compton length. This scale assigned with quark is longer than the size scale of hadrons characterized by  $M_{89}$ . Classically this does not make sense but in quantum theory Uncertainty Principle predicts it from the smallness of the light quark masses as compared to the hadron mass. The large size of the color magnetic body of quark could explain the strange finding about the charge radius of proton [45].
4. For instance, the formation of quark gluon plasma would involve reconnection process for the magnetic bodies of colliding protons or nuclei in short time scale due to the Lorentz contraction of nuclei in the direction of the collision axis. Quark-gluon plasma would correspond to a situation in which the magnetic fluxes are distributed in such a manner that the system cannot be decomposed to hadrons anymore but acts like a single coherent unit. Therefore quark-gluon plasma in TGD sense does not correspond to the thermal quark-gluon plasma in the naive QCD sense in which there are no long range correlations.

Long range correlations and quantum coherence suggest that the viscosity to entropy ratio is low as indeed observed [45]. The earlier arguments suggest that the preferred extremals of Kähler action have interpretation as perfect fluid flows [28]. This means at given space-time sheet allows global time coordinate assignable to flow lines of the flow and defined by conserved isometry current defining Beltrami flow. As a matter fact, all conserved currents are predicted to define Beltrami flows. Classically perfect fluid flow implies that viscosity, which is basically due to a mixing causing the loss of Beltrami property, vanishes. Viscosity would be only due to the finite size of space-time sheets and the radiative corrections describable in terms of fractal hierarchy CDs within CDs. In quantum field theory radiative corrections indeed give rise to the absorptive parts of the scattering amplitudes.

### 10.3.4 Hadron-parton duality and TGD as a "square root" of the statistical QCD description

The main result is that generalized Feynman diagrams have dual interpretations as QCD like diagrams describing partonic reactions and stringy diagrams describing hadronic reactions so that these matrix elements can be taken between either hadronic states or partonic states. This duality is something completely new and distinguishes between QCD and TGD.

I have proposed already earlier this kind of duality but based on group theoretical arguments inspired by what I call  $M^8 - M^4 \times CP_2$  duality [28] and two hypothesis of the old fashioned hadron physics stating that vector currents are conserved and axial currents are partially conserved. This duality suggests that the group  $SO(4) = SU(2)_L \times SU(2)_R$  assignable to weak isospin degrees of freedom takes the role of color group at long length scales and can be identified as isometries of  $E^4 \subset M^8$  just like  $SU(3)$  corresponds to the isometries of  $CP_2$ .

Initial and final states correspond to positive and negative energy parts of zero energy states in ZEO. These can be regarded either partonic or hadronic many particle states. The inner products between *positive* energy parts of partonic and hadronic state basis define the "square roots" of the parton distribution functions for hadrons. The inner products of between *negative* energy parts of hadronic and partonic state basis define the "square roots" of the fragmentations functions to hadrons for partons. M-matrix defining the time-like entanglement coefficients is representable as product of hermitian square root of density matrix and S-matrix is not time reversal invariant and this partially justifies the use of statistical description of partons in QCD framework using distribution functions and fragmentation functions. Decoherence in the sum over quark intermediate states for the hadronic scattering amplitudes is essential for obtaining the standard description.

## 10.4 Quark gluon plasma in TGD framework

I listened an excellent talk by Dam Thanh Son in Harvard Monday seminar series [19]. The title of the talk was *Viscosity, Quark Gluon Plasma, and String Theory*. What the talk represents is a connection between three notions which one would not expect to have much to do with each other.

In the following I shall briefly summarize the basic points of Son's talk which I warmly recommend for anyone wanting to sharpen his or her mental images about quark gluon plasma.

1. Besides this I discuss a TGD variant of AdS/CFT correspondence based on string-parton duality allowing a concrete identification of the process leading to the formation of strongly interacting quark gluon plasma.
2. "Strongly interacting" means that partonic 2-surfaces are connected by Kähler magnetic flux tubes making the many-hadron system single large hadron in the optimal case rather than a gas of uncorrelated partons. This allows a concrete generalization of the formula of kinetic gas theory for the viscosity.
3. One ends up also to a concrete interpretation for the formula for the  $\eta/s$  ratio in terms of TGD variant of Einsteinian gravitation and the analogs of black-hole horizons identified as partonic 2-surfaces. This gravitation is not fictive gravitation in 10-D space but real sub-manifold gravitation in 4-D space-time.
4. It is essential that TGD does not assume gravitational constant as a fundamental constant but as a prediction of theory depending on the p-adic length scale and the typical value of Kähler action for the lines of generalized Feynman graphs. Feeding in the notion of gravitational Planck constant, one finds beautiful interpretation for the lower limit viscosity which is smaller than the one predicted by AdS-CFT correspondence.

### 10.4.1 Some points in Son's talk

Son discusses first the notion of shear viscosity at undergraduate level - as he expresses it. First the standard Wikipedia definition for shear viscosity is discussed in terms of the friction forces created in a system consisting two parallel plates containing liquid between them as one moves a plate with respect to another parallel plate.

Son explains how Maxwell explains the viscosity of gases in terms of kinetic gas theory and entered with a strange result: the estimate  $\eta = \rho v l_{free}$  leads to the conclusion that the viscosity has no pressure dependence: Maxwell himself verified the result experimentally. Imagining that the interaction of gas molecules can be reduced to zero leads to a paradox: the viscosity of the ideal gas is infinite. The solution of the paradox is simple: the theory applies only if  $l_{free}$  is considerably smaller than the size scale of the system, say the distance between the two plates, one of which is moving.

Son discusses the viscosity for some condensed matter systems and finds that the value of viscosity increases very rapidly as a function of temperature: does this mean a rapid increase of  $l_{free}$  with temperature? Son also notices that the viscosity seems to be bounded from below. Son discusses also  $\eta/s$  ratio for the condensed matter systems and finds that it is typically by a factor 10-100 larger than the minimal values  $\hbar/4\pi$  suggested by AdS/CFT correspondence [45].

Son describes gauge-gravity duality briefly. AdS/CFT approach does not allow simple arguments analogous to those used in the kinetic theory of gases.

1. One central formula is Kubo's formula giving viscosity as the low frequency limit for the Fourier component of the component of energy momentum tensor commutation  $[T^{yx}(x, t), T^{yx}(0, 0)]$  as

$$\eta = \frac{1}{2\hbar\omega} \int \langle [T^{yx}(x, t), T^{yx}(0, 0)] d^4x \rangle_{\omega \rightarrow 0}$$

for  $\mathcal{N} = 4$  SUSY defined in  $M^4$ . Now this theory is  $\mathcal{N} = 4$  SUSY so that there is no hope about simple interpretation. Note that the formula is consistent with the dimensions of viscosity which is  $M/L^3$ . I confess that I do not understand the origin of the formula at the level details. Green-Kubo relations [4] are certainly the starting point having very general justification as an outcome of fluctuation theorem [3] allowing understood relatively easily in Gaussian model for thermodynamics. Since energy momentum tensor serves as a source of gravitons and is the basic observable in hydrodynamics, it is clear that this formula is consistent with gauge theory-gravity correspondence.  $\omega \rightarrow 0$  limit means that the low energy sector of the gauge theory is in question so that the perturbative approach fails.

2. In TGD framework the analog of this formula need not be useful. If it apply it should apply to partonic 2-surfaces and  $AdS_5 \times S_5$  should be replaced with space-time surface. The energy momentum tensor should be the energy momentum tensor of partonic 2-surface fixed to a high degree by conformal invariance. One should sum over all partonic 2-surfaces. The partonic 2-surfaces would correspond to both ends of a braid strands at the opposite light-like boundaries of  $CD$ . The integral at the level of the partonic 2-surface is now only 2-dimensional and the dimension of  $\eta$  would be  $1\hbar/L$  in this case. In the kinetic gas theory formula this follows from the fact that mass density has now dimension  $m/L$  rather than  $m/L^3$ . The summation over the partonic 2-surfaces could correspond in many particle system integration. I tend to see this kind of approach as too formal.

AdS/CFT duality [45] reduces the calculation of the viscosity to that for the graviton absorption cross section for  $AdS_5 \times S_5$  black hole when the N-stack of branes is replaced with a brane black hole in  $AdS_5 \times S^5$ . Viscosity is reduced essentially to the area of the black-hole multiplied by Planck constant. Since the dimension of 4-D viscosity is  $\hbar/L^3$ , the area must be measured using Planck length squared  $G$  as a unit. Is viscosity the number density multiplied by this dimensionless quantity? I must admit that I do not really understand this result.

### 10.4.2 What is known about quark-gluon plasma?

Son summarizes some facts about quark-gluon plasma and they are included in the following summary about what little I know.

1. The first surprise was produced by RHIC observing that the viscosity to entropy density ratio for quark gluon plasma is near  $\hbar/4\pi$  -its lower limit as predicted by AdS/CFT duality. The low value of  $\eta/s$  ratio does not mean that the viscosity would be low. As a matter fact it is gigantic - of order  $10^{14}$  centipoise and therefore 14 orders of magnitude higher than for water! Glass is the the only condensed matter system possessing a higher viscosity in the list of Son. The challenge

is to understand why the ratio is so small in terms of QCD or perhaps a theory transcending the limitations of QCD at low energies. From Kubo's formula it is clear that the low energy limit of QCD is indeed needed to understand the viscosity.

2. In the nuclear collisions allowing to deduce information about viscosity the nuclei do not collide quite head on. The time of collision is short due to the Lorentz contraction. The projection of the collision region in the plane orthogonal to the collision axes is almond shaped so that rotational symmetry is lost and implies that viscous forces enters the game. If the system reaches thermal equilibrium, the notion of pressure make senses. The force caused by the pressure gradient is stronger in transversal than longitudinal direction of almond since the almond in transversal direction is shorter than in longitudinal direction. That hets in this direction are more energetic supports the view that pressure is a well-defined concept. On the other hand, the viscous force in the longitudinal direction is large and tends to compensate this effect. This effect gives hopes of measuring the viscosity.
3.  $\eta/s$  ratio seems to be near  $\hbar/4\pi$  for the quark-gluon plasma formed in both heavy ion collisions and in proton-proton collisions although the energy scales are quite different. This is not expected on basis of the strong temperature dependence of viscosity in condensed matter systems.
4. On basis of RHIC results [5, 14] for heavy ion collisions and the LHC results for proton-proton collisions, which unexpectedly demonstrated similar plasma behavior for proton-proton collisions one can conclude that quark gluon plasma is a strongly interacting system. The temperature assignable to the quark-gluon plasma possibly formed in proton-proton collisions is of course must higher than at RHIC. Recently also the results from lead-lead collisions at LHC have emerged: the temperature of the plasma should be about 500 MeV as compared to the temperature 250 MeV at RHIC. In this case AdS/CFT duality gives hopes for describing the non-perturbative aspects of the system. This is just a hope: AdS/CFT correspondence requires many assumptions which might not hold true for the quark-gluon plasma and there are preliminary indications [16], which do not support AdS/CFT duality [1, 2]. The experiments favor a model in which the situation is described based old-fashioned Lund model [3] treating gluons as strings. This description is a a simplified version of the description provided by TGD.

### 10.4.3 Gauge-gravity duality in TGD framework

AdS/CFT duality is one variant of a more general gauge-gravity duality. Gauge-gravity in turn involves several variants depending on whether one assumes that Einstein's curvature scalar provides a good approximation to the description of gravitational sector. This requires that higher spin excitations of string like objects are very heavy and can be neglected. It might be that since low energy limit is in question as is clear from Kubo's formula, the use of Einstein's action makes sense very generally.

#### String-gauge theory duality in TGD framework

If I were enemy of string theory and follower of the usual habits of my species, I would be very skeptic from the beginning. There are however no rational reasons to be hostile since string worlds sheets at 4-D space time sheets appear also in TGD and there very strong reasons to expect duality between QFT like descriptions and stringy description. I indeed discussed in previous section how this duality can be understood directly at the level of generalized Feynman diagrams as a kind of combinatorial identity. There is no need to introduce strings in  $AdS_5 \times S^5$  as in the usual AdS/CFT approach and  $N_c \rightarrow \infty$  implying the vanishing of the contribution of non-planar Feynman diagrams is not needed.

#### The reduction to Einsteinian gravity need not take place

String-gauge theory duality need not reduce QCD to Einsteinian gravity allowing modeling in terms of curvature scalar.

1. In TGD framework the physics for small deformations of vacuum extremals - whose number is gigantic (any Lagrangian sub-manifold of  $CP_2$  defines a vacuum sector of the theory) - would

be governed by Einstein's equations. The value of gravitational constant is however dynamical and a little dimensional analysis argument suggests that the gravitational constant satisfies [53]

$$G_{eff}(p) = L^2(k)exp(-2S_K) ,$$

where  $L_p$  is p-adic length scales associated with p-adic prime  $p \simeq 2^k$  and  $S_K$  is the Kähler action for a deformation of  $CP_2$  type vacuum extremal in general smaller than for full  $CP_2$ .

2. Ordinary gravitational constant would correspond to  $p = M_{127} = 2^{127} - 1$  assignable to electron:  $M_{127}$  is the largest Mersenne prime which does not define a completely super-astrophysical p-adic length scale. The value of  $S_K$  would be almost maximal and induce an enormous reduction of the value of  $G$ .
3. For hadron physics  $S_K$  should not be large and in reasonable approximation this would give  $G_{eff} \simeq \hbar L^2(k = 107)$ . The deformations of  $CP_2$  type vacuum extremals, whose  $M^4$  projections are random light-like curves. are assignable to elementary particles such as gluons. In the case of hadrons these projections are expected to be short and so that the exponent is expected to be near unity. One might hope that these contributions dominate in the calculation of viscosity so that Einstein's picture indeed works.
4. In the case of hadron physics there are no strong reason to expect a general reduction to Einsteinian gravity. Higher spin states at the hadronic Regge trajectories are important and hadron physics does not reduce to gravitational theory involving the exchanges of only spin two strong gravitons.

This requires additional assumption which the lecture of Son tried to clarify. The assumption is that the coordinate of  $AdS_5$  orthogonal to its boundary  $M^4$  representing 4-D Minkowski space represents scaling of the physical system and that the interactions in the bulk are ultra-local with respect to this coordinate. Only systems with same scale size interact. This assumption looks very strange to me but has analog in quantum TGD. Personally I would take this argument with a big grain of salt.

### Reduction to hydrodynamics

The  $AdS_5/CFT$  duality in the strong form reduces the dynamics at the boundary of  $AdS_5$  to Einstein's gravity in the interior of AdS and the  $N$ -stack of 3-branes corresponds to brane black-hole in  $AdS_5 \times S_5$ . There are also good reasons to expect that Einstein's gravity in turn reduces to hydrodynamics.

The field equations of TGD are conservation laws for isometry currents and Kähler currents plus their super counterparts. Also in hydrodynamics the basic equations reduce to conservation laws. The structural equations of hydrodynamics correspond to the identification of gauge fields and metrics as induced structures.

The reduction to 4-D hydrodynamics in much stronger sense is suggestive since a large class of preferred extremals of Kähler action have interpretation as hydrodynamic flows for which flow lines define coordinate curves of a global coordinate [28]. Beltrami flows are in question. For instance, a magnetic field for which Lorentz force vanishes is a good example of 3-D Beltrami flow. There are good arguments in favore of the existence of a unique preferred coordinate system defined in terms of light-like local direction and its dual direction plus two orthogonal local polarization directions.

### Could AdS/CFT duality have some interpretation in TGD framework?

In TGD framework the duality between strings and particles replacing AdS/CFT duality means the replacement of  $AdS \times S_5$  with space-time surface represented as surface in  $M^4 \times CP_2$ . Furthermore  $M^4$  is replaced with partonic 2-surfaces the super-conformal invariance of  $\mathcal{N} = 4$  SUSY in  $M^4$  is replaces with 2-D super-conformal invariance. Therefore the attempts to build analogies with AdS/CFT duality type description might be waste of time. The temptation for the search of analogies is however too high.

In the case of AdS/CFT duality for Minkowski space that coordinate of  $AdS_5$  orthogonal to its  $M^4$  boundary is interpreted as a scale parameter for the system and also has interpretation as a scalar field in  $M^4$ . Could this scaling degree have some sensible interpretation in TGD framework. What about the N-stack of 3-branes representing a copy of  $M^4$  identified as the boundary of  $AdS_5$ ?

1. In TGD framework the only physically sensible interpretation would be in terms of the hierarchy of Planck constants [27]. The quantum size of the particle scales like  $\hbar$  and is therefore integer valued. This suggests that the continuous  $AdS_5$  coordinate orthogonal to  $M^4$  could be replaced with the integer labeling the effective values of Planck constant and hence the local coverings of  $M^4 \times CP_2$  providing a convenient description for the fact that -due to the enormous vacuum degeneracy of Kähler action- the time derivatives of the imbedding space coordinates are multi-valued functions of the canonical momentum densities. Different coverings that they effectively correspond to different sectors of the effective imbedding space which can be seen as a finite covering of  $M^4 \times CP_2$ . Only the particles with the same value of Planck constant can appear in the same vertex of generalized Feynman diagrams and this is nothing but the strange assumption made to guarantee the locality of AdS dynamics.
2. Same collapse of the sheets of the covering actually applies in the directions transversal to space-like and light-like 3-surfaces so that both of them represent branchings and the total number of branches in the interior is  $n_1 n_2$ .
3. One must assume that the sheets of the covering collapse at the partonic 2-surfaces and perhaps also at the string world sheets. This strange orbifold property brings strongly in mind the stack of N-branes which collapse to single 3 brane however remembering its N-stack property: for instance, a dynamical gauge group  $SU(N) \times U(1)$  describing finite measurement resolution emerges. The loss of the infinitely thin stack property in the interior guarantees that N-stack property is not forgotten. I have indeed proposed that similar emergence of gauge groups allowing to represent finite measurement resolution in terms of gauge symmetry emerges also in TGD framework.
4. The effective dimensionless coupling in the perturbative expansion is  $g^2 N / \hbar$  and for large  $N$  limit the series does not converge. If  $N$  corresponds to the number of colors for dynamically generated gauge group labeling colors, the substitution  $\hbar = N \hbar_0$  however implies that the expansion parameter does not change at all so that the limit would be different from the usual  $N \rightarrow \infty$  limit used to derive AdS/CFT duality.

An integrable QFT in  $M^2$  identified as hyper-complex plane in number theoretic vision is necessary for interpreting generalized Feynman diagrams as generalized braids. One can of course ask whether one would have super-conformal QFT in  $M^2$  and whether  $AdS_3$  could be replaced with its discrete version with normal coordinate identified as the integer characterizing the value of Planck constant. To me this approach seems highly artificial although it might make sense formally.

One can of course ask whether  $M^4 \times CP_2$  could have some deep connection with  $AdS_5 \times S_5$ . This might be the case:  $CP_2$  is obtained from  $S^5$  by identifying all points of its geodesic circles and  $M^4$  is obtained from  $AdS_5$  by identifying all points of radial geodesics in the the scaling direction.

### Do black-holes in $AdS_5 \times S_5$ have TGD counterpart?

The black-holes in  $AdS_5 \times S_5$  have very natural counterparts as regions of the space-time surfaces with Euclidian signature of the induced metric. These regions represent generalized Feynman diagrams. By holography one could restrict the consideration also to the partonic 2-surfaces at the ends of CDs and if string world sheets and partonic 2-surfaces are dual to string world sheets coming as Minkowskian and Euclidian variants.

Black-holes in TGD framework would have Euclidian metric and their presence is absolutely essential for reducing the functional integral to a genuine integral. Otherwise one would have the analog of path integral with the exponential of Kähler action defining a mere phase factor.

The entropy area law for the black-holes generalizes to p-adic thermodynamics and the p-adic mass squared value for the particle predicted by p-adic thermodynamics is essentially the p-adic entropy: both are mapped to the real sector by canonical identification. Also the black hole entropy is proportional to mass squared.

The gigantic value of the gravitational Planck constants brings in additional interpretational issues to be discussed later.

### 10.4.4 TGD view about strongly interacting quark gluon plasma

The magnetic flux tubes/strings connecting quarks make the QCD plasma strongly interacting in TGD framework.

1. In the hadronic phase the network formed by these flux tubes decomposes to sub-networks assignable to the colliding protons. In the final state the sub-networks are associated with the outgoing hadrons. In the collision a network is formed in which the flux tubes can connect larger number of quarks and one obtains much longer cycles in the network as in the initial and final states. This can be regarded as a defining property of strongly interaction quark gluon plasma. In quantum world one obtains a quantum superposition over networks with different connectedness structures. The quark-gluon plasma is not ideal in quantum sense.
2. The presence of plasma blob predicts the reduction of jet production cross section. Typically a pair of jets is produced. If this occurs in deep interior of the plasma, the jets cannot escape the plasma. If this occurs near the surface of the plasma, the other jet escapes. This predicts reduction of the jet production cross section.
3. The decomposition to connected flux tube networks could explain why the experimentally detected ratio for jet production cross section nucleonic total scattering cross section is larger than the predicted one: the flux tube network would consist of disconnected network with a considerably property and for these the jet production cross section would not be so dramatically reduced by the fact that the other member of the never gets out from the plasma blob.

In TGD context the basic process leading to the formation of the quark-gluon plasma is reconnection for the flux tubes describable in terms of string diagrams  $AB - CD \rightarrow AD + BC$ . In the case of ordinary quark gluon plasma the density is so high that nucleons overlap geometrically and lead to the formation of the plasma. In TGD framework the magnetic bodies of quarks having size scale characterized by quark Compton length would overlap. The Compton lengths for light quarks with masses estimated to be of order 10 MeV are much larger than the size scale of nucleon and even that of nucleus. What does this mean? Does the reconnection process take place in several scales so that the notion of quark gluon plasma would be fractal? Note that in the recent proton-proton collisions the energy per nucleon is about 200 GeV. Does quark gluon plasma at LHC involve the fusion of the flux tubes of the color magnetic bodies of nucleons? Do these form connected structures.

In the kinetic gas theory viscous force in the system of parallel plates is caused by the diffusion of particles moving with velocity  $u$  which depends on the coordinate orthogonal to the parallel plates. One can imagine a fictive plane through which the particles diffuse in both directions and the forces is due to that fact that the diffusing particles have different velocities differing by  $\Delta u_x = \partial_y u_x l_{free}$  on the average. In the case of magnetic flux tubes the presence of magnetic flux tube connection the two quarks at the opposite sides of the fictive plane leads to a stretching of the flux tube and this costs energy. This favors the diffusion of either quark to the other side of the fictive plane and this induces the transformed of momentum parallel to the plates. Similar argument could apply also in the case of the ordinary liquids if one allows also electric flux tubes.

#### Jets and flux tubes structures

Magnetic flux tube provide also a more concrete vision about the notion of jet.

1. Jets are collinear particle like objects producing collinear hadrons. The precise definition of jets is however problematic in QCD framework. TGD suggests a more precise definition of jets as connected sub-networks formed by partons and by definition having vanishing total Kähler magnetic charge. Jet would be kind of super-hadron which decays to ordinary nearly collinear hadrons as the flux tube structure decomposes by reconnection process to smaller connected flux tube structures during hadronization.
2. Factorization theorems of QCD discussed in very clear manner by Ian Stewart [20] state that the dynamics at widely different scales separate for each other so that quantum mechanical interference effects can be neglected and probabilistic description applies in long length scales and quantal effects reduce to non-perturbative ones. The initial and final stages of the collision

process proceed slowly as compared to those describable in terms of perturbative QCD. Hence one can apply partonic distribution functions and fragmentation functions. These functions should have a description in terms of reconnection process.

3. The presence of different scales means in TGD framework to p-adic length scale hierarchy assignable to flux tubes gives a much more precise articulation for the notion of scale. No quantum interference effects can take place between different p-adic scales if the real amplitudes are obtained from p-adic valued amplitudes by the generalization of canonical identification discussed in [86]. For instance, in p-adic mass calculations the values p-adic mass squared are summed for for given p-adic prime before the mapping to real mass squared by canonical identification. For different values of p-adic primes the additive quantities are the real masses.

### Possible generalizations of Maxwell's formula formula for the viscosity

Could one understand the viscosity if one assumes that the reconnection of the magnetic flux tubes replaces the collisions of particles in the kinetic theory of gases? One can imagine several alternatives.

1. The free path of the particle appears in the kinetic gas theory estimate  $\eta = nmvl_{free}$  for the viscosity. If this decomposition makes sense now,  $l_{free}$  should correspond to the size scale of the magnetic body of light quark and if its size corresponds to the Compton length of the quark one would have  $l_{free} \sim \hbar/m$ . If one assumes  $s \sim n$  one has  $\eta = nv\hbar$ . For  $v = c = 1$  this would give  $\eta/s \sim \hbar/4\pi$  apart from numerical constant.

If  $\hbar$  indeed appears in  $l_{free}$  and the magnetic flux tube size scales as  $\hbar$ , the minimum value for the viscosity would scale as  $\hbar$ . It is difficult to say whether one should regard this as good or bad prediction from the point of view of the hierarchy of Planck constants. Over-optimistically one might ask whether large  $\hbar$  could explain the non-minimal values of  $\eta/s$  in terms of large  $\hbar$ . Note however that the minimal value of  $\eta/s$  can be smaller than  $\hbar/4\pi$  in some systems.

2. One could consider the replacement of the Compton length  $r_C = \hbar/m_q$  with the classical charge radius of quark defined as  $r_{cl} = g^2/m_q$ . In this case the size scale of the magnetic body would not depend on  $\hbar$ . For color coupling strength  $\alpha_s = .1$  one would have  $r_{cl}/r_C = 1.26$  so that experimental data do not allow to distinguish between these options. At low energies  $r_{cl}$  would grow and therefore also the viscosity since the lengths of flux tubes would get longer.
3. One can also purely gravitational view about single partonic 2-surface. Taking the notion of gravitational Planck constant seriously [64], one can consider the replacement of  $v$  with the velocity parameter  $v_0$  (dimensionless in the units used) appearing in the gravitational Planck constant  $\hbar_{gr} = G_{eff}M^2/v_0$  and the identification  $l_{free} = 2r_S = 4G_{eff}M$ : the diameter of the black hole identified as partonic 2-surface. Note that Schwarchild radius would be equal to Planck length. Entropy would be given  $4\pi(2G_{eff}M)^2/\hbar G_{eff}$  multiplied by the number  $N = \hbar/\hbar_0$  of the sheets of the covering. This would give the lower bound  $\hbar_0 v_0/4\pi$  which is smaller than that provided by AdS/CFT approach. This option looks the most attractive one.

For all three options one would expect that  $\eta/s$  ratio is same for the quark-gluon plasma formed in heavy ion collisions and in proton-proton collisions. The critical reader probably wonders what one means with the entropy in the strongly interacting system. Magnetic flux tubes could be seen as space-time correlates for entanglement. Can one regard the entropy as a single particle observable? Can one assign to each partonic 2-surfaces an entanglement entropy or does the entropy characterizes pairs of parton surfaces being analogous to potential energy rather than kinetic energy?

### The formula for viscosity based on black-hole analogy

The following argument is a longer version of very concise argument of previous section suggesting that the notion of gravitational Planck constant allows to generalize the formula of the kinetic gas theory to give viscosity in the more general case. Partonic 2-surface is regarded as an analog the horizon of a black-hole. The interior of the black-hole corresponds to a region with an Euclidian signature of the induced metric. The space-time metric in question could be either the induced metric or the effective metric defined by the modified gamma matrices defined by Kähler action [28]. Induced metric seems to be the correct option since it is non-trivial for vacuum extremals of Kähler action but

also the effective metric probably has physical meaning. Only the data at horizon having by definition degenerate four-metric appear in the formula for  $\eta/s$ .

1. The notion of gravitational Planck constant for space-time sheets carrying self gravitational interaction is given by  $\hbar_{gr} = kGM^2/v_0$ , where  $v_0 < c = 1$  has dimensions of velocity. The interpretation is in terms of Planck constant assignable with flux tubes mediating self gravitation and carrying dark energy identified as magnetic energy. The enormous value of Planck constant means cosmological quantum coherence explaining why this energy density is very slow varying and can be therefore described in terms of cosmological constant in good approximation. Negative "pressure" corresponds to magnetic tension.
2. Suppose that  $v_0$  is identified as the velocity appearing as typical velocity in the kinetic theory estimate  $\eta = Mnv l_{free}$ . Suppose that  $l_{free}$  corresponds to Schwarzschild radius for the effective gravitational constant  $l_{free} = 2r_s = 4G_{eff}M$ . Another possible identification is as the scaled up Planck length  $l_{free} = l_P = \sqrt{\hbar G} = GM/\sqrt{v_0}$ . Suppose that the formula for black hole entropy holds true and gives for the entropy of single particle the expression  $S = 4\pi(2G_{eff}M)^2/\hbar G_{eff}$ . This gives  $\eta/s = \hbar v_0/4\pi$  for the first option (note that  $v_0$  dependence disappears. One obtains  $\eta/s = \hbar/16\pi\sqrt{v_0}$  for the second option so that  $v_0$  dependence remains.
3. The objection is that black hole entropy goes to zero as  $\hbar$  increases. One can indeed argue that the  $S = 4\pi(2G_{eff}M)^2/\hbar G_{eff}$  gives only the contribution of single sheet in the  $N = \hbar\bar{a}/\hbar_0$  fold covering of  $M^4 \times CP_2$  so that one must multiply this entropy with  $N$ . This would give

$$\frac{\eta}{S} = \frac{\hbar_0}{4\pi} \times \frac{v_0}{c} .$$

The minimum viscosity can be smaller than  $\hbar_0/4\pi$  and the essential parameter is the velocity parameter  $v_0 = v_0 < c = 1$ . This is true also in AdS-CFT correspondence.

This argument suggests that the Einsteinian dark gravity with gravitational gauge coupling having as parameters p-adic length scale and the typical Kähler action of deformed  $CP_2$  type vacuum extremal could allow to understand viscosity in terms of string-QFT duality in the idealization that the situation reduces to a black-hole physics with partonic 2-surfaces taking the role of black holes. This proposal might make even in the case of condensed matter if one gives up the assumption that the basic objects are more analogous to stars than black-holes.

#### 10.4.5 AdS/CFT is not favored by LHC

As already noticed that the first experimental results from LHC [16] do not favor AdS/CFT duality but are qualitatively consistent with TGD view about gauge-gravity duality. Because of the importance of the results I add a version of my blog posting [2] about these results.

Sabine Hossenfelder told in BackReaction blog about the first results from lead-lead ion collisions at LHC, which have caused a cold shower for AdS/CFT enthusiasts. Or summarizing it in the words of Sabine Hossenfelder:

*As the saying goes, a picture speaks a thousand words, but since links and image sources have a tendency to deteriorate over time, let me spell it out for you: The AdS/CFT scaling does not agree with the data at all.*

#### The results

The basic message is that AdS/CFT fails to explain the heavy ion collision data about jets at LHC. The model should be able to predict how partons lose their momentum in quark gluon plasma assumed to be formed by the colliding heavy nuclei. The situation is of course not simple. Plasma corresponds to low energy QCD and strong coupling and is characterized by temperature. Therefore it could allow description in terms of AdS/CFT duality allowing to treat strong coupling phase. Quarks themselves have a high transversal momentum and perturbative QCD applies to them. One has to understand how plasma affects the behavior of partons. This boils to simple question: What is the energy loss of the jet in plasma before it hadronizes.

The prediction of AdS/CFT approach is a scaling law for the energy loss  $E \propto L^3 T$ , where  $L$  is the length that parton travels through the plasma and the temperature  $T$  is about 500 MeV is the temperatures of the plasma (at RHIC it was about 350 MeV). The figure in the posting of Sabine Hossenfelder [1] compares the prediction for the ratio  $R_{AA}$  of the predicted nuclear cross section for jets in lead-lead collisions to those in proton-proton collisions to experimental data normalized in such a manner that if the nucleus behaved like a collection of independent nucleons the ratio would be equal to one.

That the prediction for  $R_{AA}$  is too small is not so bad a problem: the real problem is that the curve has quite different shape than the curve representing the experimental data. In the real situation  $R_{AA}$  as a function of the average transversal momentum  $p_T$  of the jets approaches faster to the "nucleus as a collection of independent nucleons" situation than predicted by AdS/CFT approach. Both perturbative QCD and AdS/CFT based model fail badly: their predictions do not actually differ much.

An imaginative theoretician can of course invent a lot of excuses. It might be that the number  $N_c = 3$  of quark colors is not large enough so that strong coupling expansion and AdS/CFT fails. Supersymmetry and conformal invariance actually fail. Maybe the plasma temperature is too high (higher than at RHIC where the observed low viscosity of gluon plasma motivated AdS/CFT approach). The presence of both weak coupling regime (high energy partons) and strong coupling regime (the plasma) might have not been treated correctly. One could also defend AdS/CFT by saying that maybe one should take into account higher stringy corrections for strings moving in 10 dimensional  $AdS_5 \times S^5$ . Why not branes? Why not black holes? And so on....

### Could the space-time be 4-dimensional after all?

What is remarkable that a model called "Yet another Jet Energy-loss Model" (YaJEM) based on the simple old Lund model [3] treating gluons as strings in 4-D space-time works best! Also the parameters derived for RHIC do not need large re-adjustment at LHC.

4-D space-time has been out of fashion for decades and now every-one well-informed theoretician talks about emergent space-time. Don't ask what this means. Despite my attempts to understand I (and very probably any-one) do not have a slightest idea. What I know is that string world sheets are 2-dimensional and the only hope to get 4-D space-time is by this magic phenomenon of emergence. In other worlds, 3-brane is what is wanted and it should emerge "non-perturbatively" (do not ask what *this* means!).

Since there are no stringy authorities nearby, I however dare to raise a heretic question. Could it be that string like objects in 4-D space-time are indeed the natural description? Could strings, branes, blackholes, etc. in 10-D space-time be completely un-necessary stuff needed to keep several generations of misled theoreticians busy? Why not to start by trying to build abstraction from something which works? Why not start from Lund model or hadronic string model and generalize it?

This is what TGD indeed was when it emerged some day in October year 1977: a generalization of the hadronic string model by replacing string world sheets with space-time sheets. Another motivation for TGD was as a solution to the energy problem of GRT. In this framework the notion of (color) magnetic flux tubes emerges naturally and magnetic flux tubes are one of the basic structures of the theory now applied in all length scales. The improved mathematical understanding of the theory has led to notions like effective 2-dimensionality and stringy worlds sheets and partonic 2-surfaces at 4-D space-time surface of  $M^4 \times CP_2$  as basic structures of the theory.

### What TGD can say about the situation?

In TGD framework a naive interpretation for LHC results would be that the colliding nuclei do not form a complete plasma and this non-ideality becomes stronger as  $p_T$  increases. As if for higher  $p_T$  the parton would traverse several blobs rather than only single big one and situation would be between an ideal plasma and to that in which nucleons form collections of independent nucleons. Could quantum superposition of states with each of them representing a collection of some number of plasma blobs consisting of several nucleons be in question. Single plasma blob would correspond to the ideal situation. This picture would conform with the vision about color magnetic flux tubes as a source of long range correlations implying that what is called quark-gluon plasma is in the ideal case like single very large hadron and thus a diametrical opposite for parton gas.

In TGD framework where hadrons themselves correspond to space-time sheets, this interpretation is suggestive. The increase of the temperature of the plasma corresponds to the reduction of  $\alpha_s$ , suggesting that with at  $T=500$  GeV at LHC the plasma is more "blobby" than at  $T=350$  GeV at RHIC. This would conform with the fact that at lower temperature at RHIC the AdS/CFT model works better. Note however that at RHIC the model parameters for AdS/CFT are very different from those at LHC [1]: not a good sign at all.

I have also discussed the TGD based explanation of RHIC results for heavy ion collisions and the unexpected behavior of quark-gluon plasma in proton-proton (rather than heavy ion) collisions at LHC [46].

## 10.5 Proposal for a twistorial description of generalized Feynman graphs

Listening of the lectures of Nima Arkani-Hamed is always an inspiring experience and so also at this time [21]. The first recorded lectures was mostly about the basic "philosophical" ideas behind the approach and the second lecture continued discussion of the key points about twistor kinematics which I should already have in my backbone but do not. The lectures stimulated again the feeling that the generalized Feynman diagrammatics has all the needed elements to allow a twistorial description. It should be possible to interpret the diagrams as the analogs of twistorial diagrams.

A couple of new ideas emerged as a result of concentrate effort to build bridge to the twistorial approach.

1. Generalized Feynman diagrams involve only massless states at wormhole throats so that twistorial description makes sense for the kinematical variables. One should identify the counterparts of the lines and vertices of the twistor diagrams constructed from planar polygons and counterparts of the region momenta.
2.  $M^2 \subset M^4$  appears as a central element of TGD based Feynman diagrammatics and  $M^2$  projection of the four momentum appears in propagator and also in the modified Dirac equation. I realized that p-adic mass calculations must give the thermal expectation value of the  $M^2$  mass squared. Since the throats are massless this means that the transversal momentum squared equal to  $CP_2$  contribution plus conformal weight contribution to mass squared.
3. It is not too surprising that a very beautiful interpretation in terms of the analogs of twistorial diagrams becomes possible. The idea is to interpret wormhole contacts as pairs of lines of twistor diagrams carrying on mass shell momenta. In this manner triangles with truncated apexes with double line representing the wormhole throats become the basic objects in generalized Feynman diagrammatics. The somewhat mysterious region momenta of twistor approach correspond to momentum exchanges at the wormhole contacts defining the vertices. A reasonable expectation is that the Yangian invariants used to construct the amplitudes of  $\mathcal{N} = 4$  SUSY can be used as basic building bricks also now.
4. Renormalization group is not understood in the usual twistor approach and p-adic considerations and quantization of the size of causal diamond ( $CD$ ) suggests that the old proposal about discretization of coupling constant evolution to p-adic length scale evolution makes sense. A very concrete realization of the evolution indeed suggest itself and would mean the replacement of each triangle with the quantum superposition of amplitudes associated with triangles with smaller size scale and contained with the original triangle characterized by the size scale of corresponding  $CD$  containing it. In fact the incoming and outgoing particles of of vertex could be located at the light-like boundaries of  $CD$ .
5. The approach should be also number theoretically universal and this suggests that the amplitudes should be expressible in terms of quantum rationals and rational functions having quantum rationals as coefficients of powers of the arguments. Quantum rationals are characterized by p-adic prime  $p$  and p-adic momentum with mass squared interpreted as p-adic integer appears in the propagator. This means that the propagator proportional to  $1/P^2$  is proportional to  $1/p$  when mass squared is divisible by  $p$ , which means that one has pole like contribution. The real

counterpart of propagator in canonical identification is proportional to  $p$ . This would select the all  $CD$  characterized by  $n$  divisible by  $p$  as analogs of poles.

### 10.5.1 What generalized Feynman diagrams could be?

Let us first list briefly what these generalized Feynman diagrams emerge and what they should be.

1. Zero energy ontology and the closely related notion of causal diamond ( $CD$ ) are absolutely essential for the whole approach.  $U$ -matrix between zero energy states is unitary but does not correspond to the  $S$ -matrix. Rather,  $U$ -matrix has as its orthonormal rows  $M$ -matrices which are "complex" square roots of density matrices representable as a product of a Hermitian square root of density matrix and unitary and universal  $S$ -matrix commuting with it so that the Lie algebra of these Hermitian matrices acts as symmetries of  $S$ -matrix. One can allow all  $M$ -matrices obtained by allowing integer powers of  $S$ -matrix and obtains the analog of Kac-Moody algebra. The powers of  $S$  correspond to  $CD$  with temporal distance between its tips coming as integer multiple of  $CP_2$  size. The goal is to construct  $M$ -matrices and these could be non-unitary because of the presence of the hermitian square root of density matrix.
2. If it is assumed that  $M$ -matrix elements can be constructed in terms of generalized Feynman diagrams. What generalized Feynman diagrams strictly speaking are is left open. The basic properties of generalized Feynman diagrams - in particular the property that only massless on mass shell states but with both signs of energy appear - however suggest strongly that they are much more like twistor diagrams and that twistorial method used to sum up Feynman diagrams apply.

#### The lines of the generalized Feynman diagrams

Generalized Feynman diagrams are constructed using solely diagrams containing on mass shell massless particles in both external and internal lines. Massless-ness could mean also massless-ness in  $M^4 \times CP_2$  sense, and p-adic thermodynamics indeed suggests that this is true in some sense.

1. For massless-ness in  $M^4 \times CP_2$  sense the standard twistor description should fail for massive excitations having mass scale of order  $10^4$  Planck masses. At external lines massless states form massive on mass shell particles. In the following this possible difficulty will be neglected. Stringy picture suggests that this problem cannot be fatal.
2. Second possibility is that massless states form composites which in the case of fermions have the mass spectrum determined by  $CP_2$  Dirac operator and that that physical states correspond to states of super-conformal representations with ground states weight determined by the sum of vacuum conformal weight and the contribution of  $CP_2$  mass squared. In this case, one would have massless-ness in  $M^4$  sense but composite would be massless in  $M^4 \times CP_2$  sense. In this case twistorial description would work.
3. The third and the most attractive option is based on the fact that it is  $M^2$  momentum that appears in the propagators. The picture behind p-adic mass calculations is string picture inspired by hadronic string model and in hadron physics one can assign  $M^2$  to longitudinal parts of the parton momenta.

One can therefore consider the possibility that  $M^2$  momentum square obeys p-adic thermodynamics.  $M^2$  momentum appears also in the solutions of the modified Dirac equation so that this identification looks physically very natural.  $M^2$  momentum characterizes naturally also massless extremals (topological light rays) and is in this case massless. Therefore throats could be massless but  $M^2$  momentum identifiable as the physical momentum would be predicted by p-adic thermodynamics and its p-adic norm could correspond to the scale of  $CD$ .

Mathematically this option is certainly the most attractive one and it might be also physically acceptable since integration over moduli characterizing  $M^2$  is performed to get the full amplitude so that there is no breaking of Poincare invariance.

There are also other complications.

1. Massless wormhole throats carry magnetic charges bind to form magnetically neutral composite particles consisting of wormholes connected by magnetic flux tubes. The wormhole throat at the other end of the wormhole carries opposite magnetic charge and neutrino pair canceling the electro-weak isospin of the physical particle. This complication is completely analogous to the appearance of the color magnetic flux tubes in TGD description of hadrons and will be neglected for a moment.
2. Free fermions correspond to single wormhole throats and the ground state is massless for them. Topologically condensed fermions carry mass and the ground states has developed mass by p-adic thermodynamics. Above considerations suggests that the correct interpretation of p-adic thermal mass squared is as  $M^2$  mass squared and that the free fermions are still massless! Bosons are always pairs of wormhole throats. It is convenient to denote bosons and topologically condensed fermions by a pair of parallel lines very close to each other and free fermion by single line.
3. Each wormhole throat carries a braid and braid strands are carriers of four-momentum.
  - (a) The four momenta are parallel and only the  $M^2$  projection of the momentum appears in the fermionic propagator. To obtain Lorentz invariance one must integrate over boosts of  $M^2$  and this corresponds to integrating over the moduli space of causal diamond ( $CD$ ) inside which the generalized Feynman diagrams reside.
  - (b) Each line gives rise to a propagator. The sign of the energy for the wormhole throat can be negative so that one obtains also space-like momentum exchanges.
  - (c) It is not quite clear whether one can allow also purely bosonic braid strands. The dependence of the over all propagator factor on longitudinal momentum is  $1/p^{2n}$  so that throats carrying 1 or 2 fermionic strands (or single purely bosonic strand) are in preferred position and braid strand numbers larger than 2 give rise to something different than ordinary elementary particle. It is probably not an accident that quantum phases  $q = \exp(i2\pi/n)$  give rise to bosonic and fermionic statistics for  $n = 1, 2$  and to braid statistics for  $n > 2$ . States with  $n \geq 3$  are expected to be anyonic. This also reduces the large super symmetry generated by fermionic oscillator operators at the partonic 2-surfaces effectively to  $\mathcal{N} = 1$  SUSY.

In the following It will be assume that all braid strands appearing in the lines are massless and have parallel four-momenta and that  $M^2$  momentum squared is given by p-adic thermodynamics and actually mass squared vanishes. It is also assumed that  $M^2$  momenta of the throats of the wormhole throats are parallel in accordance with the classical idea that wormhole throats move in parallel. It is convenient to denote graphically the wormhole throat by a pair of parallel lines very close to each other.

### Vertices

The following proposal for vertices neglects the fact that physical elementary particles are constructed from wormhole throat pairs connected by magnetic flux tubes. It is however easy to generalizes the proposal to that case.

1. Conservation of momentum holds in each vertex but only for the total momentum assignable to the wormhole contact rather than for each throat. The latter condition would force all partons to have parallel massless four-momenta and the S-matrix would be more or less trivial. Conservation of four-momentum, the massless on mass shell conditions for 4-momenta of wormhole throats and on mass shell conditions  $M^2$  momentum squared given by stringy mass squared spectrum are extremely powerful and it is quite possible that one obtains in a given resolution defined by the largest and smallest causal diamonds finite number of diagrams.
2. I have already earlier developed arguments strongly suggesting that that only three-vertices are fundamental [18]. The three vertex at the level of wormhole throats means gluing of the ends of the generalized line along 2-D partonic two surface defining their ends so that diagrams are generalization of Feynman diagrams rather than 4-D generalizations of string diagrams so that a

generalization of a trouser diagram does not describe particle decay). The vertex can be BFF or BBB vertex or a variant of this kind of vertex obtained by replacing some B:s and F:s with their super-partners obtained by adding right handed neutrino or antineutrino on the wormhole throat carrying fermion number. Massless on mass shell conditions hold true for wormhole throats in internal lines but they are not on mass shell as massive particles like external lines.

3. What happens in the vertex is momentum exchange between different wormhole throats regarded as braids with strands carrying parallel momenta. This momentum exchange in general corresponds to a non-vanishing mass squared and can be graphically described as a line connecting two vertices of a triangle defined by the particles emerging into the vertex. To each vertex of the triangle either massless fermion line or pair of lines describing topologically condensed fermion or boson enters. The lines connecting the vertices of the triangle carry the analogs of region momenta [84], which are in general massive but the differences of two adjacent region momenta are massless. The outcome is nothing but the analog of the twistor diagram. 3- vertices are fundamental and one would obtain only 3-gons and the Feynman graph would be a collection of 3-gons such that from each line emerges an internal or external line.
4. A more detailed graphical description utilizes double lines. For FFB vertices with free fermions one would have 4-gon containing a pair of vertices very near to each other corresponding to the outgoing boson wormhole described by double line. This is obtained by truncating the bosonic vertex of 3-gon and attaching bosonic double line to it. For topologically condensed fermions and BBB vertex one would have 6-gon obtained by truncating all apices of a 3-gon.

Some comments about the diagrammatics is in order.

1. On mass shell conditions and momentum conservation conditions are extremely powerful so that one has excellent reasons to expect that in a given resolution defined by the largest and smallest  $CD$  involves the number of contributing diagrams is finite.
2. The resulting diagrams are very much like twistor diagrams in  $\mathcal{N} = 4$  D=4 SYM for which also three-vertex and its conjugate are the fundamental building bricks from which tree amplitudes are constructed: from tree amplitudes one in turn obtains loop amplitudes by using the recursion formulas. Since all momenta are massless, one can indeed use twistor formalism. For topologically condensed fermions one just forms all possible diagrams consisting of 6-gons for which the truncated apices are connected by double lines and takes care that  $n$  lines are taken to be incoming lines.
3. The lines can cross, and this corresponds to the analog of non-planar diagram. I have proposed a knot-theoretic description of this situation based on the generalized braiding matrix appearing in integrable QFTs defined in  $M^2$ . By using a representation for the braiding operation which can be used to eliminate the crossings of the lines one could transform all diagrams to planar diagrams for which one could apply existing construction recipe.
4. The basic conjecture is that the basic building bricks are Yangian invariants. Not only for the conformal group of  $M^4$  but also for the super-conformal algebra should have an extension to Yangian. This Yangian should be related to the symmetry algebra generated by the M-matrices and analogous to Kac-Moody algebra. For this Yangian points as vertices of the momentum polygon are replaced with partonic 2-surfaces.

### Generalization of the diagrammatics to apply to the physical particles

The previous discussion has neglected the fact that the physical particles are not wormhole contacts. Topologically condensed elementary fermions and bosons indeed correspond to magnetic flux pairs at different space-time sheets with wormhole contacts at the ends. How could one describe this situation in terms of the generalization Feynman diagrams?

The natural guess is that one just puts two copies of diagrams above each other so that the triangles are replaced with small cylinders with cross section given by the triangle and the edges of this triangular cylinder representing magnetic flux tubes. It is natural to allow momentum exchanges also at the other end of the cylinder: for ordinary elementary particle these ends carry only neutrino pairs

so that the contribution to interactions is screening at small momenta. Also momentum exchanges long the direction of the cylinder should be allowed and would correspond to the non-perturbative low energy degrees of freedom in the case of hadrons. This momentum exchange assignable to flux tube would be between the truncated triangle rather than separately along the three vertical edges of the triangular cylinder.

### 10.5.2 Number theoretical universality and quantum arithmetics

The approach should be also number theoretically universal meaning that amplitudes should make sense also in p-adic number fields or perhaps in adelic sense in the tensor product of p-adic numbers fields. Quantum arithmetics is characterized by p-adic prime and canonical identification mapping p-adic amplitudes to real amplitudes is expected to make number theoretical universality possible.

This is achieved if the amplitudes should be expressible in terms of quantum rationals and rational functions having quantum rationals as coefficients of powers of the arguments. This would be achieved by simply mapping ordinary rationals to quantum rationals if they appear as coefficients of polynomials appearing in rational functions.

Quantum rationals are characterized by p-adic prime  $p$  and p-adic momentum with mass squared interpreted as p-adic integer appears in the propagator. If  $M^2$  mass squared is proportional to this p-adic prime  $p$ , propagator behaves as  $1/P^2 \propto 1/p$ , which means that one has pole like contribution for these on mass shell longitudinal masses. p-Adic mass calculations indeed give mass squared proportional to  $p$ . The real counterpart of propagator in canonical identification is proportional to  $p$ . This would select the all  $CD$  characterized by  $n$  divisible by  $p$  as analogs of propagator poles. Note that the infrared singularity is moved and the largest p-adic prime appearing as divisor of integer characterizing the largest  $CD$  indeed serves as a physical IR cutoff.

It would seem that one must allow different p-adic primes in the generalized Feynman diagram since physical particles are in general characterized by different p-adic primes. This would require the analog of tensor product for different quantum rationals analogous to adeles. These numbers would be mapped to real (or complex) numbers by canonical identification.

#### How to get only finite number of diagrams in a given IR and UV resolution?

In gauge theory one obtains infinite number of diagrams. In zero energy ontology the overall important additional constraint comes from on mass shell conditions at internal lines and external lines and from the requirement that the  $M^2$  momentum squared is quantized for super-conformal representation in terms of stringy mass squared spectrum.

This condition alone does not however imply that the number of diagrams is finite. If forward scattering diagram is non-vanishing also scattering without on mass shell massive conditions on final state lines is possible. One can construct diagrams representing a repeated  $n \rightarrow n$  scattering and combining these amplitudes with non-forward scattering amplitude one obtains infinite number of scattering diagrams with fixed initial and final states. Number theoretic universality however requires that the number of the contributing diagrams must be finite unless some analytic miracles happens.

The finite number of diagrams could be achieved if one gives for the vision about  $CD$ s within  $CD$ s a more concrete metric meaning. In spirit of Uncertainty Principle, the size scale of the  $CD$  defined by the temporal distance between its tips could correspond to the inverse of the momentum scale defined as its inverse. A further condition would be that the sub- $CD$ s and their Lorentz boosts are indeed within the  $CD$  and do not overlap. Obviously the number of diagrams representing repeated  $n - n$  scattering forward scattering is finite if these assumptions are made. This would also suggest a scale hierarchy in powers of 2 for  $CD$ s: the reason is that given  $CD$  with scale  $T = nT(CP_2)$  can contain two non-overlapping sub- $CD$ s with the same rest frame only if sub- $CD$  has size scale smaller than  $nT_{CP_2}/2$ . This applies also to the Lorentz boosts of the sub- $CD$ s.

Amplitudes would be constructed by labeling the  $CD$ s by integer  $n$  defining its size scale. p-Adicity suggests that the factorization of  $n$  to primes must be important and if  $n = p$  condition holds true, a new resonant like contribution appears corresponding to p-adic diagrams involving propagator.

Should one allow all  $M^2$  momenta in the loops in all scales or should one restrict the  $M^2$  momenta to have a particular mass squared scale determined somehow by the size of  $CD$  involved? If this kind of constraint is posed it must be posed in mathematically elegant manner and it is not clear how to this.

Is this kind of constraint really necessary? Quantum arithmetics for the length scale characterized by p-adic prime  $p$  would make  $M^2$  mass squared values divisible by  $p$  to almost poles of the propagators, and this might be enough to effectively select the particular  $p$  and corresponding momentum scale and  $CD$  scale. Consider only the Mersenne prime  $M_{127} = 2^{127} - 1$  as a concrete example.

### How to realize the number theoretic universality?

One should be able to realized the p-adicity in some elegant manner. One must certainly allow different p-adic primes in the same diagram and here adelic structure seems unavoidable as tensor product of amplitudes in different p-adic number fields or rather - their quantum arithmetic counterparts characterized by a preferred prime  $p$  and mapped to reals by the substitution  $p \rightarrow 1/p$ . What does this demand?

1. One must be able to glue amplitudes in different p-adic number fields together so that the lines in some case must have dual interpretation as lines of two p-adic number fields. It also seems that one must be able to assign p-adic prime and quantum arithmetics characterized by a given prime  $p$  to a given propagator line. This prime is probably not arbitrarily and it will be found that it should not be larger than the largest prime dividing  $n$  characterizing the  $CD$  considered.
2. Should one assign p-adic prime to a given vertex?
  - (a) Suppose first that bare 3-vertices reduce to algebraic numbers containing no rational factors. This would guarantee that they are same in both real and p-adic sense. Propagators would be however quantum rationals and depend on  $p$  and have almost pole when the integer valued mass squared is proportional to  $p$ .
  - (b) The radiative corrections to the vertex would involve propagators and this suggests that they bring in the dependence on  $p$  giving rise to p-adic coupling constant evolution for the real counterparts of the amplitudes obtained by canonical identification.
    - i. Should also vertices obey p-adic quantum arithmetics for some  $p$ ? What about a vertex in which particles characterized by different p-adic primes enter? Which prime defines the vertex or should the vertex somehow be multi-p p-adic? It seems that vertex cannot contain any prime as such although it could depend on incoming p-adic primes in algebraic or transcendental manner.
    - ii. Could the radiative corrections sum up to algebraic number depending on the incoming p-adic primes? Or are the corrections transcendental as ordinary perturbation theory suggests and involve powers of  $\pi$  and logarithm of mass squared and basically logarithms of some primes requiring infinite-dimensional transcendental extension of p-adic numbers? If radiative corrections depend only on the logarithms of these primes p-adic coupling constant evolution would be obtained. The requirement that radiative vertex corrections vanish does not look physically plausible.
  - (c) Only sub- $CD$ s corresponding to integers  $m < n$  would be possible as sub- $CD$ . A geometrically attractive possibility is that  $CD$  characterized by integer  $n$  allows only propagator lines which correspond to prime factors of integers not larger than the largest prime dividing  $n$  in their quantum arithmetics. Bare vertices in turn could contain only primes larger than the maximal prime dividing  $n$ . This would simplify the situation considerably- This could give rise to coupling constant evolution even in the case that the radiative corrections are vanishing since the rational factors possibly present in vertices would drop away as  $n$  would increase.
  - (d) Integers  $n = 2^k$  give rise to an objection. They would allow only 2-adic propagators and vertices containing no powers of 2. For  $p = 2$  the quantum arithmetics reduces to ordinary arithmetics and ordinary rationals correspond to  $p = 2$  apart from the fact that powers of 2 mapped to their inverses in the canonical identification. This is not a problem and might relate to the fact that primes near powers of 2 are physically preferred. Indeed, the  $CD$ s with  $n = 2^k$  would be in a unique position number theoretically. This would conform with the original - and as such wrong - hypothesis that only these time scales are possible for  $CD$ s. The preferred role of powers of two supports also p-adic length scale hypothesis.

These observations give rather strong clues concerning the construction of the amplitudes. Consider a  $CD$  with time scale characterized by integer  $n$ .

1. For given  $CD$  all sub- $CD$ s with  $m < n$  are allowed and all p-adicities corresponding to the primes appearing as prime factors of given  $m$  are possible.  $m = 2^k$  are in a preferred position since  $p = 2$  quantum rationals not containing 2 reduce to ordinary rationals.
2. The geometric condition that sub- $CD$ s and their boosts remain inside  $CD$  and do not overlap together with momentum conservation and on-mass-shell conditions on internal lines implies that only a finite number of generalized Feynman diagrams are possible for given  $CD$ . This is essential for number theoretical universality. To each sub- $CD$  one must assign its moduli spaces including its not-too-large boosts. Also the planes  $M^2$  associated with sub- $CD$ s should be regarded as independent and one should integrate over their moduli.
3. The construction of amplitudes with a given resolution would be a process involving a finite number of steps. The notion of renormalization group evolution suggests a generalization as a change of the amplitude induced by adding  $CD$ s with size smaller than smallest  $CD$ s and their boosts in a given resolution.
4. It is not clear whether increase of the upper length scale interpreted as IR cutoff makes sense in the similar manner although physical intuition would encourage this expectation.

### 10.5.3 How to understand renormalization flow in twistor context?

In twistor context the notion of mass renormalization is not straightforward since everything is massless. In TGD framework p-adic mass scale hypothesis suggests a solution to the problem.

1. At the fundamental level all elementary particles are massless and only their composites forming physical particles are massive.
2.  $M^2$  mass squared is given by p-adic mass calculations and should correspond to the mass squared of the physical particle. There are contributions from magnetic flux tubes and in the case of baryons this contribution dominates.
3. p-Adic physics discretizes coupling constant flow. Once the p-adic length scale of the particle is fixed its  $M^2$  momentum squared is fixed and massless takes care of the rest.

Consider now how renormalization flow would emerge in this picture. At the level of generalized Feynman diagrams the change of the IR (UV) resolution scale means that the maximal size of the  $CD$ s involve increases (the minimal size of the sides decreases).

Concerning the question what  $CD$  scales should be allowed, the situation is not completely clear.

1. The most general assumption allows integer multiples of  $CP_2$  scale and would guarantee that the products of hermitian matrices and powers of S-matrix commuting with them define Kac-Moody type algebra assignable to M-matrices. If one uses in renormalization group evolution equation  $CD$ s corresponding to integer multiples of  $CP_2$  length scale, the equation would become a difference equation for integer valued variable.
2. p-Adicity would suggest that the scales of  $CD$ s come as prime multiples of  $CP_2$  scale. The proposed realization of p-adicity indeed puts  $CD$ s characterized by p-adic primes  $p$  in a special position since they correspond to the emergence of a vertex corresponding to p-adic prime  $p$  which depends on  $p$  in the sense that the radiative corrections to 3-vertex can give it a dependence on  $\log(p)$ . This requires infinite-D transcendental extension of p-adic numbers.

As far as coupling constant evolution in strict sense is considered, a natural looking choice is evolution of vertices as a function of p-adic primes of the particles arriving to the vertex since radiative corrections are expected to depend on their logarithms.

3. p-Adic length scale hypothesis would allow only p-adic length scales near powers of two. There are excellent reasons to expect that these scales are selected by a kind of evolutionary process favoring those scales for  $CD$ s for which particles are maximally stable. The fact that quantum

arithmetics for  $p = 2$  reduces to ordinary arithmetics when quantum integers do not contain 2 raises with size scales coming as powers of 2 in a special position and also supports p-adic length scale hypothesis.

Renormalization group equations are based on studying what happens in an infinitesimal reduction of UV resolution scale would mean. Now the change cannot be infinitesimal but must correspond to a change in the scale of  $CD$  by one unit defined by  $CP_2$  size scale.

1. The decrease of UV cutoff means addition of new details represented as bare 3-vertices represented by truncated triangle having size below the earlier length scale resolution. The addition can be done inside the original  $CD$  and inside any sub- $CD$  would be in question taking care that the details remain inside  $CD$ . The hope is that this addition of details allows a recursive definition. Typically addition would involve attaching two sub- $CD$ s to propagator line or two propagator lines and connecting them with propagator. The vertex in question would correspond to a p-adic prime dividing the integer characterizing the sub- $CD$ s. Also the increase of the shortest length scale makes sense and means just the deletion of the corresponding sub- $CD$ s. Note that also the positions of sub- $CD$ s inside  $CD$  manner since the number of allowed boosts depends on the position. This would mean an additional complication.
2. The increase of IR cutoff length means that the size of the largest  $CD$  increases. The physical interpretation would be in terms of the time scale in which one observes the process. If this time scale is too long, the process is not visible. For instances, the study of strong interactions between quarks requires short enough scale for  $CD$ . At long scales one only observes hadrons and in even longer scales atomic nuclei and atoms.
3. One could also allow the UV scale to depend on the particle. This scale should correspond to the p-adic mass scales assignable to the stable particle. In hadron physics this kind of renormalization is standard operation.

#### 10.5.4 Comparison with $\mathcal{N} = 4$ SYM

The ultimate hope is to formulate all these ideas in precise formulas. This goal is still far away but one can make trials. Let us first compare the above proposal to the formalism in  $\mathcal{N} = 4$  SYM.

1. In the construction of twistorial amplitudes the 4-D loop integrals are interpreted as residue integrals in complexified momentum space and reduces to residues around the poles. This is analogous to using "on mass shell states" defined by this poles. In TGD framework the situation is different since one explicitly assigns massless on-mass-shell fermions to braid strands and allows the sign of the energy to be both positive and negative.
2. Twistor formalism and description of momentum and helicity in terms of the twistor  $(\lambda, \mu)$  certainly makes sense for any spin. The well-known complications relate to the necessity to use complex twistors for  $M^4$  signature: this would correspond to complexified space-time or momentum space. Also region momenta and associated momentum twistors are the TGD counterparts so that the basic building bricks for defining the analogs of twistorial amplitudes exist.

An important special feature is that the gauge potential is replaced with its  $\mathcal{N} = 4$  super version.

1. This has some non-generic implications. In particular gluon helicity -1 is obtained from 1 ground state by "adding" four spartners with helicity +1/2 each. This interpretation of the two helicities of a massless particle is not possible in  $\mathcal{N} < 4$  theories nor in TGD and the question is whether this is something deep or not remains open.
2. In TGD framework it is natural to interpret all fermion modes associated with partonic 2-surface (and corresponding light-like 3-surfaces) as generators of super-symmetry and fermions are fundamental objects instead of helicity +1 gauge bosons. Right-handed neutrino has special role since it has no electroweak or color interactions and generates SUSY for which breaking is smallest.

3. The  $\mathcal{N} = 2$  SUSY generated by right-handed neutrino and antineutrino is broken since the propagator for states containing three fermion braid strands at the same wormhole throat behaves like  $1/p^3$ : this is already an anyon-like state. The least broken SUSY is  $\mathcal{N} = 1$  SUSY with spartners of fermions being spin zero states. The proposal is that one could construct scattering amplitudes by using a generalize chiral super-field associated with  $\mathcal{N}$  equal to the number of spinor modes acting on ground state that has vanishing helicity. For  $\mathcal{N} = 4$  it has helicity +1 [29]. This would suggest that the analogs of twistorial amplitudes exist and could even have very similar formulas in terms of twistor variables.
4. The all-loop integrand [32] for scattering amplitudes in planar  $\mathcal{N} = 4$  SYM relies of BCFW formula allowing to sew two n-particle three amplitudes together using single analog of propagator line christened as BCFW bridge. Denote by  $Y_{n,k,l}$  n-particle amplitudes with  $k$  positive helicity gluons and  $l$  loops. One can glue  $Y_{n_L,k_L,l_L}$  and  $Y_{n_R,k_R,l_R}$  by using BCFW bridge and "entangled" removal of two external lines  $Y_{n_L+n_R,k=k_L+k_R+1,l=l_L+l_R-1}$  amplitude to get  $Y_{n=n_L+n_R-2,k=k_L+k_R+1,l=l_L+l_R}$  amplitude recursively by starting from just two amplitudes defining the 3-vertices. The procedure involves only residue integral over the  $Gl(k,n)$  for a quantity which is Yangian invariant. The question is whether one could apply this procedure by replacing  $\mathcal{N} = 4$  SUSY with SUSY in TGD sense and generalizing the fundamental three particle vertices appropriately by requiring that they are Yangian invariants?
5. One can also make good guesses for the BCFW bridge and entangled removal. By looking the structure of the amplitudes obtained by the procedure from 3-amplitudes, one learns that one obtains tree diagrams for which some external lines are connected to give loop. The simplest situation would be that BCFW bridge corresponds to  $M^2$  fermion propagator for a given braid strand and entangled removal corresponds to a short cut of two external lines to internal loop line. One would have just ordinary Feynman graphs but vertices connected with Yangian invariants (not that there is sum over loop corrections). It should be easy to kill this conjecture.

### 10.5.5 Very Special Relativity as justification for the special role of $M^2$

The preferred role of  $M^2$  in the construction of generalized Feynman diagrams could be used as a criticism. Poincare invariance is lost. The first answer to the criticism is that one integrates of the choices of  $M^2$  so that Poincare invariance is lost. One can however defend this assumption also from different view point. Actually Glashow and Cohen did this in their Very Special Relativity proposal [29]! While scanning old files, I found an old text about Very Special Relativity of Glashow and Cohen, and realized that it relates very closely to the special role of  $M^2$  in the construction of generalized Feynman diagrams. There is article Very Special Relativity and TGD [2] at my homepage but for some reason the text has disappeared from the book that contained it. I add the article more or less as such here.

Configuration space ("world of classical worlds", WCW) decomposes into a union of sub-configuration spaces associated with future and past light-cones and these in turn decompose to sub-sub-configuration spaces characterized by selection of quantization axes of spin and color quantum numbers. At this level Poincare and even Lorentz group are reduced. The possibility that this kind of breaking might be directly relevant for physics is discussed below.

One might think that Poincare symmetry is something thoroughly understood but the Very Special Relativity [29] proposed by nobelist Sheldon Glashow and Andrew Cohen suggests that this might belief might be wrong. Glashow and Cohen propose that instead of Poincare group, call it  $P$ , some subgroup of  $P$  might be physically more relevant than the whole  $P$ . To not lose four-momentum one must assume that this group is obtained as a semi-direct product of some subgroup of Lorentz group with translations. The smallest subgroup, call it  $L_2$ , is a 2-dimensional Abelian group generated by  $K_x + J_y$  and  $K_y - J_x$ . Here  $K$  refers to Lorentz boosts and  $J$  to rotations. This group leaves invariant light-like momentum in  $z$  direction. By adding  $J_z$  acting in  $L_2$  like rotations in plane, one obtains  $L_3$ , the maximal subgroup leaving invariant light-like momentum in  $z$  direction. By adding also  $K_z$  one obtains the scalings of light-like momentum or equivalently, the isotropy group  $L_4$  of a light-like ray.

The reasons why Glashow and Cohen regard these groups so interesting are following.

1. All kinematical tests of Lorentz invariance are consistent with the reduction of Lorentz invariance to these symmetries.

2. The representations of group  $L_3$  are one-dimensional in both *massive* and massless case (the latter is familiar from massless representations of Poincare group where particle states are characterized by helicity). The mass is invariant only under the smaller group. This might allow to have left-handed massive neutrinos as well as massive fermions with spin dependent mass.
3. The requirement of CP invariance extends all these reduced symmetry groups to the full Poincare group. The observed very small breaking of CP symmetry might correlate with a small breaking of Lorentz symmetry. Matter antimatter asymmetry might relate to the reduced Lorentz invariance.

The idea is highly interesting from TGD point of view. The groups  $L_3$  and  $L_4$  indeed play a very prominent role in TGD.

1. The full Lorentz invariance is obtained in TGD only at the level of the entire configuration space which is union over sub-configuration spaces associated with future and past light-cones (space-time sheets inside future or past light-cone) [35, 17]. These sub-configuration spaces decompose further into a union of sub-sub-configuration spaces for which a choice of quantization axes of spin reflects itself at the level of generalized geometry of the imbedding space (quantum classical correspondence requires that the choice of quantization axes has imbedding space and space-time correlates) [83, 27]. The construction of the geometry for these sub-worlds of classical worlds reduces to light-cone boundary so that the little group  $L_3$  leaving a given point of light-cone boundary invariant is in a special role in TGD framework.
2. The selection of a preferred light-like momentum direction at light-cone boundary corresponds to the selection of quantization axis for angular momentum playing a key role in TGD view about hierarchy of Planck constants associated with a hierarchy of Jones inclusions implying a breaking of Lorentz invariance induced by the selection of quantization axis [83, 27]. The number theoretic vision about quantum TGD implies a selection of two preferred axes corresponding to time-like and space-like direction corresponding to real and preferred imaginary unit for hyperoctonions [72, 70]. In both cases  $L_4$  emerges naturally.
3. The TGD based identification of Kac-Moody symmetries as local isometries of the imbedding space acting on 3-D light-like orbits of partonic 2-surfaces involves a selection of a preferred light-like direction and thus the selection of  $L_4$ .
4. Also the so called massless extremals representing a precisely targeted propagation of patterns of classical gauge fields with light velocity along typically cylindrical tubes without a change in the shape involve  $L_4$ . A very general solution ansatz to classical field equations involves a local decomposition of  $M^4$  to longitudinal and transversal spaces and selection of a light-like direction [8].
5. The parton model of hadrons assumes a preferred longitudinal direction of momentum and mass squared decomposes naturally to longitudinal and transversal mass squared. Also p-adic mass calculations rely heavily on this picture and thermodynamics mass squared might be regarded as a longitudinal mass squared [48]. In TGD framework right handed covariantly constant neutrino generates a super-symmetry in  $CP_2$  degrees of freedom and it might be better to regard left-handed neutrino mass as a longitudinal mass.

This list justifies my own hunch that Glashow and Cohen might have discovered something very important.

HIERARCHY OF PLANCK  
CONSTANTS**

# Chapter 11

## Was von Neumann Right After All?

### 11.1 Introduction

The work with TGD inspired model [81] for topological quantum computation [50] led to the realization that von Neumann algebras [75, 124, 106, 71], in particular so called hyper-finite factors of type  $II_1$  [89], seem to provide the mathematics needed to develop a more explicit view about the construction of S-matrix. In this chapter I will discuss various aspects of type  $II_1$  factors and their physical interpretation in TGD framework. The lecture notes of R. Longo [98] give a concise and readable summary about the basic definitions and results related to von Neumann algebras and I have used this material freely in this chapter. The original discussion has transformed during years from free speculation reflecting in many aspects my ignorance about the mathematics involved to a more realistic view about the role of these algebras in quantum TGD.

#### 11.1.1 Philosophical ideas behind von Neumann algebras

The goal of von Neumann was to generalize the algebra of quantum mechanical observables. The basic ideas behind the von Neumann algebra are dictated by physics. The algebra elements allow Hermitian conjugation  $*$  and observables correspond to Hermitian operators. Any measurable function  $f(A)$  of operator  $A$  belongs to the algebra and one can say that non-commutative measure theory is in question.

The predictions of quantum theory are expressible in terms of traces of observables. Density matrix defining expectations of observables in ensemble is the basic example. The highly non-trivial requirement of von Neumann was that identical a priori probabilities for a detection of states of infinite state system must make sense. Since quantum mechanical expectation values are expressible in terms of operator traces, this requires that unit operator has unit trace:  $tr(Id) = 1$ .

In the finite-dimensional case it is easy to build observables out of minimal projections to 1-dimensional eigen spaces of observables. For infinite-dimensional case the probability of projection to 1-dimensional sub-space vanishes if each state is equally probable. The notion of observable must thus be modified by excluding 1-dimensional minimal projections, and allow only projections for which the trace would be infinite using the straightforward generalization of the matrix algebra trace as the dimension of the projection.

The non-trivial implication of the fact that traces of projections are never larger than one is that the eigen spaces of the density matrix must be infinite-dimensional for non-vanishing projection probabilities. Quantum measurements can lead with a finite probability only to mixed states with a density matrix which is projection operator to infinite-dimensional subspace. The simple von Neumann algebras for which unit operator has unit trace are known as factors of type  $II_1$  [89].

The definitions adopted by von Neumann allow however more general algebras. Type  $I_n$  algebras correspond to finite-dimensional matrix algebras with finite traces whereas  $I_\infty$  associated with a separable infinite-dimensional Hilbert space does not allow bounded traces. For algebras of type  $III$  non-trivial traces are always infinite and the notion of trace becomes useless being replaced by the notion of state which is generalization of the notion of thermodynamical state. The fascinating feature of this notion of state is that it defines a unique modular automorphism of the factor defined apart from unitary inner automorphism and the question is whether this notion or its generalization might be relevant for the construction of M-matrix in TGD.

### 11.1.2 Von Neumann, Dirac, and Feynman

The association of algebras of type  $I$  with the standard quantum mechanics allowed to unify matrix mechanism with wave mechanics. Note however that the assumption about continuous momentum state basis is in conflict with separability but the particle-in-box idealization allows to circumvent this problem (the notion of space-time sheet brings the box in physics as something completely real).

Because of the finiteness of traces von Neumann regarded the factors of type  $II_1$  as fundamental and factors of type  $III$  as pathological. The highly pragmatic and successful approach of Dirac [70] based on the notion of delta function, plus the emergence of  $s$  [77], the possibility to formulate the notion of delta function rigorously in terms of distributions [87, 114], and the emergence of path integral approach [107] meant that von Neumann approach was forgotten by particle physicists.

Algebras of type  $II_1$  have emerged only much later in conformal and topological quantum field theories [112, 128] allowing to deduce invariants of knots, links and 3-manifolds. Also algebraic structures known as bi-algebras, Hopf algebras, and ribbon algebras [94] relate closely to type  $II_1$  factors. In topological quantum computation [50] based on braid groups [56] modular S-matrices they play an especially important role.

In algebraic quantum field theory [38] defined in Minkowski space the algebras of observables associated with bounded space-time regions correspond quite generally to the type  $III_1$  hyper-finite factor [64, 27].

### 11.1.3 Hyper-finite factors in quantum TGD

The following argument suggests that von Neumann algebras known as hyper-finite factors (HFFs) of type  $III_1$  appearing in relativistic quantum field theories provide also the proper mathematical framework for quantum TGD.

1. The Clifford algebra of the infinite-dimensional Hilbert space is a von Neumann algebra known as HFF of type  $II_1$ . There also the Clifford algebra at a given point (light-like 3-surface) of world of classical worlds (WCW) is therefore HFF of type  $II_1$ . If the fermionic Fock algebra defined by the fermionic oscillator operators assignable to the induced spinor fields (this is actually not obvious!) is infinite-dimensional it defines a representation for HFF of type  $II_1$ . Super-conformal symmetry suggests that the extension of the Clifford algebra defining the fermionic part of a super-conformal algebra by adding bosonic super-generators representing symmetries of WCW respects the HFF property. It could however occur that HFF of type  $II_\infty$  results.
2. WCW is a union of sub-WCWs associated with causal diamonds ( $CD$ ) defined as intersections of future and past directed light-cones. One can allow also unions of  $CD$ s and the proposal is that  $CD$ s within  $CD$ s are possible. Whether  $CD$ s can intersect is not clear.
3. The assumption that the  $M^4$  proper distance  $a$  between the tips of  $CD$  is quantized in powers of 2 reproduces p-adic length scale hypothesis but one must also consider the possibility that  $a$  can have all possible values. Since  $SO(3)$  is the isotropy group of  $CD$ , the  $CD$ s associated with a given value of  $a$  and with fixed lower tip are parameterized by the Lobatchevski space  $L(a) = SO(3,1)/SO(3)$ . Therefore the  $CD$ s with a free position of lower tip are parameterized by  $M^4 \times L(a)$ . A possible interpretation is in terms of quantum cosmology with  $a$  identified as cosmic time [65]. Since Lorentz boosts define a non-compact group, the generalization of so called crossed product construction strongly suggests that the local Clifford algebra of WCW is HFF of type  $III_1$ . If one allows all values of  $a$ , one ends up with  $M^4 \times M^4_+$  as the space of moduli for WCW.
4. An interesting special aspect of 8-dimensional Clifford algebra with Minkowski signature is that it allows an octonionic representation of gamma matrices obtained as tensor products of unit matrix 1 and 7-D gamma matrices  $\gamma_k$  and Pauli sigma matrices by replacing 1 and  $\gamma_k$  by octonions. This inspires the idea that it might be possible to end up with quantum TGD from purely number theoretical arguments. This seems to be the case. One can start from a local octonionic Clifford algebra in  $M^8$ . Associativity condition is satisfied if one restricts the octonionic algebra to a subalgebra associated with any hyper-quaternionic and thus 4-D sub-manifold of  $M^8$ . This means that the modified gamma matrices associated with the Kähler action span a complex quaternionic sub-space at each point of the sub-manifold. This associative

sub-algebra can be mapped a matrix algebra. Together with  $M^8 - H$  duality [15, 20] this leads automatically to quantum TGD and therefore also to the notion of WCW and its Clifford algebra which is however only mappable to an associative algebra and thus to HFF of type  $II_1$ .

#### 11.1.4 Hyper-finite factors and M-matrix

HFFs of type  $III_1$  provide a general vision about M-matrix.

1. The factors of type III allow unique modular automorphism  $\Delta^{it}$  (fixed apart from unitary inner automorphism). This raises the question whether the modular automorphism could be used to define the M-matrix of quantum TGD. This is not the case as is obvious already from the fact that unitary time evolution is not a sensible concept in zero energy ontology.
2. Concerning the identification of M-matrix the notion of state as it is used in theory of factors is a more appropriate starting point than the notion modular automorphism but as a generalization of thermodynamical state is certainly not enough for the purposes of quantum TGD and quantum field theories (algebraic quantum field theorists might disagree!). Zero energy ontology requires that the notion of thermodynamical state should be replaced with its "complex square root" abstracting the idea about M-matrix as a product of positive square root of a diagonal density matrix and a unitary S-matrix. This generalization of thermodynamical state -if it exists- would provide a firm mathematical basis for the notion of M-matrix and for the fuzzy notion of path integral.
3. The existence of the modular automorphisms relies on Tomita-Takesaki theorem, which assumes that the Hilbert space in which HFF acts allows cyclic and separable vector serving as ground state for both HFF and its commutant. The translation to the language of physicists states that the vacuum is a tensor product of two vacua annihilated by annihilation oscillator type algebra elements of HFF and creation operator type algebra elements of its commutant isomorphic to it. Note however that these algebras commute so that the two algebras are not hermitian conjugates of each other. This kind of situation is exactly what emerges in zero energy ontology: the two vacua can be assigned with the positive and negative energy parts of the zero energy states entangled by M-matrix.
4. There exists infinite number of thermodynamical states related by modular automorphisms. This must be true also for their possibly existing "complex square roots". Physically they would correspond to different measurement interactions giving rise to Kähler functions of WCW differing only by a real part of holomorphic function of complex coordinates of WCW and arbitrary function of zero mode coordinates and giving rise to the same Kähler metric of WCW.

The concrete construction of M-matrix utilizing the idea of bosonic emergence (bosons as fermion anti-fermion pairs at opposite throats of wormhole contact) meaning that bosonic propagators reduce to fermionic loops identifiable as wormhole contacts leads to generalized Feynman rules for M-matrix in which modified Dirac action containing measurement interaction term defines stringy propagators. This M-matrix should be consistent with the above proposal.

#### 11.1.5 Connes tensor product as a realization of finite measurement resolution

The inclusions  $\mathcal{N} \subset \mathcal{M}$  of factors allow an attractive mathematical description of finite measurement resolution in terms of Connes tensor product but do not fix M-matrix as was the original optimistic belief.

1. In zero energy ontology  $\mathcal{N}$  would create states experimentally indistinguishable from the original one. Therefore  $\mathcal{N}$  takes the role of complex numbers in non-commutative quantum theory. The space  $\mathcal{M}/\mathcal{N}$  would correspond to the operators creating physical states modulo measurement resolution and has typically fractal dimension given as the index of the inclusion. The corresponding spinor spaces have an identification as quantum spaces with non-commutative  $\mathcal{N}$ -valued coordinates.

2. This leads to an elegant description of finite measurement resolution. Suppose that a universal M-matrix describing the situation for an ideal measurement resolution exists as the idea about square root of state encourages to think. Finite measurement resolution forces to replace the probabilities defined by the M-matrix with their  $\mathcal{N}$  "averaged" counterparts. The "averaging" would be in terms of the complex square root of  $\mathcal{N}$ -state and a direct analog of functionally or path integral over the degrees of freedom below measurement resolution defined by (say) length scale cutoff.
3. One can construct also directly M-matrices satisfying the measurement resolution constraint. The condition that  $\mathcal{N}$  acts like complex numbers on M-matrix elements as far as  $\mathcal{N}$ -"averaged" probabilities are considered is satisfied if M-matrix is a tensor product of M-matrix in  $\mathcal{M}(\mathcal{N}$  interpreted as finite-dimensional space with a projection operator to  $\mathcal{N}$ . The condition that  $\mathcal{N}$  averaging in terms of a complex square root of  $\mathcal{N}$  state produces this kind of M-matrix poses a very strong constraint on M-matrix if it is assumed to be universal (apart from variants corresponding to different measurement interactions).

### 11.1.6 Quantum spinors and fuzzy quantum mechanics

The notion of quantum spinor leads to a quantum mechanical description of fuzzy probabilities. For quantum spinors state function reduction cannot be performed unless quantum deformation parameter equals to  $q = 1$ . The reason is that the components of quantum spinor do not commute: it is however possible to measure the commuting operators representing moduli squared of the components giving the probabilities associated with 'true' and 'false'. The universal eigenvalue spectrum for probabilities does not in general contain (1,0) so that quantum qbits are inherently fuzzy. State function reduction would occur only after a transition to  $q=1$  phase and decoherence is not a problem as long as it does not induce this transition.

This chapter represents a summary about the development of the ideas with last sections representing the recent vision about the role of HFFs in TGD. I have saved the reader from those speculations that have turned out to reflect my own ignorance or are inconsistent with what I regarded established parts of quantum TGD.

## 11.2 Von Neumann algebras

In this section basic facts about von Neumann algebras are summarized using as a background material the concise summary given in the lecture notes of Longo [98].

### 11.2.1 Basic definitions

A formal definition of von Neumann algebra [124, 106, 71] is as a  $*$ -subalgebra of the set of bounded operators  $\mathcal{B}(\mathcal{H})$  on a Hilbert space  $\mathcal{H}$  closed under weak operator topology, stable under the conjugation  $J = *: x \rightarrow x^*$ , and containing identity operator  $Id$ . This definition allows also von Neumann algebras for which the trace of the unit operator is not finite.

Identity operator is the only operator commuting with a simple von Neumann algebra. A general von Neumann algebra allows a decomposition as a direct integral of simple algebras, which von Neumann called factors. Classification of von Neumann algebras reduces to that for factors.

$\mathcal{B}(\mathcal{H})$  has involution  $*$  and is thus a  $*$ -algebra.  $\mathcal{B}(\mathcal{H})$  has order structure  $A \geq 0 : (Ax, x) \geq 0$ . This is equivalent to  $A = BB^*$  so that order structure is determined by algebraic structure.  $\mathcal{B}(\mathcal{H})$  has metric structure in the sense that norm defined as supremum of  $\|Ax\|$ ,  $\|x\| \leq 1$  defines the notion of continuity.  $\|A\|^2 = \inf\{\lambda > 0 : AA^* \leq \lambda I\}$  so that algebraic structure determines metric structure.

There are also other topologies for  $\mathcal{B}(\mathcal{H})$  besides norm topology.

1.  $A_i \rightarrow A$  strongly if  $\|Ax - A_i x\| \rightarrow 0$  for all  $x$ . This topology defines the topology of  $C^*$  algebra.  $\mathcal{B}(\mathcal{H})$  is a Banach algebra that is  $\|AB\| \leq \|A\| \times \|B\|$  (inner product is not necessary) and also  $C^*$  algebra that is  $\|AA^*\| = \|A\|^2$ .
2.  $A_i \rightarrow A$  weakly if  $(A_i x, y) \rightarrow (Ax, y)$  for all pairs  $(x, y)$  (inner product is necessary). This topology defines the topology of von Neumann algebra as a sub-algebra of  $\mathcal{B}(\mathcal{H})$ .

Denote by  $M'$  the commutant of  $\mathcal{M}$  which is also algebra. Von Neumann's bicommutant theorem says that  $\mathcal{M}$  equals to its own bi-commutant. Depending on whether the identity operator has a finite trace or not, one distinguishes between algebras of type  $II_1$  and type  $II_\infty$ .  $II_1$  factor allow trace with properties  $tr(Id) = 1$ ,  $tr(xy) = tr(yx)$ , and  $tr(x^*x) > 0$ , for all  $x \neq 0$ . Let  $L^2(\mathcal{M})$  be the Hilbert space obtained by completing  $\mathcal{M}$  respect to the inner product defined  $\langle x|y \rangle = tr(x^*y)$  defines inner product in  $\mathcal{M}$  interpreted as Hilbert space. The normalized trace induces a trace in  $M'$ , natural trace  $Tr_{M'}$ , which is however not necessarily normalized.  $JxJ$  defines an element of  $M'$ : if  $\mathcal{H} = L^2(\mathcal{M})$ , the natural trace is given by  $Tr_{M'}(JxJ) = tr_M(x)$  for all  $x \in M$  and bounded.

### 11.2.2 Basic classification of von Neumann algebras

Consider first some definitions. First of all, Hermitian operators with positive trace expressible as products  $xx^*$  are of special interest since their sums with positive coefficients are also positive.

In quantum mechanics Hermitian operators can be expressed in terms of projectors to the eigen states. There is a natural partial order in the set of isomorphism classes of projectors by inclusion:  $E < F$  if the image of  $\mathcal{H}$  by  $E$  is contained to the image of  $\mathcal{H}$  by a suitable isomorph of  $F$ . Projectors are said to be metrically equivalent if there exist a partial isometry which maps the images  $\mathcal{H}$  by them to each other. In the finite-dimensional case metric equivalence means that isomorphism classes are identical  $E = F$ .

The algebras possessing a minimal projection  $E_0$  satisfying  $E_0 \leq F$  for any  $F$  are called type  $I$  algebras. Bounded operators of  $n$ -dimensional Hilbert space define algebras  $I_n$  whereas the bounded operators of infinite-dimensional separable Hilbert space define the algebra  $I_\infty$ .  $I_n$  and  $I_\infty$  correspond to the operator algebras of quantum mechanics. The states of harmonic oscillator correspond to a factor of type  $I$ .

The projection  $F$  is said to be finite if  $F < E$  and  $F \equiv E$  implies  $F = E$ . Hence metric equivalence means identity. Simple von Neumann algebras possessing finite projections but no minimal projections so that any projection  $E$  can be further decomposed as  $E = F + G$ , are called factors of type  $II$ .

Hyper-finiteness means that any finite set of elements can be approximated arbitrary well with the elements of a finite-dimensional sub-algebra. The hyper-finite  $II_\infty$  algebra can be regarded as a tensor product of hyper-finite  $II_1$  and  $I_\infty$  algebras. Hyper-finite  $II_1$  algebra can be regarded as a Clifford algebra of an infinite-dimensional separable Hilbert space sub-algebra of  $I_\infty$ .

Hyper-finite  $II_1$  algebra can be constructed using Clifford algebras  $C(2n)$  of  $2n$ -dimensional spaces and identifying the element  $x$  of  $2^n \times 2^n$  dimensional  $C(n)$  as the element  $diag(x, x)/2$  of  $2^{n+1} \times 2^{n+1}$ -dimensional  $C(n+1)$ . The union of algebras  $C(n)$  is formed and completed in the weak operator topology to give a hyper-finite  $II_1$  factor. This algebra defines the Clifford algebra of infinite-dimensional separable Hilbert space and is thus a sub-algebra of  $I_\infty$  so that hyper-finite  $II_1$  algebra is more regular than  $I_\infty$ .

von Neumann algebras possessing no finite projections (all traces are infinite or zero) are called algebras of type  $III$ . It was later shown by [65] [61] that these algebras are labeled by a parameter varying in the range  $[0, 1]$ , and referred to as algebras of type  $III_x$ .  $III_1$  category contains a unique hyper-finite algebra. It has been found that the algebras of observables associated with bounded regions of 4-dimensional Minkowski space in quantum field theories correspond to hyper-finite factors of type  $III_1$  [98]. Also statistical systems at finite temperature correspond to factors of type  $III$  and temperature parameterizes one-parameter set of automorphisms of this algebra [64]. Zero temperature limit correspond to  $I_\infty$  factor and infinite temperature limit to  $II_1$  factor.

### 11.2.3 Non-commutative measure theory and non-commutative topologies and geometries

von Neumann algebras and  $C^*$  algebras give rise to non-commutative generalizations of ordinary measure theory (integration), topology, and geometry. It must be emphasized that these structures are completely natural aspects of quantum theory. In particular, for the hyper-finite type  $II_1$  factors quantum groups and Kac Moody algebras [41] emerge quite naturally without any need for ad hoc modifications such as making space-time coordinates non-commutative. The effective 2-dimensionality of quantum TGD (partonic or stringy 2-surfaces code for states) means that these structures appear completely naturally in TGD framework.

### Non-commutative measure theory

von Neumann algebras define what might be a non-commutative generalization of measure theory and probability theory [98].

1. Consider first the commutative case. Measure theory is something more general than topology since the existence of measure (integral) does not necessitate topology. Any measurable function  $f$  in the space  $L^\infty(X, \mu)$  in measure space  $(X, \mu)$  defines a bounded operator  $M_f$  in the space  $\mathcal{B}(L^2(X, \mu))$  of bounded operators in the space  $L^2(X, \mu)$  of square integrable functions with action of  $M_f$  defined as  $M_f g = fg$ .
2. Integral over  $\mathcal{M}$  is very much like trace of an operator  $f_{x,y} = f(x)\delta(x,y)$ . Thus trace is a natural non-commutative generalization of integral (measure) to the non-commutative case and defined for von Neumann algebras. In particular, generalization of probability measure results if the case  $tr(Id) = 1$  and algebras of type  $I_n$  and  $II_1$  are thus very natural from the point of view of non-commutative probability theory.

The trace can be expressed in terms of a cyclic vector  $\Omega$  or vacuum/ground state in physicist's terminology.  $\Omega$  is said to be cyclic if the completion  $\overline{M\Omega} = H$  and separating if  $x\Omega$  vanishes only for  $x = 0$ .  $\Omega$  is cyclic for  $\mathcal{M}$  if and only if it is separating for  $M'$ . The expression for the trace given by

$$Tr(ab) = \left( \frac{(ab + ba)}{2}, \Omega \right) \quad (11.2.1)$$

is symmetric and allows to defined also inner product as  $(a, b) = Tr(a^*b)$  in  $\mathcal{M}$ . If  $\Omega$  has unit norm  $(\Omega, \Omega) = 1$ , unit operator has unit norm and the algebra is of type  $II_1$ . Fermionic oscillator operator algebra with discrete index labeling the oscillators defines  $II_1$  factor. Group algebra is second example of  $II_1$  factor.

The notion of probability measure can be abstracted using the notion of state. State  $\omega$  on a  $C^*$  algebra with unit is a positive linear functional on  $\mathcal{U}$ ,  $\omega(1) = 1$ . By so called KMS construction [98] any state  $\omega$  in  $C^*$  algebra  $\mathcal{U}$  can be expressed as  $\omega(x) = (\pi(x)\Omega, \Omega)$  for some cyclic vector  $\Omega$  and  $\pi$  is a homomorphism  $\mathcal{U} \rightarrow \mathcal{B}(\mathcal{H})$ .

### Non-commutative topology and geometry

$C^*$  algebras generalize in a well-defined sense ordinary topology to non-commutative topology.

1. In the Abelian case Gelfand Naimark theorem [98] states that there exists a contravariant functor  $F$  from the category of unital abelian  $C^*$  algebras and category of compact topological spaces. The inverse of this functor assigns to space  $X$  the continuous functions  $f$  on  $X$  with norm defined by the maximum of  $f$ . The functor assigns to these functions having interpretation as eigen states of mutually commuting observables defined by the function algebra. These eigen states are delta functions localized at single point of  $X$ . The points of  $X$  label the eigenfunctions and thus define the spectrum and obviously span  $X$ . The connection with topology comes from the fact that continuous map  $Y \rightarrow X$  corresponds to homomorphism  $C(X) \rightarrow C(Y)$ .
2. In non-commutative topology the function algebra  $C(X)$  is replaced with a general  $C^*$  algebra. Spectrum is identified as labels of simultaneous eigen states of the Cartan algebra of  $C^*$  and defines what can be observed about non-commutative space  $X$ .
3. Non-commutative geometry can be very roughly said to correspond to  $*$ -subalgebras of  $C^*$  algebras plus additional structure such as symmetries. The non-commutative geometry of Connes [62] is a basic example here.

#### 11.2.4 Modular automorphisms

von Neumann algebras allow a canonical unitary evolution associated with any state  $\omega$  fixed by the selection of the vacuum state  $\Omega$  [98]. This unitary evolution is an automorphism fixed apart form unitary automorphisms  $A \rightarrow UAU^*$  related with the choice of  $\Omega$ .

Let  $\omega$  be a normal faithful state:  $\omega(x^*x) > 0$  for any  $x$ . One can map  $\mathcal{M}$  to  $L^2(\mathcal{M})$  defined as a completion of  $\mathcal{M}$  by  $x \rightarrow x\Omega$ . The conjugation  $*$  in  $\mathcal{M}$  has image at Hilbert space level as a map  $S_0 : x\Omega \rightarrow x^*\Omega$ . The closure of  $S_0$  is an anti-linear operator and has polar decomposition  $S = J\Delta^{1/2}$ ,  $\Delta = SS^*$ .  $\Delta$  is positive self-adjoint operator and  $J$  anti-unitary involution. The following conditions are satisfied

$$\begin{aligned} \Delta^{it}\mathcal{M}\Delta^{-it} &= \mathcal{M} , \\ J\mathcal{M}J &= \mathcal{M}' . \end{aligned} \tag{11.2.2}$$

$\Delta^{it}$  is obviously analogous to the time evolution induced by positive definite Hamiltonian and induces also the evolution of the expectation  $\omega$  as  $\pi \rightarrow \Delta^{it}\pi\Delta^{-it}$ .

### 11.2.5 Joint modular structure and sectors

Let  $\mathcal{N} \subset \mathcal{M}$  be an inclusion. The unitary operator  $\gamma = J_N J_M$  defines a canonical endomorphisms  $M \rightarrow N$  in the sense that it depends only up to inner automorphism on  $\mathcal{N}$ ,  $\gamma$  defines a sector of  $\mathcal{M}$ . The sectors of  $\mathcal{M}$  are defined as  $Sect(\mathcal{M}) = End(\mathcal{M})/Inn(\mathcal{M})$  and form a semi-ring with respected to direct sum and composition by the usual operator product. It allows also conjugation.

$L^2(\mathcal{M})$  is a normal bi-module in the sense that it allows commuting left and right multiplications. For  $a, b \in M$  and  $x \in L^2(\mathcal{M})$  these multiplications are defined as  $axb = aJb^*Jx$  and it is easy to verify the commutativity using the factor  $Jy^*J \in \mathcal{M}'$ . [65] [62] has shown that all normal bi-modules arise in this way up to unitary equivalence so that representation concepts make sense. It is possible to assign to any endomorphism  $\rho$  index  $Ind(\rho) \equiv M : \rho(\mathcal{M})$ . This means that the sectors are in 1-1 correspondence with inclusions. For instance, in the case of hyper-finite  $II_1$  they are labeled by Jones index. Furthermore, the objects with non-integral dimension  $\sqrt{[M : \rho(\mathcal{M})]}$  can be identified as quantum groups, loop groups, infinite-dimensional Lie algebras, etc...

### 11.2.6 Basic facts about hyper-finite factors of type III

Hyper-finite factors of type  $II_1$ ,  $II_\infty$  and  $III_1$ ,  $III_0$ ,  $III_\lambda$ ,  $\lambda \in (0, 1)$ , allow by definition hierarchy of finite approximations and are unique as von Neumann algebras. Also hyper-finite factors of type  $II_\infty$  and type  $III$  could be relevant for the formulation of TGD. HFFs of type  $II_\infty$  and  $III$  could appear at the level operator algebra but that at the level of quantum states one would obtain HFFs of type  $II_1$ . These extended factors inspire highly non-trivial conjectures about quantum TGD. The book of Connes [62] provides a detailed view about von Neumann algebras in general.

#### Basic definitions and facts

A highly non-trivial result is that HFFs of type  $II_\infty$  are expressible as tensor products  $II_\infty = II_1 \otimes I_\infty$ , where  $II_1$  is hyper-finite [62] .

1. *The existence of one-parameter family of outer automorphisms*

The unique feature of factors of type  $III$  is the existence of one-parameter unitary group of outer automorphisms. The automorphism group originates in the following manner.

1. Introduce the notion of linear functional in the algebra as a map  $\omega : \mathcal{M} \rightarrow C$ .  $\omega$  is said to be hermitian it respects conjugation in  $\mathcal{M}$ ; positive if it is consistent with the notion of positivity for elements of  $\mathcal{M}$  in which case it is called weight; state if it is positive and normalized meaning that  $\omega(1) = 1$ , faithful if  $\omega(A) > 0$  for all positive  $A$ ; a trace if  $\omega(AB) = \omega(BA)$ , a vector state if  $\omega(A)$  is "vacuum expectation"  $\omega_\Omega(A) = (\Omega, \omega(A)\Omega)$  for a non-degenerate representation  $(\mathcal{H}, \pi)$  of  $\mathcal{M}$  and some vector  $\Omega \in \mathcal{H}$  with  $\|\Omega\| = 1$ .
2. The existence of trace is essential for hyper-finite factors of type  $II_1$ . Trace does not exist for factors of type  $III$  and is replaced with the weaker notion of state. State defines inner product via the formula  $(x, y) = \phi(y^*x)$  and  $*$  is isometry of the inner product.  $*$ -operator has property known as pre-closedness implying polar decomposition  $S = J\Delta^{1/2}$  of its closure.  $\Delta$  is positive definite unbounded operator and  $J$  is isometry which restores the symmetry between  $\mathcal{M}$  and its commutant  $\mathcal{M}'$  in the Hilbert space  $\mathcal{H}_\phi$ , where  $\mathcal{M}$  acts via left multiplication:  $\mathcal{M}' = J\mathcal{M}J$ .

3. The basic result of Tomita-Takesaki theory is that  $\Delta$  defines a one-parameter group  $\sigma_\phi^t(x) = \Delta^{it}x\Delta^{-it}$  of automorphisms of  $\mathcal{M}$  since one has  $\Delta^{it}\mathcal{M}\Delta^{-it} = \mathcal{M}$ . This unitary evolution is an automorphism fixed apart from unitary automorphism  $A \rightarrow UAU^*$  related with the choice of  $\phi$ . For factors of type I and II this automorphism reduces to inner automorphism so that the group of outer automorphisms is trivial as is also the outer automorphism associated with  $\omega$ . For factors of type III the group of these automorphisms divided by inner automorphisms gives a one-parameter group of  $Out(\mathcal{M})$  of outer automorphisms, which does not depend at all on the choice of the state  $\phi$ .

More precisely, let  $\omega$  be a normal faithful state:  $\omega(x^*x) > 0$  for any  $x$ . One can map  $\mathcal{M}$  to  $L^2(\mathcal{M})$  defined as a completion of  $\mathcal{M}$  by  $x \rightarrow x\Omega$ . The conjugation  $*$  in  $\mathcal{M}$  has image at Hilbert space level as a map  $S_0 : x\Omega \rightarrow x^*\Omega$ . The closure of  $S_0$  is an anti-linear operator and has polar decomposition  $S = J\Delta^{1/2}$ ,  $\Delta = SS^*$ .  $\Delta$  is positive self-adjoint operator and  $J$  anti-unitary involution. The following conditions are satisfied

$$\begin{aligned} \Delta^{it}\mathcal{M}\Delta^{-it} &= \mathcal{M} , \\ J\mathcal{M}J &= \mathcal{M}' . \end{aligned} \tag{11.2.3}$$

$\Delta^{it}$  is obviously analogous to the time evolution induced by positive definite Hamiltonian and induces also the evolution of the expectation  $\omega$  as  $\pi \rightarrow \Delta^{it}\pi\Delta^{-it}$ . What makes this result thought provoking is that it might mean a universal quantum dynamics apart from inner automorphisms and thus a realization of general coordinate invariance and gauge invariance at the level of Hilbert space.

### 2. Classification of HFFs of type III

Connes achieved an almost complete classification of hyper-finite factors of type III completed later by others. He demonstrated that they are labeled by single parameter  $0 \leq \lambda \leq 1$  and that factors of type  $III_\lambda$ ,  $0 \leq \lambda < 1$  are unique. Haagerup showed the uniqueness for  $\lambda = 1$ . The idea was that the the group has an invariant, the kernel  $T(M)$  of the map from time like  $R$  to  $Out(M)$ , consisting of those values of the parameter  $t$  for which  $\sigma_\phi^t$  reduces to an inner automorphism and to unity as outer automorphism. Connes also discovered also an invariant, which he called spectrum  $S(\mathcal{M})$  of  $\mathcal{M}$  identified as the intersection of spectra of  $\Delta_\phi \setminus \{0\}$ , which is closed multiplicative subgroup of  $R^+$ .

Connes showed that there are three cases according to whether  $S(\mathcal{M})$  is

1.  $R^+$ , type  $III_1$
2.  $\{\lambda^n, n \in Z\}$ , type  $III_\lambda$ .
3.  $\{1\}$ , type  $III_0$ .

The value range of  $\lambda$  is this by convention. For the reversal of the automorphism it would be that associated with  $1/\lambda$ .

Connes constructed also an explicit representation of the factors  $0 < \lambda < 1$  as crossed product  $II_\infty$  factor  $\mathcal{N}$  and group  $Z$  represented as powers of automorphism of  $II_\infty$  factor inducing the scaling of trace by  $\lambda$ . The classification of HFFs of type III reduced thus to the classification of automorphisms of  $\mathcal{N} \otimes \mathcal{B}(\mathcal{H})$ . In this sense the theory of HFFs of type III was reduced to that for HFFs of type  $II_\infty$  or even  $II_1$ . The representation of Connes might be also physically interesting.

### Probabilistic view about factors of type III

Second very concise representation of HFFs relies on thermodynamical thinking and realizes factors as infinite tensor product of finite-dimensional matrix algebras acting on state spaces of finite state systems with a varying and finite dimension  $n$  such that one assigns to each factor a density matrix characterized by its eigen values. Intuitively one can think the finite matrix factors as associated with  $n$ -state system characterized by its energies with density matrix  $\rho$  defining a thermodynamics. The logarithm of the  $\rho$  defines the single particle quantum Hamiltonian as  $H = \log(\rho)$  and  $\Delta = \rho = \exp(H)$  defines the automorphism  $\sigma_\phi$  for each finite tensor factor as  $\exp(iHt)$ . Obviously free field representation is in question.

Depending on the asymptotic behavior of the eigenvalue spectrum one obtains different factors [62]

1. Factor of type I corresponds to ordinary thermodynamics for which the density matrix as a function of matrix factor approaches sufficiently fast that for a system for which only ground state has non-vanishing Boltzmann weight.
2. Factor of type  $II_1$  results if the density matrix approaches to identity matrix sufficiently fast. This means that the states are completely degenerate which for ordinary thermodynamics results only at the limit of infinite temperature. Spin glass could be a counterpart for this kind of situation.
3. Factor of type  $III$  results if one of the eigenvalues is above some lower bound for all tensor factors in such a manner that neither factor of type I or  $II_1$  results but thermodynamics for systems having infinite number of degrees of freedom could yield this kind of situation.

This construction demonstrates how varied representations factors can have, a fact which might look frustrating for a novice in the field. In particular, the infinite tensor power of  $M(2, C)$  with state defined as an infinite tensor power of  $M(2, C)$  state assigning to the matrix  $A$  the complex number  $(\lambda^{1/2} A_{11} + \lambda^{-1/2} \phi(A) = A_{22}) / (\lambda^{1/2} + \lambda^{-1/2})$  defines HFF  $III_\lambda$  [62], [10]. Formally the same algebra which for  $\lambda = 1$  gives ordinary trace and HFF of type  $II_1$ , gives  $III$  factor only by replacing trace with state. This simple model was discovered by Powers in 1967.

It is indeed the notion of state or thermodynamics is what distinguishes between factors. This looks somewhat weird unless one realizes that the Hilbert space inner product is defined by the "thermodynamical" state  $\phi$  and thus probability distribution for operators and for their thermal expectation values. Inner product in turn defines the notion of norm and thus of continuity and it is this notion which differs dramatically for  $\lambda = 1$  and  $\lambda < 1$  so that the completions of the algebra differ dramatically.

In particular, there is no sign about  $I_\infty$  tensor factor or crossed product with  $Z$  represented as automorphisms inducing the scaling of trace by  $\lambda$ . By taking tensor product of  $I_\infty$  factor represented as tensor power with induces running from  $-\infty$  to 0 and  $II_1$  HFF with indices running from 1 to  $\infty$  one can make explicit the representation of the automorphism of  $II_\infty$  factor inducing scaling of trace by  $\lambda$  and transforming matrix factors possessing trace given by square root of index  $\mathcal{M} : \mathcal{N}$  to those with trace 2.

## 11.3 Braid group, von Neumann algebras, quantum TGD, and formation of bound states

The article of Vaughan Jones in [56] discusses the relation between knot theory, statistical physics, and von Neumann algebras. The intriguing results represented stimulate concrete ideas about how to understand the formation of bound states quantitatively using the notion of join along boundaries bond. All mathematical results represented in the following discussion can be found in [56] and in the references cited therein so that I will not bother to refer repeatedly to this article in the sequel.

### 11.3.1 Factors of von Neumann algebras

Von Neumann algebras  $M$  are algebras of bounded linear operators acting in Hilbert space. These algebras contain identity, are closed with respect to Hermitian conjugation, and are topologically complete. Finite-dimensional von Neumann algebras decompose into a direct sum of algebras  $M_n$ , which act essentially as matrix algebras in Hilbert spaces  $\mathcal{H}_{nm}$ , which are tensor products  $C^n \otimes \mathcal{H}_m$ . Here  $\mathcal{H}_m$  is an  $m$ -dimensional Hilbert space in which  $M_n$  acts trivially.  $m$  is called the multiplicity of  $M_n$ .

A factor of von Neumann algebra is a von Neumann algebra whose center is just the scalar multiples of identity. The algebra of bounded operators in an infinite-dimensional Hilbert space is certainly a factor. This algebra decomposes into "atoms" represented by one-dimensional projection operators. This kind of von Neumann algebras are called type I factors.

The so called type  $II_1$  factors and type  $III$  factors came as a surprise even for Murray and von Neumann.  $II_1$  factors are infinite-dimensional and analogs of the matrix algebra factors  $M_n$ . They allow a trace making possible to define an inner product in the algebra. The trace defines a generalized dimension for any subspace as the trace of the corresponding projection operator. This dimension is

however continuous and in the range  $[0, 1]$ : the finite-dimensional analog would be the dimension of the sub-space divided by the dimension of  $\mathcal{H}_n$  and having values  $(0, 1/n, 2/n, \dots, 1)$ .  $\text{II}_1$  factors are isomorphic and there exists a minimal "hyper-finite"  $\text{II}_1$  factor is contained by every other  $\text{II}_1$  factor.

Just as in the finite-dimensional case, one can assign a multiplicity to the Hilbert spaces where  $\text{II}_1$  factors act on. This multiplicity, call it  $\dim_M(\mathcal{H})$  is analogous to the dimension of the Hilbert space tensor factor  $\mathcal{H}_m$ , in which  $\text{II}_1$  factor acts trivially. This multiplicity can have all positive real values. Quite generally, von Neumann factors of type I and  $\text{II}_1$  are in many respects analogous to the coefficient field of a vector space.

### 11.3.2 Sub-factors

Sub-factors  $N \subset M$ , where  $N$  and  $M$  are of type  $\text{II}_1$  and have same identity, can be also defined. The observation that  $M$  is analogous to an algebraic extension of  $N$  motivates the introduction of index  $|M : N|$ , which is essentially the dimension of  $M$  with respect to  $N$ . This dimension is an analog for the complex dimension of  $CP_2$  equal to 2 or for the algebraic dimension of the extension of p-adic numbers.

The following highly non-trivial results about the dimensions of the tensor factors hold true.

1. If  $N \subset M$  are  $\text{II}_1$  factors and  $|M : N| < 4$ , there is an integer  $n \geq 3$  such  $|M : N| = r = 4\cos^2(\pi/n)$ ,  $n \geq 3$ .
2. For each number  $r = 4\cos^2(\pi/n)$  and for all  $r \geq 4$  there is a sub-factor  $R_r \subset R$  with  $|R : R_r| = r$ .

One can say that  $M$  effectively decomposes to a tensor product of  $N$  with a space, whose dimension is quantized to a certain algebraic number  $r$ . The values of  $r$  corresponding to  $n = 3, 4, 5, 6, \dots$  are  $r = 1, 2, 1 + \Phi \simeq 2.61, 3, \dots$  and approach to the limiting value  $r = 4$ . For  $r \geq 4$  the dimension becomes continuous.

An even more intriguing result is that by starting from  $N \subset M$  with a projection  $e_N: M \rightarrow N$  one can extend  $M$  to a larger  $\text{II}_1$  algebra  $\langle M, e_N \rangle$  such that one has

$$\begin{aligned} |\langle M, e_N \rangle : M| &= |M : N| , \\ \text{tr}(xe_N) &= |M : N|^{-1} \text{tr}(x) , \quad x \in M . \end{aligned} \tag{11.3.1}$$

One can continue this process and the outcome is a tower of  $\text{II}_1$  factors  $M_i \subset M_{i+1}$  defined by  $M_1 = N$ ,  $M_2 = M$ ,  $M_{i+1} = \langle M_i, e_{M_{i-1}} \rangle$ . Furthermore, the projection operators  $e_{M_i} \equiv e_i$  define a Temperley-Lieb representation of the braid algebra via the formulas

$$\begin{aligned} e_i^2 &= e_i , \\ e_i e_{i\pm 1} e_i &= \tau e_i , \quad \tau = 1/|M : N| \\ e_i e_j &= e_j e_i , \quad |i - j| \geq 2 . \end{aligned} \tag{11.3.2}$$

Temperley Lieb algebra will be discussed in more detail later. Obviously the addition of a tensor factor of dimension  $r$  is analogous with the addition of a strand to a braid.

The hyper-finite algebra  $R$  is generated by the set of braid generators  $\{e_1, e_2, \dots\}$  in the braid representation corresponding to  $r$ . Sub-factor  $R_1$  is obtained simply by dropping the lowest generator  $e_1, R_2$  by dropping  $e_1$  and  $e_2$ , etc..

### 11.3.3 $\text{II}_1$ factors and the spinor structure of infinite-dimensional configuration space of 3-surfaces

The following observations serve as very suggestive guidelines for how one could interpret the above described results in TGD framework.

1. The discrete spectrum of dimensions  $1, 2, 1 + \Phi, 3, \dots$  below  $r < 4$  brings in mind the discrete energy spectrum for bound states whereas the for  $r \geq 4$  the spectrum of dimensions is analogous to a continuum of unbound states. The fact that  $r$  is an algebraic number for  $r < 4$  conforms

with the vision that bound state entanglement corresponds to entanglement probabilities in an extension of rationals defining a finite-dimensional extension of p-adic numbers for every prime  $p$ .

2. The discrete values of  $r$  correspond precisely to the angles  $\phi$  allowed by the unitarity of Temperley-Lieb representations of the braid algebra with  $d = -\sqrt{r}$ . For  $r \geq 4$  Temperley-Lieb representation is not unitary since  $\cos^2(\pi/n)$  becomes formally larger than one ( $n$  would become imaginary and continuous). This could mean that  $r \geq 4$ , which in the generic case is a transcendental number, represents unbound entanglement, which in TGD Universe is not stable against state preparation and state function reduction processes.
3. The formula  $tr(xe_N) = |M : N|^{-1}tr(x)$  is completely analogous to the formula characterizing the normalization of the link invariant induced by the second Markov move in which a new strand is added to a braid such that it braids only with the leftmost strand and therefore does not change the knot resulting as a link closure. Hence the addition of a single strand seems to correspond to an introduction of an  $r$ -dimensional sub-factor to  $II_1$  factor.

In TGD framework the generation of bound state has the formation of (possibly braided join along boundaries bonds as a space-time correlate and this encourages a rather concrete interpretation of these findings. Also the  $I_1$  factors themselves have a nice interpretation in terms of the configuration space spinor structure.

1. *The interpretation of  $II_1$  factors in terms of Clifford algebra of configuration space*

The Clifford algebra of an infinite-dimensional Hilbert space defines a  $II_1$  factor. The counterparts for  $e_i$  would naturally correspond to the analogs of projection operators  $(1 + \sigma_i)/2$  and thus to operators of form  $(1 + \Sigma_{ij})/2$ , defined by a subset of sigma matrices. The first guess is that the index pairs are  $(i, j) = (1, 2), (2, 3), (3, 4), \dots$ . The dimension of the Clifford algebra is  $2^N$  for  $N$ -dimensional space so that  $\Delta N = 1$  would correspond to  $r = 2$  in the classical case and to one qubit. The problem with this interpretation is  $r > 2$  has no physical interpretation: the formation of bound states is expected to reduce the value of  $r$  from its classical value rather than increase it.

One can however consider also the sequence  $(i, j) = (1, 1 + k), (1 + k, 1 + 2k), (1 + 2k, 1 + 3k), \dots$ . For  $k = 2$  the reduction of  $r$  from  $r = 4$  would be due to the loss of degrees of freedom due to the formation of a bound state and  $(r = 4, \Delta N = 2)$  would correspond to the classical limit resulting at the limit of weak binding. The effective elimination of the projection operators from the braid algebra would reflect this loss of degrees of freedom. This interpretation could at least be an appropriate starting point in TGD framework.

In TGD Universe physical states correspond to configuration space spinor fields, whose gamma matrix algebra is constructed in terms of second quantized free induced spinor fields defined at space-time sheets. The original motivation was the idea that the quantum states of the Universe correspond to the modes of purely classical free spinor fields in the infinite-dimensional configuration space of 3-surfaces (the world of classical worlds) possessing general coordinate invariant (in 4-dimensional sense!) Kähler geometry. Quantum information-theoretical motivation could have come from the requirement that these fields must be able to code information about the properties of the point (3-surface, and corresponding space-time sheet). Scalar fields would treat the 3-surfaces as points and are thus not enough. Induced spinor fields allow however an infinite number of modes: according to the naive Fourier analyst's intuition these modes are in one-one correspondence with the points of the 3-surface. Second quantization gives much more. Also non-local information about the induced geometry and topology must be coded, and here quantum entanglement for states generated by the fermionic oscillator operators coding information about the geometry of 3-surface provides enormous information storage capacity.

In algebraic geometry also the algebra of the imbedding space of algebraic variety divided by the ideal formed by functions vanishing on the surface codes information about the surface: for instance, the maximal ideals of this algebra code for the points of the surface (functions of imbedding space vanishing at a particular point). The function algebra of the imbedding space indeed plays a key role in the construction of the configuration space-geometry besides second quantized fermions.

The Clifford algebra generated by the configuration space gamma matrices at a given point (3-surface) of the configuration space of 3-surfaces could be regarded as a  $II_1$ -factor associated with the local tangent space endowed with Hilbert space structure (configuration space Kähler metric). The

counterparts for  $e_i$  would naturally correspond to the analogs of projection operators  $(1 + \sigma_i)/2$  and thus operators of form  $(G_{\overline{AB}} \times 1 + \Sigma_{\overline{AB}})$  formed as linear combinations of components of the Kähler metric and of the sigma matrices defined by gamma matrices and contracted with the generators of the isometries of the configuration space. The addition of single complex degree of freedom corresponds to  $\Delta N = 2$  and  $r = 4$  and the classical limit and would correspond to the addition of single braid. ( $r < 4, \Delta N < 2$ ) would be due to the binding effects.

$r = 1$  corresponds to  $\Delta N = 0$ . The first interpretation is in terms of strong binding so that the addition of particle does not increase the number of degrees of freedom. In TGD framework  $r = 1$  might also correspond to the addition of zero modes which do not contribute to the configuration space metric and spinor structure but have a deep physical significance. ( $r = 2, \Delta N = 1$ ) would correspond to strong binding reducing the spinor and space-time degrees of freedom by a factor of half.  $r = \Phi^2$  ( $n = 5$ ) *resp.*  $r = 3$  ( $n = 6$ ) corresponds to  $\Delta N_r \simeq 1.3885$  *resp.*  $\Delta N_r = 1.585$ . Using the terminology of quantum field theories, one might say that in the infinite-dimensional context a given complex bound state degree of freedom possesses anomalous real dimension  $r < 2$ .  $r \geq 4$  would correspond to a unbound entanglement and increasingly classical behavior.

### 11.3.4 About possible space-time correlates for the hierarchy of $\text{II}_1$ sub-factors

By quantum classical correspondence the infinite-dimensional physics at the configuration space level should have definite space-time correlates. In particular, the dimension  $r$  should have some fractal dimension as a space-time correlate.

#### 1. Quantum classical correspondence

Join along boundaries bonds serve as correlates for bound state formation. The presence of join along boundaries bonds would lead to a generation of bound states just by reducing the degrees of freedom to those of connected 3-surface. The bonds would constrain the two 3-surfaces to single space-like section of imbedding space.

This picture would allow to understand the difficulties related to Bethe-Salpeter equations for bound states based on the assumption that particles are points moving in  $M^4$ . The restriction of particles to time=constant section leads to a successful theory which is however non-relativistic. The basic binding energy would relate to the entanglement of the states associated with the bonded 3-surfaces. Since the classical energy associated with the bonds is positive, the binding energy tends to be reduced as  $r$  increases.

By spin glass degeneracy join along boundaries bonds have an infinite number of degrees of freedom in the ordinary sense. Since the system is infinite-dimensional and quantum critical, one expects that the number  $r$  of degrees freedom associated with a single join along boundaries bond is universal. Since join along boundaries bonds correspond to the strands of a braid and are correlates for the bound state formation, the natural guess is that  $r = 4\cos^2(\pi/n)$ ,  $n = 3, 4, 5, \dots$  holds true.  $r < 4$  should characterize both binding energy and the dimension of the effective tensor factor introduced by a new join along boundaries bond.

The assignment of 2 "bare" and  $\Delta N \leq 2$  renormalized real dimensions to single join along boundaries bond is consistent with the effective two-dimensionality of anyon systems and with the very notion of the braid group. The picture conforms also with the fact that the degrees of freedom in question are associated with metrically 2-dimensional light-like boundaries (of say magnetic flux tubes) acting as causal determinants. Also vibrational degrees of freedom described by Kac-Moody algebra are present and the effective 2-dimensionality means that these degrees of freedom are not excited and only topological degrees of freedom coded by the position of the puncture remain.

( $r \geq 4, \Delta N \geq 2$ ), if possible at all, would mean that the tensor factor associated with the join along boundaries bond is effectively more than 4-dimensional due to the excitation of the vibrational Kac-Moody degrees of freedom. The finite value of  $r$  would mean that most of them are eliminated also now but that their number is so large that bound state entanglement is not possible anymore.

The introduction of non-integer dimension could be seen as an effective description of an infinite-dimensional system as a finite-dimensional system in the spirit of renormalization group philosophy. The non-unitarity of  $r \geq 4$  Temperley-Lieb representations could mean that they correspond to unbound entanglement unstable against state function reduction and preparation processes. Since

this kind of entanglement does not survive in quantum jump it is not representable in terms of braid groups.

2. Does  $r$  define a fractal dimension of  $CP_2$  projection of partonic 2-surface?

On basis of the quantum classical correspondence one expects that  $r$  should define some fractal dimension at the space-time level. Since  $r$  varies in the range  $1, \dots, 4$  and corresponds to the fractal dimension of 2-D Clifford algebra the corresponding spinors would have dimension  $d = \sqrt{r}$ . There are two options.

1.  $D = r/2$  is suggested on basis of the construction of quantum version of  $M^d$ .
2.  $D = \log_2(r)$  is natural on basis of the dimension  $d = 2^{D/2}$  of spinors in D-dimensional space.

$r$  can be assigned with  $CP_2$  degrees of freedom in the model for the quantization of Planck constant based on the explicit identification of Josephson inclusions in terms of finite subgroups of  $SU(2) \subset SU(3)$ . Hence  $D$  should relate to the  $CP_2$  projection of the partonic 2-surface and one could have  $D = D(X^2)$ , the latter being the average dimension of the  $CP_2$  projection of the partonic 2-surface for the preferred extremals of Kähler action.

Since a strongly interacting non-perturbative phase should be in question, the dimension for the  $CP_2$  projection of the space-time surface must be at least  $D(X^4) = 2$  to guarantee that non-vacuum extremals are in question. This is true for  $D(X^2) = r/2 \geq 1$ . The logarithmic formula  $D(X^2) = \log_2(r) \geq 0$  gives  $D(X^2) = 0$  for  $n = 3$  meaning that partonic 2-surfaces are vacua: space-time surface can still be a non-vacuum extremal.

As  $n$  increases, the number of  $CP_2$  points covering a given  $M^4$  point and related by the finite subgroup of  $G \subset SU(2) \subset SU(3)$  defining the inclusion increases so that the fractal dimension of the  $CP_2$  projection is expected to increase also.  $D(X^2) = 2$  would correspond to the space-time surfaces for which partons have topological magnetic charge forcing them to have a 2-dimensional  $CP_2$  projection. There are reasons to believe that the projection must be homologically non-trivial geodesic sphere of  $CP_2$ .

### 11.3.5 Could binding energy spectra reflect the hierarchy of effective tensor factor dimensions?

If one takes completely seriously the idea that join along boundaries bonds are a correlate of binding then the spectrum of binding energies might reveal the hierarchy of the fractal dimensions  $r(n)$ . Hydrogen atom and harmonic oscillator have become symbols for bound state systems. Hence it is of interest to find whether the binding energy spectrum of these systems might be expressed in terms of the "binding dimension"  $x(n) = 4 - r(n)$  characterizing the deviation of dimension from that at the limit of a vanishing binding energy. The binding energies of hydrogen atom are in a good approximation given by  $E(n)/E(1) = 1/n^2$  whereas in the case of harmonic oscillator one has  $E(n)/E_0 = 2n + 1$ . The constraint  $n \geq 3$  implies that the principal quantum number must correspond  $n - 2$  in the case of hydrogen atom and to  $n - 3$  in the case of harmonic oscillator.

Before continuing one must face an obvious objection. By previous arguments different values of  $r$  correspond to different values of  $\hbar$ . The value of  $\hbar$  cannot however differ for the states of hydrogen atom. This is certainly true. The objection however leaves open the possibility that the states of the light-like boundaries of join along boundaries bonds correspond to reflective level and represent some aspects of the physics of, say, hydrogen atom.

In the general case the energy spectrum satisfies the condition

$$\frac{E_B(n)}{E_B(3)} = \frac{f(4 - r(n))}{f(3)}, \tag{11.3.3}$$

where  $f$  is some function. The simplest assumption is that the spectrum of binding energies  $E_B(n) = E(n) - E(\infty)$  is a linear function of  $r(n) - 4$ :

$$\frac{E_B(n)}{E_B(3)} = \frac{4 - r(n)}{3} = \frac{4}{3} \sin^2\left(\frac{\pi}{n}\right) \rightarrow \frac{4\pi^2}{3} \times \frac{1}{n^2}. \tag{11.3.4}$$

In the linear approximation the ratio  $E(n+1)/E(n)$  approaches  $(n/n+1)^2$  as in the case of hydrogen atom but for small values the linear approximation fails badly. An exact correspondence results for

$$\frac{E(n)}{E(1)} = \frac{1}{n^2} ,$$

$$n = \frac{1}{\pi \arcsin(\sqrt{1-r(n+2)/4})} - 2 .$$

Also the ionized states with  $r \geq 4$  would correspond to bound states in the sense that two particle would be constrained to move in the same space-like section of space-time surface and should be distinguished from genuinely free states when particles correspond to disjoint space-time sheets.

For the harmonic oscillator one express  $E(n) - E(0)$  instead of  $E(n) - E(\infty)$  as a function of  $x = 4 - r$  and one would have

$$\frac{E(n)}{E(0)} = 2n + 1 ,$$

$$n = \frac{1}{\pi \arcsin(\sqrt{1-r(n+3)/4})} - 3 .$$

In this case ionized states would not be possible due to the infinite depth of the harmonic oscillator potential well.

### 11.3.6 Four-color problem, $\Pi_1$ factors, and anyons

The so called four-color problem can be phrased as a question whether it is possible to color the regions of a plane map using only four colors in such a manner that no adjacent regions have the same color (for an enjoyable discussion of the problem see [48] ). One might call this kind of coloring complete. There is no loss of generality in assuming that the map can be represented as a graph with regions represented as triangle shaped faces of the graph. For the dual graph the coloring of faces becomes coloring of vertices and the question becomes whether the coloring is possible in such a manner that no vertices at the ends of the same edge have same color. The problem can be generalized by replacing planar maps with maps defined on any two-dimensional surface with or without boundary and arbitrary topology. The four-color problem has been solved with an extensive use of computer [44] but it would be nice to understand why the complete coloring with four colors is indeed possible.

There is a mysterious looking connection between four-color problem and the dimensions  $r(n) = 4\cos^2(\pi/n)$ , which are in fact known as Beraha numbers in honor of the discoverer of this connection [111] . Consider a more general problem of coloring two-dimensional map using  $m$  colors. One can construct a polynomial  $P(m)$ , so called chromatic polynomial, which tells the number of colorings satisfying the condition that no neighboring vertices have the same color. The vanishing of the chromatic polynomial for an integer value of  $m$  tells that the complete coloring using  $m$  colors is not possible.

$P(m)$  has also other than integer valued real roots. The strange discovery due to Beraha is that the numbers  $B(n)$  appear as approximate roots of the chromatic polynomial in many situations. For instance, the four non-integral real roots of the chromatic polynomial of the truncated icosahedron are very close to  $B(5)$ ,  $B(7)$ ,  $B(8)$  and  $B(9)$ . These findings led Beraha to formulate the following conjecture. Let  $P_i$  be a sequence of chromatic polynomials for a graph for which the number of vertices approaches infinity. If  $r_i$  is a root of the polynomial approaching a well-defined value at the limit  $i \rightarrow \infty$ , then the limiting value of  $r(i)$  is Beraha number.

A physicist's proof for Beraha's conjecture based on quantum groups and conformal theory has been proposed [111] . It is interesting to look for the a possible physical interpretation of 4-color problem and Beraha's conjecture in TGD framework.

1. In TGD framework  $B(n)$  corresponds to a renormalized dimension for a 2-spin system consisting of two qubits, which corresponds to 4 different colors. For  $B(n) = 4$  two spin 1/2 fermions obeying Fermi statistics are in question. Since the system is 2-dimensional, the general case corresponds to two anyons with fractional spin  $B(n)/4$  giving rise to  $B(n) < 4$  colors and obeying fractional statistics instead of Fermi statistics. One can replace coloring problem with the problem whether an ideal antiferro-magnetic lattice using anyons with fractional spin  $B(n)/4$

is possible energetically. In other words, does this system form a quantum mechanical bound state even at the limit when the lengths of the edges approach to zero.

2. The failure of coloring means that there are at least two neighboring vertices in the lattice with the property that the spins at the ends of the same edge are in the same direction. Lattice defect would be in question. At the limit of an infinitesimally short edge length the failure of coloring is certainly not an energetically favored option for fermionic spins ( $m = 4$ ) but is allowed by anyonic statistics for  $m = B(n) < 4$ . Thus one has reasons to expect that when anyonic spin is  $B(n)/4$  the formation of a purely 2-anyon bound states becomes possible and they form at the limit of an infinitesimal edge length a kind of topological macroscopic quantum phase with a non-vanishing binding energy. That  $B(n)$  are roots of the chromatic polynomial at the continuum limit would have a clear physical interpretation.
3. Only  $B(n) < 4$  defines a sub-factor of von Neumann algebra allowing unitary Temperley-Lieb representations. This is consistent with the fact that for  $m = 4$  complete coloring must exist. The physical argument is that otherwise a macroscopic quantum phase with non-vanishing binding energy could result at the continuum limit and the upper bound for  $r$  from unitarity would be larger than 4. For  $m = 4$  the completely anti-ferromagnetic state would represent the ground state and the absence of anyon-pair condensate would mean a vanishing binding energy.

## 11.4 Inclusions of $II_1$ and $III_1$ factors

Inclusions  $\mathcal{N} \subset \mathcal{M}$  of von Neumann algebras have physical interpretation as a mathematical description for sub-system-system relation. For type  $I$  algebras the inclusions are trivial and tensor product description applies as such. For factors of  $II_1$  and  $III$  the inclusions are highly non-trivial. The inclusion of type  $II_1$  factors were understood by Vaughan Jones [4] and those of factors of type  $III$  by Alain Connes [61].

Sub-factor  $\mathcal{N}$  of  $\mathcal{M}$  is defined as a closed  $*$ -stable C-subalgebra of  $\mathcal{M}$ . Let  $\mathcal{N}$  be a sub-factor of type  $II_1$  factor  $\mathcal{M}$ . Jones index  $\mathcal{M} : \mathcal{N}$  for the inclusion  $\mathcal{N} \subset \mathcal{M}$  can be defined as  $\mathcal{M} : \mathcal{N} = \dim_{\mathcal{N}}(L^2(\mathcal{M})) = \text{Tr}_{\mathcal{N}'}(\text{id}_{L^2(\mathcal{M})})$ . One can say that the dimension of completion of  $\mathcal{M}$  as  $\mathcal{N}$  module is in question.

### 11.4.1 Basic findings about inclusions

What makes the inclusions non-trivial is that the position of  $\mathcal{N}$  in  $\mathcal{M}$  matters. This position is characterized in case of hyper-finite  $II_1$  factors by index  $\mathcal{M} : \mathcal{N}$  which can be said to the dimension of  $\mathcal{M}$  as  $\mathcal{N}$  module and also as the inverse of the dimension defined by the trace of the projector from  $\mathcal{M}$  to  $\mathcal{N}$ . It is important to notice that  $\mathcal{M} : \mathcal{N}$  does not characterize either  $\mathcal{M}$  or  $\mathcal{N}$ , only the imbedding.

The basic facts proved by Jones are following [4].

1. For pairs  $\mathcal{N} \subset \mathcal{M}$  with a finite principal graph the values of  $\mathcal{M} : \mathcal{N}$  are given by

$$\begin{aligned}
 a) \quad \mathcal{M} : \mathcal{N} &= 4\cos^2(\pi/h) \quad , \quad h \geq 3 \quad , \\
 b) \quad \mathcal{M} : \mathcal{N} &\geq 4 \quad .
 \end{aligned}
 \tag{11.4.1}$$

the numbers at right hand side are known as Beraha numbers [111]. The comments below give a rough idea about what finiteness of principal graph means.

2. As explained in [41], for  $\mathcal{M} : \mathcal{N} < 4$  one can assign to the inclusion Dynkin graph of ADE type Lie-algebra  $g$  with  $h$  equal to the Coxeter number  $h$  of the Lie algebra given in terms of its dimension and dimension  $r$  of Cartan algebra  $r$  as  $h = (\dim g - r)/r$ . The Lie algebras of  $SU(n)$ ,  $E_7$  and  $D_{2n+1}$  are however not allowed. For  $\mathcal{M} : \mathcal{N} = 4$  one can assign to the inclusion an extended Dynkin graph of type ADE characterizing Kac Moody algebra. Extended ADE diagrams characterize also the subgroups of  $SU(2)$  and the interpretation proposed in [90] is

following. The ADE diagrams are associated with the  $n = \infty$  case having  $\mathcal{M} : \mathcal{N} \geq 4$ . There are diagrams corresponding to infinite subgroups:  $SU(2)$  itself, circle group  $U(1)$ , and infinite dihedral groups (generated by a rotation by a non-rational angle and reflection). The diagrams corresponding to finite subgroups are extension of  $A_n$  for cyclic groups, of  $D_n$  dihedral groups, and of  $E_n$  with  $n=6,7,8$  for tetrahedron, cube, dodecahedron. For  $\mathcal{M} : \mathcal{N} < 4$  ordinary Dynkin graphs of  $D_{2n}$  and  $E_6, E_8$  are allowed.

The interpretation of [90] is that the subfactors correspond to inclusions  $\mathcal{N} \subset \mathcal{M}$  defined in the following manner.

1. Let  $G$  be a finite subgroup of  $SU(2)$ . Denote by  $R$  the infinite-dimensional Clifford algebras resulting from infinite-dimensional tensor power of  $M_2(C)$  and by  $R_0$  its subalgebra obtained by restricting  $M_2(C)$  element of the first factor to be unit matrix. Let  $G$  act by automorphisms in each tensor factor.  $G$  leaves  $R_0$  invariant. Denote by  $R_0^G$  and  $R^G$  the sub-algebras which remain element wise invariant under the action of  $G$ . The resulting Jones inclusions  $R_0^G \subset R^G$  are consistent with the ADE correspondence.
2. The argument suggests the existence of quantum versions of subgroups of  $SU(2)$  for which representations are truncations of those for ordinary subgroups. The results have been generalized to other Lie groups.
3. Also  $SL(2, C)$  acts as automorphisms of  $M_2(C)$ . An interesting question is what happens if one allows  $G$  to be any discrete subgroups of  $SL(2, C)$ . Could this give inclusions with  $\mathcal{M} : \mathcal{N} > 4$ ?. The strong analogy of the spectrum of indices with spectrum of energies with hydrogen atom would encourage this interpretation: the subgroup  $SL(2, C)$  not reducing to those of  $SU(2)$  would correspond to the possibility for the particle to move with respect to each other with constant velocity.

### 11.4.2 The fundamental construction and Temperley-Lieb algebras

It was shown by Jones [76] that for a given Jones inclusion with  $\beta = \mathcal{M} : \mathcal{N} < \infty$  there exists a tower of finite  $II_1$  factors  $\mathcal{M}_k$  for  $k = 0, 1, 2, \dots$  such that

1.  $\mathcal{M}_0 = \mathcal{N}, \mathcal{M}_1 = \mathcal{M}$ ,
2.  $\mathcal{M}_{k+1} = \text{End}_{\mathcal{M}_{k-1}} \mathcal{M}_k$  is the von Neumann algebra of operators on  $L^2(\mathcal{M}_k)$  generated by  $\mathcal{M}_k$  and an orthogonal projection  $e_k : L^2(\mathcal{M}_k) \rightarrow L^2(\mathcal{M}_{k-1})$  for  $k \geq 1$ , where  $\mathcal{M}_k$  is regarded as a subalgebra of  $\mathcal{M}_{k+1}$  under right multiplication.

It can be shown that  $\mathcal{M}_{k+1}$  is a finite factor. The sequence of projections on  $\mathcal{M}_\infty = \cup_{k \geq 0} \mathcal{M}_k$  satisfies the relations

$$\begin{aligned}
 e_i^2 &= e_i, & e_i^- e_i &, \\
 e_i &= \beta e_i e_j e_i & \text{for } |i - j| = 1 &, \\
 e_i e_j &= e_j e_i & \text{for } |i - j| \geq 2 &.
 \end{aligned}
 \tag{11.4.2}$$

The construction of hyper-finite  $II_1$  factor using Clifford algebra  $C(2)$  represented by  $2 \times 2$  matrices allows to understand the theorem in  $\beta = 4$  case in a straightforward manner. In particular, the second formula involving  $\beta$  follows from the identification of  $x$  at  $(k - 1)^{th}$  level with  $(1/\beta) \text{diag}(x, x)$  at  $k^{th}$  level.

By replacing  $2 \times 2$  matrices with  $\sqrt{\beta} \times \sqrt{\beta}$  matrices one can understand heuristically what is involved in the more general case.  $\mathcal{M}_k$  is  $\mathcal{M}_{k-1}$  module with dimension  $\sqrt{\beta}$  and  $\mathcal{M}_{k+1}$  is the space of  $\sqrt{\beta} \times \sqrt{\beta}$  matrices  $\mathcal{M}_{k-1}$  valued entries acting in  $\mathcal{M}_k$ . The transition from  $\mathcal{M}_k$  to  $\mathcal{M}_{k-1}$  linear maps of  $\mathcal{M}_k$  happens in the transition to the next level.  $x$  at  $(k - 1)^{th}$  level is identified as  $(x/\beta) \times \text{Id}_{\sqrt{\beta} \times \sqrt{\beta}}$  at the next level. The projection  $e_k$  picks up the projection of the matrix with  $\mathcal{M}_{k-1}$  valued entries in the direction of the  $\text{Id}_{\sqrt{\beta} \times \sqrt{\beta}}$ .

The union of algebras  $A_{\beta, k}$  generated by  $1, e_1, \dots, e_k$  defines Temperley-Lieb algebra  $A_\beta$  [122]. This algebra is naturally associated with braids. Addition of one strand to a braid adds one generator to

this algebra and the representations of the Temperley Lieb algebra provide link, knot, and 3-manifold invariants [56] . There is also a connection with systems of statistical physics and with Yang-Baxter algebras [53] .

A further interesting fact about the inclusion hierarchy is that the elements in  $\mathcal{M}_i$  belonging to the commutator  $\mathcal{N}'$  of  $\mathcal{N}$  form finite-dimensional spaces. Presumably the dimension approaches infinity for  $n \rightarrow \infty$ .

### 11.4.3 Connection with Dynkin diagrams

The possibility to assign Dynkin diagrams ( $\beta < 4$ ) and extended Dynkin diagrams ( $\beta = 4$  to Jones inclusions can be understood heuristically by considering a characterization of so called bipartite graphs [91] , [41] by the norm of the adjacency matrix of the graph.

Bipartite graphs  $\Gamma$  is a finite, connected graph with multiple edges and black and white vertices such that any edge connects white and black vertex and starts from a white one. Denote by  $w(\Gamma)$  ( $b(\Gamma)$ ) the number of white (black) vertices. Define the adjacency matrix  $\Lambda = \Lambda(\Gamma)$  of size  $b(\Gamma) \times w(\Gamma)$  by

$$w_{b,w} = \begin{cases} m(e) & \text{if there exists } e \text{ such that } \delta e = b - w \text{ ,} \\ 0 & \text{otherwise .} \end{cases} \tag{11.4.3}$$

Here  $m(e)$  is the multiplicity of the edge  $e$ .

Define norm  $\|\Gamma\|$  as

$$\begin{aligned} \|X\| &= \max\{\|X\|; \|x\| \leq 1\} \text{ ,} \\ \|\Gamma\| &= \|\Lambda(\Gamma)\| = \left\| \begin{array}{cc} 0 & \Lambda(\Gamma) \\ \Lambda(\Gamma)^t & 0 \end{array} \right\| \text{ .} \end{aligned} \tag{11.4.4}$$

Note that the matrix appearing in the formula is  $(m+n) \times (m+n)$  symmetric square matrix so that the norm is the eigenvalue with largest absolute value.

Suppose that  $\Gamma$  is a connected finite graph with multiple edges (sequences of edges are regarded as edges). Then

1. If  $\|\Gamma\| \leq 2$  and if  $\Gamma$  has a multiple edge,  $\|\Gamma\| = 2$  and  $\Gamma = \tilde{A}_1$ , the extended Dynkin diagram for  $SU(2)$  Kac Moody algebra.
2.  $\|\Gamma\| < 2$  if and only if  $\Gamma$  is one of the Dynkin diagrams of A,D,E. In this case  $\|\Gamma\| = 2\cos(\pi/h)$ , where  $h$  is the Coxeter number of  $\Gamma$ .
3.  $\|\Gamma\| = 2$  if and only if  $\Gamma$  is one of the extended Dynkin diagrams  $\tilde{A}, \tilde{D}, \tilde{E}$ .

This result suggests that one can indeed assign to the Jones inclusions Dynkin diagrams. To really understand how the inclusions can be characterized in terms bipartite diagrams would require a deeper understanding of von Neumann algebras. The following argument only demonstrates that bipartite graphs naturally describe inclusions of algebras.

1. Consider a bipartite graph. Assign to each white vertex linear space  $W(w)$  and to each edge of a linear space  $W(b, w)$ . Assign to a given black vertex the vector space  $\oplus_{\delta e=b-w} W(b, w) \otimes W(w)$  where  $(b, w)$  corresponds to an edge ending to  $b$ .
2. Define  $\mathcal{N}$  as the direct sum of algebras  $End(W(w))$  associated with white vertices and  $\mathcal{M}$  as direct sum of algebras  $\oplus_{\delta e=b-w} End(W(b, w)) \otimes End(W(w))$  associated with black vertices.
3. There is homomorphism  $N \rightarrow M$  defined by imbedding direct sum of white endomorphisms  $x$  to direct sum of tensor products  $x$  with the identity endomorphisms associated with the edges starting from  $x$ .

It is possible to show that Jones inclusions correspond to the Dynkin diagrams of  $A_n, D_{2n}$ , and  $E_6, E_8$  and extended Dynkin diagrams of ADE type. In particular, the dual of the bi-partite graph associated with  $\mathcal{M}_{n-1} \subset \mathcal{M}_n$  obtained by exchanging the roles of white and black vertices describes the inclusion  $\mathcal{M}_n \subset \mathcal{M}_{n+1}$  so that two subsequent Jones inclusions might define something fundamental (the corresponding space-time dimension is  $2 \times \log_2(\mathcal{M} : \mathcal{N}) \leq 4$ .

### 11.4.4 Indices for the inclusions of type $III_1$ factors

Type  $III_1$  factors appear in relativistic quantum field theory defined in 4-dimensional Minkowski space [64]. An overall summary of basic results discovered in algebraic quantum field theory is described in the lectures of Longo [98]. In this case the inclusions for algebras of observables are induced by the inclusions for bounded regions of  $M^4$  in axiomatic quantum field theory. Tomita's theory of modular Hilbert algebras [120], [27] forms the mathematical corner stone of the theory.

The basic notion is Haag-Kastler net [104] consisting of bounded regions of  $M^4$ . Double cone serves as a representative example. The von Neumann algebra  $\mathcal{A}(O)$  is generated by observables localized in bounded region  $O$ . The net satisfies the conditions implied by local causality:

1. Isotony:  $O_1 \subset O_2$  implies  $\mathcal{A}(O_1) \subset \mathcal{A}(O_2)$ .
2. Locality:  $O_1 \subset O'_2$  implies  $\mathcal{A}(O_1) \subset \mathcal{A}(O'_2)'$  with  $O'$  defined as  $\{x : \langle x, y \rangle < 0 \text{ for all } y \in O\}$ .
3. Haag duality  $\mathcal{A}(O')' = \mathcal{A}(O)$ .

Besides this Poincare covariance, positive energy condition, and the existence of vacuum state is assumed.

DHR (Doplicher-Haag-Roberts) [110] theory allows to deduce the values of Jones index and they are squares of integers in dimensions  $D > 2$  so that the situation is rather trivial. The 2-dimensional case is distinguished from higher dimensional situations in that braid group replaces permutation group since the paths representing the flows permuting identical particles can be linked in  $X^2 \times T$  and anyonic statistics [15, 13] becomes possible. In the case of 2-D Minkowski space  $M^2$  Jones inclusions with  $\mathcal{M} : \mathcal{N} < 4$  plus a set of discrete values of  $\mathcal{M} : \mathcal{N}$  in the range (4, 6) are possible. In [98] some values are given ( $\mathcal{M} : \mathcal{N} = 5, 5.5049\dots, 5.236\dots, 5.828\dots$ ).

At least intersections of future and past light cones seem to appear naturally in TGD framework such that the boundaries of future/past directed light cones serve as seats for incoming/outgoing states defined as intersections of space-time surface with these light cones.  $III_1$  sectors cannot thus be excluded as factors in TGD framework. On the other hand, the construction of S-matrix at space-time level is reduced to  $II_1$  case by effective 2-dimensionality.

## 11.5 TGD and hyper-finite factors of type $II_1$ : ideas and questions

By effective 2-dimensionality of the construction of quantum states the hyper-finite factors of type  $II_1$  fit naturally to TGD framework. In particular, infinite dimensional spinors define a canonical representations of this kind of factor. The basic question is whether only hyper-finite factors of type  $II_1$  appear in TGD framework. Affirmative answer would allow to interpret physical  $M$ -matrix as time like entanglement coefficients.

### 11.5.1 What kind of hyper-finite factors one can imagine in TGD?

The working hypothesis has been that only hyper-finite factors of type  $II_1$  appear in TGD. The basic motivation has been that they allow a new view about  $M$ -matrix as an operator representable as time-like entanglement coefficients of zero energy states so that physical states would represent laws of physics in their structure. They allow also the introduction of the notion of measurement resolution directly to the definition of reaction probabilities by using Jones inclusion and the replacement of state space with a finite-dimensional state space defined by quantum spinors. This hypothesis is of course just an attractive working hypothesis and deserves to be challenged.

#### Configuration space spinors

For configuration space spinors the HFF  $II_1$  property is very natural because of the properties of infinite-dimensional Clifford algebra and the inner product defined by the configuration space geometry does not allow other factors than this. A good guess is that the values of conformal weights label the factors appearing in the tensor power defining configuration space spinors. Because of

the non-degeneracy and super-symplectic symmetries the density matrix representing metric must be essentially unit matrix for each conformal weight which would be the defining characteristic of hyper-finite factor of type  $II_1$ .

### Bosonic degrees of freedom

The bosonic part of the super-symplectic algebra consists of Hamiltonians of  $CH$  in one-one correspondence with those of  $\delta M_{\pm}^4 \times CP_2$ . Also the Kac-Moody algebra acting leaving the light-likeness of the partonic 3-surfaces intact contributes to the bosonic degrees of freedom. The commutator of these algebras annihilates physical states and there are also Virasoro conditions associated with ordinary conformal symmetries of partonic 2-surface [20]. The labels of Hamiltonians of configuration space and spin indices contribute to bosonic degrees of freedom.

Hyper-finite factors of type  $II_1$  result naturally if the system is an infinite tensor product finite-dimensional matrix algebra associated with finite dimensional systems [62]. Unfortunately, neither Virasoro, symplectic nor Kac-Moody algebras do have decomposition into this kind of infinite tensor product. If bosonic degrees for super-symplectic and super-Kac Moody algebra indeed give  $I_{\infty}$  factor one has HFF if type  $II_{\infty}$ . This looks the most natural option but threatens to spoil the beautiful idea about  $M$ -matrix as time-like entanglement coefficients between positive and negative energy parts of zero energy state.

The resolution of the problem is surprisingly simple and trivial after one has discovered it. The requirement that state is normalizable forces to project  $M$ -matrix to a finite-dimensional sub-space in bosonic degrees of freedom so that the reduction  $I_{\infty} \rightarrow I_n$  occurs and one has the reduction  $II_{\infty} \rightarrow II_1 \times I_n = II_1$  to the desired HFF.

One can consider also the possibility of taking the limit  $n \rightarrow \infty$ . One could indeed say that since  $I_{\infty}$  factor can be mapped to an infinite tensor power of  $M(2, C)$  characterized by a state which is not trace, it is possible to map this representation to HFF by replacing state with trace [62]. The question is whether the forcing the bosonic foot to fermionic shoe is physically natural. One could also regard the  $II_1$  type notion of probability as fundamental and also argue that it is required by full super-symmetry realized also at the level of many-particle states rather than mere single particle states.

### How the bosonic cutoff is realized?

Normalizability of state requires that projection to a finite-dimensional bosonic sub-space is carried out for the bosonic part of the  $M$ -matrix. This requires a cutoff in quantum numbers of super-conformal algebras. The cutoff for the values of conformal weight could be formulated by replacing integers with  $Z_n$  or with some finite field  $G(p, 1)$ . The cutoff for the labels associated with Hamiltonians defined as an upper bound for the dimension of the representation looks also natural.

Number theoretical braids which are discrete and finite structures would define space-time correlate for this cutoff. p-Adic length scale  $p \simeq 2^k$  hypothesis could be interpreted as stating the fact that only powers of  $p$  up to  $p^k$  are significant in p-adic thermodynamics which would correspond to finite field  $G(k, 1)$  if  $k$  is prime. This has no consequences for p-adic mass calculations since already the first two terms give practically exact results for the large primes associated with elementary particles [48].

Finite number of strands for the theoretical braids would serve as a correlate for the reduction of the representation of Galois group  $S_{\infty}$  of rationals to an infinite produce of diagonal copies of finite-dimensional Galois group so that same braid would repeat itself like a unit cell of lattice i condensed matter [18].

### HFF of type $III$ for field operators and HFF of type $II_1$ for states?

One could also argue that the Hamiltonians with fixed conformal weight are included in fermionic  $II_1$  factor and bosonic factor  $I_{\infty}$  factor, and that the inclusion of conformal weights leads to a factor of type  $III$ . Conformal weight could relate to the integer appearing in the crossed product representation  $III = Z \times_{cr} II_{\infty}$  of HFF of type  $III$  [62].

The value of conformal weight is non-negative for physical states which suggests that  $Z$  reduces to semigroup  $N$  so that a factor of type  $III$  would reduce to a factor of type  $II_{\infty}$  since trace would become finite. If unitary process corresponds to an automorphism for  $II_{\infty}$  factor, the action of automorphisms affecting scaling must be uni-directional. Also thermodynamical irreversibility suggests the same. The

assumption that state function reduction for positive energy part of state implies unitary process for negative energy state and vice versa would only mean that the shifts for positive and negative energy parts of state are opposite so that  $Z \rightarrow N$  reduction would still hold true.

### HFF of type $II_1$ for the maxima of Kähler function?

Probabilistic interpretation allows to gain heuristic insights about whether and how hyper-finite factors of type  $II_1$  might be associated with configuration space degrees of freedom. They can appear both in quantum fluctuating degrees of freedom associated with a given maximum of Kähler function and in the discrete space of maxima of Kähler function.

Spin glass degeneracy is the basic prediction of classical TGD and means that instead of a single maximum of Kähler function analogous to single free energy minimum of a thermodynamical system there is a fractal spin glass energy landscape with valleys inside valleys. The discretization of the configuration space in terms of the maxima of Kähler function crucial for the p-adicization problem, leads to the analog of spin glass energy landscape and hyper-finite factor of type  $II_1$  might be the appropriate description of the situation.

The presence of the tensor product structure is a powerful additional constraint and something analogous to this should emerge in configuration space degrees of freedom. Fractality of the many-sheeted space-time is a natural candidate here since the decomposition of the original geometric structure to parts and replacing them with the scaled down variant of original structure is the geometric analog of forming a tensor power of the original structure.

### 11.5.2 Direct sum of HFFs of type $II_1$ as a minimal option

HFF  $II_1$  property for the Clifford algebra of the configuration space means a definite distinction from the ordinary Clifford algebra defined by the fermionic oscillator operators since the trace of the unit matrix of the Clifford algebra is normalized to one. This does not affect the anti-commutation relations at the basic level and delta functions can appear in them at space-time level. At the level of momentum space  $I_\infty$  property requires discrete basis and anti-commutators involve only Kronecker deltas. This conforms with the fact that HFF of type  $II_1$  can be identified as the Clifford algebra associated with a separable Hilbert space.

#### $II_\infty$ factor or direct sum of HFFs of type $II_1$ ?

The expectation is that super-symplectic algebra is a direct sum over HFFs of type  $II_1$  labeled by the radial conformal weight. In the same manner the algebra defined by fermionic anti-commutation relations at partonic 2-surface would decompose to a direct sum of algebras labeled by the conformal weight associated with the light-like coordinate of  $X_l^3$ . Super-conformal symmetry suggests that also the configuration space degrees of freedom correspond to a direct sum of HFFs of type  $II_1$ .

One can of course ask why not  $II_\infty = I_\infty \times II_1$  structures so that one would have single factor rather than a direct sum of factors.

1. The physical motivation is that the direct sum property allow to decompose M-matrix to direct summands associated with various sectors with weights whose moduli squared have an interpretation in terms of the density matrix. This is also consistent with p-adic thermodynamics where conformal weights take the place of energy eigen values.
2.  $II_\infty$  property would predict automorphisms scaling the trace by an arbitrary positive real number  $\lambda \in R_+$ . These automorphisms would require the scaling of the trace of the projectors of Clifford algebra having values in the range  $[0, 1]$  and it is difficult to imagine how these automorphisms could be realized geometrically.

#### How HFF property reflects itself in the construction of geometry of WCW?

The interesting question is what HFF property and finite measurement resolution realizing itself as the use of projection operators means concretely at the level of the configuration space geometry.

Super-Hamiltonians define the Clifford algebra of the configuration space. Super-conformal symmetry suggests that the unavoidable restriction to projection operators instead of complex rays is

realized also configuration space degrees of freedom. Of course, infinite precision in the determination of the shape of 3-surface would be physically a completely unrealistic idea.

In the fermionic situation the anti-commutators for the gamma matrices associated with configuration space individual Hamiltonians in 3-D sense are replaced with anti-commutators where Hamiltonians are replaced with projectors to subspaces of the space spanned by Hamiltonians. This projection is realized by restricting the anti-commutator to partonic 2-surfaces so that the anti-commutator depends only the restriction of the Hamiltonian to those surfaces.

What is interesting that the measurement resolution has a concrete particle physical meaning since the parton content of the system characterizes the projection. The larger the number of partons, the better the resolution about configuration space degrees of freedom is. The degeneracy of configuration space metric would be interpreted in terms of finite measurement resolution inherent to HFFs of type  $II_1$ , which is not due to Jones inclusions but due to the fact that one can project only to infinite-D subspaces rather than complex rays.

Effective 2-dimensionality in the sense that configuration space Hamiltonians reduce to functionals of the partonic 2-surfaces of  $X_l^3$  rather than functionals of  $X_l^3$  could be interpreted in this manner. For a wide class of Hamiltonians actually effective 1-dimensionality holds true in accordance with conformal invariance.

The generalization of configuration space Hamiltonians and super-Hamiltonians by allowing integrals over the 2-D boundaries of the patches of  $X_l^3$  would be natural and is suggested by the requirement of discretized 3-dimensionality at the level of configuration space.

By quantum classical correspondence the inclusions of HFFs related to the measurement resolution should also have a geometric description. Measurement resolution corresponds to braids in given time scale and as already explained there is a hierarchy of braids in time scales coming as negative powers of two corresponding to the addition of zero energy components to positive/negative energy state. Note however that particle reactions understood as decays and fusions of braid strands could also lead to a notion of measurement resolution.

### 11.5.3 Bott periodicity, its generalization, and dimension $D = 8$ as an inherent property of the hyper-finite $II_1$ factor

Hyper-finite  $II_1$  factor can be constructed as infinite-dimensional tensor power of the Clifford algebra  $M_2(C) = C(2)$  in dimension  $D = 2$ . More precisely, one forms the union of the Clifford algebras  $C(2n) = C(2)^{\otimes n}$  of  $2n$ -dimensional spaces by identifying the element  $x \in C(2n)$  as block diagonal elements  $\text{diag}(x, x)$  of  $C(2(n+1))$ . The union of these algebras is completed in weak operator topology and can be regarded as a Clifford algebra of real infinite-dimensional separable Hilbert space and thus as sub-algebra of  $I_\infty$ . Also generalizations obtained by replacing complex numbers by quaternions and octonions are possible.

1. The dimension 8 is an inherent property of the hyper-finite  $II_1$  factor since Bott periodicity theorem states  $C(n+8) = C_n(16)$ . In other words, the Clifford algebra  $C(n+8)$  is equivalent with the algebra of  $16 \times 16$  matrices with entries in  $C(n)$ . Or articulating it still differently:  $C(n+8)$  can be regarded as  $16 \times 16$  dimensional module with  $C(n)$  valued coefficients. Hence the elements in the union defining the canonical representation of hyper-finite  $II_1$  factor are  $16^n \times 16^n$  matrices having  $C(0)$ ,  $C(2)$ ,  $C(4)$  or  $C(6)$  valued elements.
2. The idea about a local variant of the infinite-dimensional Clifford algebra defined by power series of space-time coordinate with Taylor coefficients which are Clifford algebra elements fixes the interpretation. The representation as a linear combination of the generators of Clifford algebra of the finite-dimensional space allows quantum generalization only in the case of Minkowski spaces. However, if Clifford algebra generators are representable as gamma *matrices*, the powers of coordinate can be absorbed to the Clifford algebra and the local algebra is lost. Only if the generators are represented as quantum versions of octonions allowing no matrix representation because of their non-associativity, the local algebra makes sense. From this it is easy to deduce both quantum and classical TGD.

### 11.5.4 The interpretation of Jones inclusions in TGD framework

By the basic self-referential property of von Neumann algebras one can consider several interpretations of Jones inclusions consistent with sub-system-system relationship, and it is better to start by considering the options that one can imagine.

#### How Jones inclusions relate to the new view about sub-system?

Jones inclusion characterizes the imbedding of sub-system  $\mathcal{N}$  to  $\mathcal{M}$  and  $\mathcal{M}$  as a finite-dimensional  $\mathcal{N}$ -module is the counterpart for the tensor product in finite-dimensional context. The possibility to express  $\mathcal{M}$  as  $\mathcal{N}$  module  $\mathcal{M}/\mathcal{N}$  states fractality and can be regarded as a kind of self-referential "Brahman=Atman identity" at the level of infinite-dimensional systems.

Also the mysterious looking almost identity  $CH^2 = CH$  for the configuration space of 3-surfaces would fit nicely with the identity  $M \oplus M = M$ .  $M \otimes M \subset M$  in configuration space Clifford algebra degrees of freedom is also implied and the construction of  $\mathcal{M}$  as a union of tensor powers of  $C(2)$  suggests that  $M \otimes M$  allows  $\mathcal{M} : \mathcal{N} = 4$  inclusion to  $\mathcal{M}$ . This paradoxical result conforms with the strange self-referential property of factors of  $II_1$ .

The notion of many-sheeted space-time forces a considerable generalization of the notion of sub-system and simple tensor product description is not enough. Topological picture based on the length scale resolution suggests even the possibility of entanglement between sub-systems of un-entangled sub-systems. The possibility that hyper-finite  $II_1$ -factors describe the physics of TGD also in bosonic degrees of freedom is suggested by configuration space super-symmetry. On the other hand, bosonic degrees could naturally correspond to  $I_\infty$  factor so that hyper-finite  $II_\infty$  would be the net result.

The most general view is that Jones inclusion describes all kinds of sub-system-system inclusions. The possibility to assign conformal field theory to the inclusion gives hopes of rather detailed view about dynamics of inclusion.

1. The topological condensation of space-time sheet to a larger space-time sheet mediated by worm-hole contacts could be regarded as Jones inclusion.  $\mathcal{N}$  would correspond to the condensing space-time sheet,  $\mathcal{M}$  to the system consisting of both space-time sheets, and  $\sqrt{\mathcal{M}} : \mathcal{N}$  would characterize the number of quantum spinorial degrees of freedom associated with the interaction between space-time sheets. Note that by general results  $\mathcal{M} : \mathcal{N}$  characterizes the fractal dimension of quantum group ( $\mathcal{M} : \mathcal{N} < 4$ ) or Kac-Moody algebra ( $\mathcal{M} : \mathcal{N} = 4$ ) [41].
2. The branchings of space-time sheets (space-time surface is thus homologically like branching like of Feynman diagram) correspond naturally to n-particle vertices in TGD framework. What is nice is that vertices are nice 2-dimensional surfaces rather than surfaces having typically pinch singularities. Jones inclusion would naturally appear as inclusion of operator spaces  $\mathcal{N}_i$  (essentially Fock spaces for fermionic oscillator operators) creating states at various lines as sub-spaces  $N_i \subset M$  of operators creating states in common von Neumann factor  $\mathcal{M}$ . This would allow to construct vertices and vertices in natural manner using quantum groups or Kac-Moody algebras.

The fundamental  $\mathcal{N} \subset \mathcal{M} \subset \mathcal{M} \otimes_{\mathcal{N}} \mathcal{M}$  inclusion suggests a concrete representation based on the identification  $N_i = M$ , where  $M$  is the universal Clifford algebra associated with incoming line and  $\mathcal{N}$  is defined by the condition that  $\mathcal{M}/\mathcal{N}$  is the quantum variant of Clifford algebra of  $H$ .  $N$ -particle vertices could be defined as traces of Connes products of the operators creating incoming and outgoing states. It will be found that this leads to a master formula for S-matrix if the generalization of the old-fashioned string model duality implying that all generalized Feynman diagrams reduce to diagrams involving only single vertex is accepted.

3. If 4-surfaces can branch as the construction of vertices requires, it is difficult to argue that 3-surfaces and partonic/stringy 2-surfaces could not do the same. As a matter fact, the master formula for S-matrix to be discussed later explains the branching of 4-surfaces as an apparent affect. Despite this one can consider the possibility that this kind of joins are possible so that a new kind of mechanism of topological condensation would become possible. 3-space-sheets and partonic 2-surfaces whose p-adic fractality is characterized by different p-adic primes could be connected by "joins" representing branchings of 2-surfaces. The structures formed by soap film foam provide a very concrete illustration about what would happen. In the TGD based model

of hadrons [51] it has been assumed that join along boundaries bonds (JABs) connect quark space-time space-time sheets to the hadronic space-time sheet. The problem is that, at least for identical primes, the formation of join along boundaries bond fuses two systems to single bound state. If JABs are replaced joins, this objection is circumvented.

4. The space-time correlate for the formation of bound states is the formation of JABs. Standard intuition tells that the number of degrees of freedom associated with the bound state is smaller than the number of degrees of freedom associated with the pair of free systems. Hence the inclusion of the bound state to the tensor product could be regarded as Jones inclusion. On the other hand, one could argue that the JABs carry additional vibrational degrees of freedom so that the idea about reduction of degrees of freedom might be wrong: free system could be regarded as sub-system of bound state by Jones inclusion. The self-referential holographic properties of von Neumann algebras allow both interpretations: any system can be regarded as sub-system of any system in accordance with the bootstrap idea.
5. Maximal deterministic regions inside given space-time sheet bounded by light-like causal determinants define also sub-systems in a natural manner and also their inclusions would naturally correspond to Jones inclusions.
6. The TGD inspired model for topological quantum computation involves the magnetic flux tubes defined by join along boundaries bonds connecting space-time sheets having light-like boundaries. These tubes condensed to background 3-space can become linked and knotted and code for quantum computations in this manner. In this case the addition of new strand to the system corresponds to Jones inclusion in the hierarchy associated with inclusion  $\mathcal{N} \subset \mathcal{M}$ . The anyon states associated with strands would be represented by a finite tensor product of quantum spinors assignable to  $\mathcal{M}/\mathcal{N}$  and representing quantum counterpart of  $H$ -spinors.

One can regard  $\mathcal{M} : \mathcal{N}$  degrees of freedom correspond to quantum group or Kac-Moody degrees of freedom. Quantum group degrees of freedom relate closely to the conformal and topological degrees of freedom as the connection of II<sub>1</sub> factors with topological quantum field theories and braid matrices suggests itself. For the canonical inclusion this factorization would correspond to factorization of quantum  $H$ -spinor from configuration space spinor.

A more detailed study of canonical inclusions to be carried out later demonstrates what this factorization corresponds at the space-time level to a formation of space-time sheets which can be regarded as multiple coverings of  $M^4$  and  $CP_2$  with invariance group  $G = G_a \times G_b \subset SL(2, C) \times SU(2)$ ,  $SU(2) \subset SU(3)$ . The unexpected outcome is that Planck constants assignable to  $M^4$  and  $CP_2$  degrees of freedom depend on the canonical inclusions. The existence of macroscopic quantum phases with arbitrarily large Planck constants is predicted.

It would seem possible to assign the  $\mathcal{M} : \mathcal{N}$  degrees quantum spinorial degrees of freedom to the interface between subsystems represented by  $\mathcal{N}$  and  $\mathcal{M}$ . The interface could correspond to the worm-hole contacts, joins, JABs, or light-like causal determinants serving as boundary between maximal deterministic regions, etc... In terms of the bipartite diagrams representing the inclusions, joins (say) would correspond to the edges connecting white vertices representing sub-system (the entire system without the joins) to black vertices (entire system).

### About the interpretation of $\mathcal{M} : \mathcal{N}$ degrees of freedom

The Clifford algebra  $\mathcal{N}$  associated with a system formed by two space-time sheet can be regarded as  $1 \leq \mathcal{M} : \mathcal{N} \leq 4$ -dimensional module having  $\mathcal{N}$  as its coefficients. It is possible to imagine several interpretations the degrees of freedom labeled by  $\beta$ .

1. The  $\beta = \mathcal{M} : \mathcal{N}$  degrees of freedom could relate to the interaction of the space-time sheets. Beraha numbers appear in the construction of S-matrices of topological quantum field theories and an interpretation in terms of braids is possible. This would suggest that the interaction between space-time sheets can be described in terms of conformal quantum field theory and the S-matrices associated with braids describe this interaction. Jones inclusions would characterize the effective number of active conformal degrees of freedom. At  $n = 3$  limit these degrees of freedom disappear completely since the conformal field theory defined by the Chern-Simons action describing this interaction would become trivial ( $c = 0$  as will be found).

2. The interpretation in terms of imbedding space Clifford algebra would suggest that  $\beta$ -dimensional Clifford algebra of  $\sqrt{\beta}$ -dimensional spinor space is in question. For  $\beta = 4$  the algebra would be the Clifford algebra of 2-dimensional space.  $\mathcal{M}/\mathcal{N}$  would have interpretation as complex quantum spinors with components satisfying  $z_1 z_2 = q z_2 z_1$  and its conjugate and having fractal complex dimension  $\sqrt{\beta}$ . This would conform with the effective 2-dimensionality of TGD. For  $\beta < 4$  the fractal dimension of partonic quantum spinors defining the basic conformal fields would be reduced and become  $d = 1$  for  $n = 3$ : the interpretation is in terms of strong correlations caused by the non-commutativity of the components of quantum spinor. For number theoretical generalizations of infinite-dimensional Clifford algebras  $Cl(C)$  obtained by replacing  $C$  with Abelian complexification of quaternions or octonions one would obtain higher-dimensional spinors.

### 11.5.5 Configuration space, space-time, and imbedding space and hyper-finite type $II_1$ factors

The preceding considerations have by-passed the question about the relationship of the configuration space tangent space to its Clifford algebra. Also the relationship between space-time and imbedding space and their quantum variants could be better. In particular, one should understand how effective 2-dimensionality can be consistent with the 4-dimensionality of space-time.

#### Super-conformal symmetry and configuration space Poisson algebra as hyper-finite type $II_1$ factor

It would be highly desirable to achieve also a description of the configuration space degrees of freedom using von Neumann algebras. Super-conformal symmetry relating fermionic degrees of freedom and configuration space degrees of freedom suggests that this might be the case. Super-symplectic algebra has as its generators configuration space Hamiltonians and their super-counterparts identifiable as  $CH$  gamma matrices. Super-symmetry requires that the Clifford algebra of  $CH$  and the Hamiltonian vector fields of  $CH$  with symplectic central extension both define hyper-finite  $II_1$  factors. By super-symmetry Poisson bracket corresponds to an anti-commutator for gamma matrices. The ordinary quantized version of Poisson bracket is obtained as  $\{P_i, Q_j\} \rightarrow [P_i, Q_j] = J_{ij} Id$ . Finite trace version results by assuming that  $Id$  corresponds to the projector  $CH$  Clifford algebra having unit norm. The presence of zero modes means direct integral over these factors.

Configuration space gamma matrices anti-commuting to identity operator with unit norm corresponds to the tangent space  $T(CH)$  of  $CH$ . Thus it would be not be surprising if  $T(CH)$  could be imbedded in the sigma matrix algebra as a sub-space of operators defined by the gamma matrices generating this algebra. At least for  $\beta = 4$  construction of hyper-finite  $II_1$  factor this definitely makes sense.

The dimension of the configuration space defined as the trace of the projection operator to the sub-space spanned by gamma matrices is obviously zero. Thus configuration space has in this sense the dimensionality of single space-time point. This sounds perhaps absurd but the generalization of the number concept implied by infinite primes indeed leads to the view that single space-time point is infinitely structured in the number theoretical sense although in the real sense all states of the point are equivalent. The reason is that there is infinitely many numbers expressible as ratios of infinite integers having unit real norm in the real sense but having different p-adic norms.

#### How to understand the dimensions of space-time and imbedding space?

One should be able to understand the dimensions of 3-space, space-time and imbedding space in a convincing matter in the proposed framework. There is also the question whether space-time and imbedding space emerge uniquely from the mathematics of von Neumann algebras alone.

##### 1. The dimensions of space-time and imbedding space

Two sub-sequent inclusions dual to each other define a special kind of inclusion giving rise to a quantum counterpart of  $D = 4$  naturally. This would mean that space-time is something which emerges at the level of cognitive states.

The special role of classical division algebras in the construction of quantum TGD [72],  $D = 8$  Bott periodicity generalized to quantum context, plus self-referential property of type II<sub>1</sub> factors might explain why 8-dimensional imbedding space is the only possibility.

State space has naturally quantum dimension  $D \leq 8$  as the following simple argument shows. The space of quantum states has quark and lepton sectors which both are super-symmetric implying  $D \leq 4$  for each. Since these sectors correspond to different Hamiltonian algebras (triviality one for quarks and triviality zero for leptonic sector), the state space has quantum dimension  $D \leq 8$ .

### 2. How the lacking two space-time dimensions emerge?

3-surface is the basic dynamical unit in TGD framework. This seems to be in conflict with the effective 2-dimensionality [72] meaning that partonic 2-surface code for quantum states, and with the fact that hyper-finite II<sub>1</sub> factors have intrinsic quantum dimension 2.

A possible resolution of the problem is that the foliation of 3-surface by partonic two-surfaces defines a one-dimensional direct integral of isomorphic hyper-finite type II<sub>1</sub> factors, and the zero mode labeling the 2-surfaces in the foliation serves as the third spatial coordinate. For a given 3-surface the contribution to the configuration space metric can come only from 2-D partonic surfaces defined as intersections of 3-D light-like CDs with  $X_{\pm}^7$  [17]. Hence the direct integral should somehow relate to the classical non-determinism of Kähler action.

1. The one-parameter family of intersections of light-like CD with  $X_{\pm}^7$  inside  $X^4 \cap X_{\pm}^7$  could indeed be basically due to the classical non-determinism of Kähler action. The contribution to the metric from the normal light-like direction to  $X^3 = X^4 \cap X_{\pm}^7$  can cause the vanishing of the metric determinant  $\sqrt{g_4}$  of the space-time metric at  $X^2 \subset X^3$  under some conditions on  $X^2$ . This would mean that the space-time surface  $X^4(X^3)$  is not uniquely determined by the minimization principle defining the value of the Kähler action, and the complete dynamical specification of  $X^3$  requires the specification of partonic 2-surfaces  $X_i^2$  with  $\sqrt{g_4} = 0$ .
2. The known solutions of field equations [8] define a double foliation of the space-time surface defined by Hamilton-Jacobi coordinates consisting of complex transversal coordinate and two light-like coordinates for  $M^4$  (rather than space-time surface). Number theoretical considerations inspire the hypothesis that this foliation exists always [72]. Hence a natural hypothesis is that the allowed partonic 2-surfaces correspond to the 2-surfaces in the restriction of the double foliation of the space-time surface by partonic 2-surfaces to  $X^3$ , and are thus locally parameterized by single parameter defining the third spatial coordinate.
3. There is however also a second light-like coordinate involved and one might ask whether both light-like coordinates appear in the direct sum decomposition of II<sub>1</sub> factors defining  $T(CH)$ . The presence of two kinds of light-like CDs would provide the lacking two space-time coordinates and quantum dimension  $D = 4$  would emerge at the limit of full non-determinism. Note that the duality of space-like partonic and light-like stringy 2-surfaces conforms with this interpretation since it corresponds to a selection of partonic/stringy 2-surface inside given 3-D CD whereas the dual pairs correspond to different CDs.
4. That the quantum dimension would be  $2D_q = \beta < 4$  above  $CP_2$  length scale conforms with the fact that non-determinism is only partial and time direction is dynamically frozen to a high degree. For vacuum extremals there is strong non-determinism but in this case there is no real dynamics. For  $CP_2$  type extremals, which are not vacuum extremals as far action and small perturbations are considered, and which correspond to  $\beta = 4$  there is a complete non-determinism in time direction since the  $M^4$  projection of the extremal is a light-like random curve and there is full 4-D dynamics. Light-likeness gives rise to conformal symmetry consistent with the emergence of Kac Moody algebra [8].

### 3. Time and cognition

In a completely deterministic physics time dimension is strictly speaking redundant since the information about physical states is coded by the initial values at 3-dimensional slice of space-time. Hence the notion of time should emerge at the level of cognitive representations possible by to the non-determinism of the classical dynamics of TGD.

Since Jones inclusion means the emergence of cognitive representation, the space-time view about physics should correspond to cognitive representations provided by Feynman diagram states with zero energy with entanglement defined by a two-sided projection of the lowest level S-matrix. These states would represent the "laws of quantum physics" cognitively. Also space-time surface serves as a classical correlate for the evolution by quantum jumps with maximal deterministic regions serving as correlates of quantum states. Thus the classical non-determinism making possible cognitive representations would bring in time. The fact that quantum dimension of space-time is smaller than  $D = 4$  would reflect the fact that the loss of determinism is not complete.

4. *Do space-time and imbedding space emerge from the theory of von Neumann algebras and number theory?*

The considerations above force to ask whether the notions of space-time and imbedding space emerge from von Neumann algebras as predictions rather than input. The fact that it seems possible to formulate the S-matrix and its generalization in terms of inherent properties of infinite-dimensional Clifford algebras suggest that this might be the case.

### Inner automorphisms as universal gauge symmetries?

The continuous outer automorphisms  $\Delta^{it}$  of HFFs of type III are not completely unique and one can worry about the interpretation of the inner automorphisms. A possible resolution of the worries is that inner automorphisms act as universal gauge symmetries containing various super-conformal symmetries as a special case. For hyper-finite factors of type  $II_1$  in the representation as an infinite tensor power of  $M_2(C)$  this would mean that the transformations non-trivial in a finite number of tensor factors only act as analogs of local gauge symmetries. In the representation as a group algebra of  $S_\infty$  all unitary transformations acting on a finite number of braid strands act as gauge transformations whereas the infinite powers  $P \times P \times \dots$ ,  $P \in S_n$ , would act as counterparts of global gauge transformations. In particular, the Galois group of the closure of rationals would act as local gauge transformations but diagonally represented finite Galois groups would act like global gauge transformations and periodicity would make possible to have finite braids as space-time correlates without a loss of information.

### Do unitary isomorphisms between tensor powers of $II_1$ define vertices?

What would be left would be the construction of unitary isomorphisms between the tensor products of the HFFs of type  $II_1 \otimes I_n = II_1$  at the partonic 2-surfaces defining the vertices. This would be the only new element added to the construction of braiding  $M$ -matrices.

As a matter fact, this element is actually not completely new since it generalizes the fusion rules of conformal field theories, about which standard example is the fusion rule  $\phi_i = c_i^{jk} \phi_j \phi_k$  for primary fields. These fusion rules would tell how a state of incoming HFF decomposes to the states of tensor product of two outgoing HFFs.

These rules indeed have interpretation in terms of Connes tensor products  $\mathcal{M} \otimes_{\mathcal{N}} \dots \otimes_{\mathcal{N}} \mathcal{M}$  for which the sub-factor  $\mathcal{N}$  takes the role of complex numbers [74] so that one has  $\mathcal{M}$  becomes  $\mathcal{N}$  bimodule and "quantum quantum states" have  $\mathcal{N}$  as coefficients instead of complex numbers. In TGD framework this has interpretation as quantum measurement resolution characterized by  $\mathcal{N}$  (the group  $G$  characterizing leaving the elements of  $\mathcal{N}$  invariant defines the measured quantum numbers).

### 11.5.6 Quaternions, octonions, and hyper-finite type $II_1$ factors

Quaternions and octonions as well as their hyper counterparts obtained by multiplying imaginary units by commuting  $\sqrt{-1}$  and forming a sub-space of complexified division algebra, are in a central role in the number theoretical vision about quantum TGD [72]. Therefore the question arises whether complexified quaternions and perhaps even octonions could be somehow inherent properties of von Neumann algebras. One can also wonder whether the quantum counterparts of quaternions and octonions could emerge naturally from von Neumann algebras. The following considerations allow to get grasp of the problem.

### Quantum quaternions and quantum octonions

Quantum quaternions have been constructed as deformation of quaternions [102]. The key observation that the Glebsch Gordan coefficients for the tensor product  $3 \otimes 3 = 5 \oplus 3 \oplus 1$  of spin 1 representation of  $SU(2)$  with itself gives the anti-commutative part of quaternionic product as spin 1 part in the decomposition whereas the commutative part giving spin 0 representation is identifiable as the scalar product of the imaginary parts. By combining spin 0 and spin 1 representations, quaternionic product can be expressed in terms of Glebsch-Gordan coefficients. By replacing GGC:s by their quantum group versions for group  $sl(2)_q$ , one obtains quantum quaternions.

There are two different proposals for the construction of quantum octonions [54, 1]. Also now the idea is to express quaternionic and octonionic multiplication in terms of Glebsch-Gordan coefficients and replace them with their quantum versions.

1. The first proposal [54] relies on the observation that for the tensor product of  $j = 3$  representations of  $SU(2)$  the Glebsch-Gordan coefficients for  $7 \otimes 7 \rightarrow 7$  in  $7 \otimes 7 = 9 \oplus 7 \oplus 5 \oplus 3 \oplus 1$  defines a product, which is equivalent with the antisymmetric part of the product of octonionic imaginary units. As a matter fact, the antisymmetry defines 7-dimensional Malcev algebra defined by the anticommutator of octonion units and satisfying b definition the identity

$$[[x, y, z], x] = [x, y, [x, z]] \quad , \quad [x, y, z] \equiv [x, [y, z]] + [y, [z, x]] + [z, [x, y]] \quad . \quad (11.5.1)$$

7-element Malcev algebra defining derivations of octonionic algebra is the only complex Malcev algebra not reducing to a Lie algebra. The  $j = 0$  part of the product corresponds also now to scalar product for imaginary units. Octonions are constructed as sums of  $j = 0$  and  $j = 3$  parts and quantum Glebsch-Gordan coefficients define the octonionic product.

2. In the second proposal [1] the quantum group associated with  $SO(8)$  is used. This representation does not allow unit but produces a quantum version of octonionic triality assigning to three octonions a real number.

### Quaternionic or octonionic quantum mechanics?

There have been numerous attempts to introduce quaternions and octonions to quantum theory. Quaternionic or octonionic quantum mechanics, which means the replacement of the complex numbers as coefficient field of Hilbert space with quaternions or octonions, is the most obvious approach (for example and references to the literature see for instance [97]).

In both cases non-commutativity poses serious interpretational problems. In the octonionic case the non-associativity causes even more serious obstacles [39, 97], [39].

1. Assuming that an orthonormalized state basis with respect to an octonion valued inner product has been found, the multiplication of any basis with octonion spoils the orthonormality. The proposal to circumvent this difficulty discussed in [39], [39] eliminates non-associativity by assuming that octonions multiply states one by one (rather than multiplying each other before multiplying the state). Effectively this means that octonions are replaced with  $8 \times 8$ -matrices.
2. The definition of the tensor product leads also to difficulties since associativity is lost (recall that Yang-Baxter equation codes for associativity in case of braid statistics [94]).
3. The notion of hermitian conjugation is problematic and forces a selection of a preferred imaginary unit, which does not look nice. Note however that the local selection of a preferred imaginary unit is in a key role in the proposed construction of space-time surfaces as hyper-quaternionic or co-hyper-quaternionic surfaces and allows to interpret space-time surfaces either as surfaces in 8-D Minkowski space  $M^8$  of hyper-octonions or in  $M^4 \times CP_2$ . This selection turns out to have quite different interpretation in the proposed framework.

### Hyper-finite factor $II_1$ has a natural Hyper-Kähler structure

In the case of hyper-finite factors of type  $II_1$  quaternions a more natural approach is based on the generalization of the Hyper-Kähler structure rather than quaternionic quantum mechanics. The reason is that also configuration space tangent space should and is expected to have this structure [17]. The Hilbert space remains a complex Hilbert space but the quaternionic units are represented as operators in Hilbert space. The selection of the preferred unit is necessary and natural. The identity operator representing quaternionic real unit has trace equal to one, is expected to give rise to the series of quantum quaternion algebras in terms of inclusions  $\mathcal{N} \subset \mathcal{M}$  having interpretation as  $\mathcal{N}$ -modules.

The representation of the quaternion units is rather explicit in the structure of hyper-finite  $II_1$  factor. The  $\mathcal{M} : \mathcal{N} \equiv \beta = 4$  hierarchical construction can be regarded as Connes tensor product of infinite number of 4-D Clifford algebras of Euclidian plane with Euclidian signature of metric ( $diag(-1, -1)$ ). This algebra is nothing but the quaternionic algebra in the representation of quaternionic imaginary units by Pauli spin matrices multiplied by  $i$ .

The imaginary unit of the underlying complex Hilbert space must be chosen and there is whole sphere  $S^2$  of choices and in every point of configuration space the choice can be made differently. The space-time correlate for this local choice of preferred hyper-octonionic unit [72]. At the level of configuration space geometry the quaternion structure of the tangent space means the existence of Hyper-Kähler structure guaranteeing that configuration space has a vanishing Einstein tensor. If it would not vanish, curvature scalar would be infinite by symmetric space property (as in case of loop spaces) and induce a divergence in the functional integral over 3-surfaces from the expansion of  $\sqrt{g}$  [17].

The quaternionic units for the  $II_1$  factor, are simply limiting case for the direct sums of  $2 \times 2$  units normalized to one. Generalizing from  $\beta = 4$  to  $\beta < 4$ , the natural expectation is that the representation of the algebra as  $\beta = \mathcal{M} : \mathcal{N}$ -dimensional  $\mathcal{N}$ -module gives rise to quantum quaternions with quaternion units defined as infinite sums of  $\sqrt{\beta} \times \sqrt{\beta}$  matrices.

At Hilbert space level one has an infinite Connes tensor product of 2-component spinor spaces on which quaternionic matrices have a natural action. The tensor product of Clifford algebras gives the algebra of  $2 \times 2$  quaternionic matrices acting on 2-component quaternionic spinors (complex 4-component spinors). Thus double inclusion could correspond to (hyper-)quaternionic structure at space-time level. Note however that the correspondence is not complete since hyper-quaternions appear at space-time level and quaternions at Hilbert space level.

### Von Neumann algebras and octonions

The octonionic generalization of the Hyper-Kähler manifold does not make sense as such since octonionic units are not representable as linear operators. The allowance of anti-linear operators inherently present in von Neumann algebras could however save the situation. Indeed, the Cayley-Dickson construction for the division algebras (for a nice explanation see [48]), which allows to extend any  $*$  algebra, and thus also any von Neumann algebra, by adding an imaginary unit it and identified as  $*$ , comes in rescue.

The basic idea of the Cayley-Dickson construction is following. The  $*$  operator, call it  $J$ , representing a conjugation defines an *anti-linear* operator in the original algebra  $A$ . One can extend  $A$  by adding this operator as a new element to the algebra. The conditions satisfied by  $J$  are

$$a(Jb) = J(a*b) \quad , \quad (aJ)b = (ab*)J \quad , \quad (Ja)(bJ^{-1}) = (ab)^* \quad . \quad (11.5.2)$$

In the associative case the conditions are equivalent to the first condition.

It is intuitively clear that this addition extends the hyper-Kähler structure to an octonionic structure at the level of the operator algebra. The quantum version of the octonionic algebra is fixed by the quantum quaternion algebra uniquely and is consistent with the Cayley-Dickson construction. It is not clear whether the construction is equivalent with either of the earlier proposals [54, 1]. It would however seem that the proposal is simpler.

### Physical interpretation of quantum octonion structure

Without further restrictions the extension by  $J$  would mean that vertices contain operators, which are superpositions of linear and anti-linear operators. This would give superpositions of states and

their time-reversals and mean that state could be a superposition of states with opposite values of say fermion numbers. The problem disappears if either the linear operators  $A$  or anti-linear operators  $JA$  can be used to construct physical states from vacuum. The fact, that space-time surfaces are either hyper-quaternionic or co-hyper-quaternionic, is a space-time correlate for this restriction.

The  $HQ - coHQ$  duality discussed in [72] states that the descriptions based on hyper-quaternionic and co-hyper-quaternionic surfaces are dual to each other. The duality can have two meanings.

1. The vacuum is invariant under  $J$  so that one can use either complexified quaternionic operators  $A$  or their co-counterparts of form  $JA$  to create physical states from vacuum.
2. The vacuum is not invariant under  $J$ . This could relate to the breaking of  $CP$  and  $T$  invariance known to occur in meson-antimeson systems. In TGD framework two kinds of vacua are predicted corresponding intuitively to vacua in which either the product of all positive or negative energy fermionic oscillator operators defines the vacuum state, and these two vacua could correspond to a vacuum and its  $J$  conjugate, and thus to positive and negative energy states. In this case the two state spaces would not be equivalent although the physics associated with them would be equivalent.

The considerations of [72] related to the detailed dynamics of  $HQ - coHQ$  duality demonstrate that the variational principles defining the dynamics of hyper-quaternionic and co-hyper-quaternionic space-time surfaces are antagonistic and correspond to world as seen by a conscientious book-keeper on one hand and an imaginative artist on the other hand.  $HQ$  case is conservative: differences measured by the magnitude of Kähler action tend to be minimized, the dynamics is highly predictive, and minimizes the classical energy of the initial state.  $coHQ$  case is radical: differences are maximized (this is what the construction of sensory representations would require). The interpretation proposed in [72] was that the two space-time dynamics are just different predictions for what would happen (has happened) if no quantum jumps would occur (had occurred). A stronger assumption is that these two views are associated with systems related by time reversal symmetry.

What comes in mind first is that this antagonism follows from the assumption that these dynamics are actually time-reversals of each other with respect to  $M^4$  time (the rapid elimination of differences in the first dynamics would correspond to their rapid enhancement in the second dynamics). This is not the case so that  $T$  and  $CP$  symmetries are predicted to be broken in accordance with the  $CP$  breaking in meson-antimeson systems [45] and cosmological matter-antimatter asymmetry [65].

### 11.5.7 Does the hierarchy of infinite primes relate to the hierarchy of $II_1$ factors?

The hierarchy of Feynman diagrams accompanying the hierarchy defined by Jones inclusions  $\mathcal{M}_0 \subset \mathcal{M}_1 \subset \dots$  gives a concrete representation for the hierarchy of cognitive dynamics providing a representation for the material world at the lowest level of the hierarchy. This hierarchy seems to relate directly to the hierarchy of space-time sheets.

Also the construction of infinite primes [70] leads to an infinite hierarchy. Infinite primes at the lowest level correspond to polynomials of single variable  $x_1$  with rational coefficients, next level to polynomials  $x_1$  for which coefficients are rational functions of variable  $x_2$ , etc... so that a natural ordering of the variables is involved.

If the variables  $x_i$  are hyper-octonions (sub-space of complexified octonions for which elements are of form  $x + \sqrt{-1}y$ , where  $x$  is real number and  $y$  imaginary octonion and  $\sqrt{-1}$  is commuting imaginary unit, this hierarchy of states could provide a realistic representation of physical states as far as quantum numbers related to imbedding space degrees of freedom are considered in  $M^8$  picture dual to  $M^4 \times CP_2$  picture [72]. Infinite primes are mapped to space-time surfaces in a manner analogous to the mapping of polynomials to the loci of their zeros so that infinite primes, integers, and rationals become concrete geometrical objects.

Infinite primes are also obtained by a repeated second quantization of a super-symmetric arithmetic quantum field theory. Infinite rational numbers correspond in this description to pairs of positive energy and negative energy states of opposite energies having interpretation as pairs of initial and final states so that higher level states indeed represent transitions between the states. For these reasons this hierarchy has been interpreted as a correlate for a cognitive hierarchy coding information about quantum dynamics at lower levels. This hierarchy has also been assigned with the hierarchy of

space-time sheets. Just as the hierarchy of generalized Feynman diagrams provides self representations of the lowest matter level and is coded by it, finite primes code the hierarchy of infinite primes.

Infinite primes, integers, and rationals have finite  $p$ -adic norms equal to 1, and one can wonder whether a Hilbert space like structure with dimension given by an infinite prime or integer makes sense, and whether it has anything to do with the Hilbert space for which dimension is infinite in the sense of the limiting value for a dimension of sub-space. The Hilbert spaces with dimension equal to infinite prime would define primes for the tensor product of these spaces. The dimension of this kind of space defined as any  $p$ -adic norm would be equal to one.

One cannot exclude the possibility that infinite primes could express the infinite dimensions of hyper-finite  $III_1$  factors, which cannot be excluded and correspond to that part of quantum TGD which relates to the imbedding space rather than space-time surface. Indeed, infinite primes code naturally for the quantum numbers associated with the imbedding space. Secondly, the appearance of 7-D light-like causal determinants  $X_{\pm}^7 = M_{\pm}^4 \times CP_2$  forming nested structures in the construction of S-matrix brings in mind similar nested structures of algebraic quantum field theory [64]. If this is were the case, the hierarchy of Beraha numbers possibly associated with the phase resolution could correspond to hyper-finite factors of type  $II_1$ , and the decomposition of space-time surface to regions labeled by  $p$ -adic primes and characterized by infinite primes could correspond to hyper-finite factors of type  $III_1$  and represent imbedding space degrees of freedom.

The state space would in this picture correspond to the tensor products of hyper-finite factors of type  $II_1$  and  $III_1$  (of course, also factors  $I_n$  and  $I_{\infty}$  are also possible).  $III_1$  factors could be assigned to the sub-configuration spaces defined by 3-surfaces in regions of  $M^4$  expressible in terms of unions and intersections of  $X_{\pm}^7 = M_{\pm}^4 \times CP_2$ . By conservation of four-momentum, bounded regions of this kind are possible only for the states of zero net energy appearing at the higher levels of hierarchy. These sub-configuration spaces would be characterized by the positions of the tips of light cones  $M_{\pm}^4 \subset M^4$  involved. This indeed brings in continuous spectrum of four-momenta forcing to introduce non-separable Hilbert spaces for momentum eigen states and necessitating  $III_1$  factors. Infinities would be avoided since the dynamics proper would occur at the level of space-time surfaces and involve only  $II_1$  factors.

## 11.6 Could HFFs of type $III$ have application in TGD framework?

One can imagine several manners for how HFFs of type  $III$  could emerge in TGD although the proposed view about  $M$ -matrix in zero energy ontology suggests that HFFs of type  $III_1$  should be only an auxiliary tool at best. Same is suggested with interpretational problems associated with them. Both TGD inspired quantum measurement theory, the idea about a variant of HFF of type  $II_1$  analogous to a local gauge algebra, and some other arguments, suggest that HFFs of type  $III$  could be seen as a useful idealization allowing to make non-trivial conjectures both about quantum TGD and about HFFs of type  $III$ . Quantum fields would correspond to HFFs of type  $III$  and  $II_{\infty}$  whereas physical states ( $M$ -matrix) would correspond to HFF of type  $II_1$ . I have summarized first the problems of  $III_1$  factors so that reader can decide whether the further reading is worth of it.

### 11.6.1 Problems associated with the physical interpretation of $III_1$ factors

Algebraic quantum field theory approach [38, 64] has led to a considerable understanding of relativistic quantum field theories in terms of hyper-finite  $III_1$  factors. There are however several reasons to suspect that the resulting picture is in conflict with physical intuition. Also the infinities of non-trivial relativistic QFTs suggest that something goes wrong.

#### Are the infinities of quantum field theories due the wrong type of von Neumann algebra?

The infinities of quantum field theories involve basically infinite traces and it is now known that the algebras of observables for relativistic quantum field theories for bounded regions of Minkowski space correspond to hyper-finite  $III_1$  algebras, for which non-trivial traces are always infinite. This might be the basic cause of the divergence problems of relativistic quantum field theory.

On basis of this observations there is some temptation to think that the finite traces of hyper-finite  $II_1$  algebras might provide a resolution to the problems but not necessarily in QFT context. One can play with the thought that the subtraction of infinities might be actually a process in which  $III_1$  algebra is transformed to  $II_1$  algebra. A more plausible idea suggested by dimensional regularization is that the elimination of infinities actually gives rise to  $II_1$  inclusion at the limit  $\mathcal{M} : \mathcal{N} \rightarrow 4$ . It is indeed known that the dimensional regularization procedure of quantum field theories can be formulated in terms of bi-algebras assignable to Feynman diagrams and [63] and the emergence of bi-algebras suggests that a connection with  $II_1$  factors and critical role of dimension  $D = 4$  might exist.

### Continuum of inequivalent representations of commutation relations

There is also a second difficulty related to type III algebras. There is a continuum of inequivalent representations for canonical commutation relations [82]. In thermodynamics this is blessing since temperature parameterizes these representations. In quantum field theory context situation is however different and this problem has been usually put under the rug.

### Entanglement and von Neumann algebras

In quantum field theories where 4-D regions of space-time are assigned to observables. In this case hyper-finite type  $III_1$  von Neumann factors appear. Also now inclusions make sense and has been studied in fact, the parameters characterizing Jones inclusions appear also now and this due to the very general properties of the inclusions.

The algebras of type  $III_1$  have rather counter-intuitive properties from the point of view of entanglement. For instance, product states between systems having space-like separation are not possible at all so that one can speak of intrinsic entanglement [83]. What looks worse is that the decomposition of entangled state to product states is highly non-unique.

Mimicking the steps of von Neumann one could ask what the notion of observables could mean in TGD framework. Effective 2-dimensionality states that quantum states can be constructed using the data given at partonic or stringy 2-surfaces. This data includes also information about normal derivatives so that 3-dimensionality actually lurks in. In any case this would mean that observables are assignable to 2-D surfaces. This would suggest that hyper-finite  $II_1$  factors appear in quantum TGD at least as the contribution of single space-time surface to S-matrix is considered. The contributions for configuration space degrees of freedom meaning functional (not path-) integral over 3-surfaces could of course change the situation.

Also in case of  $II_1$  factors, entanglement shows completely new features which need not however be in conflict with TGD inspired view about entanglement. The eigen values of density matrices are infinitely degenerate and quantum measurement can remove this degeneracy only partially. TGD inspired theory of consciousness has led to the identification of rational (more generally algebraic entanglement) as bound state entanglement stable in state function reduction. When an infinite number of states are entangled, the entanglement would correspond to rational (algebraic number) valued traces for the projections to the eigen states of the density matrix. The symplectic transformations of  $CP_2$  are almost  $U(1)$  gauge symmetries broken only by classical gravitation. They imply a gigantic spin glass degeneracy which could be behind the infinite degeneracies of eigen states of density matrices in case of  $II_1$  factors.

## 11.6.2 Quantum measurement theory and HFFs of type III

The attempt to interpret the HFFs of type III in terms of quantum measurement theory based on Jones inclusions leads to highly non-trivial conjectures about these factors.

### Could the scalings of trace relate to quantum measurements?

What should be understood is the physical meaning of the automorphism inducing the scaling of trace. In the representation based of factors based on infinite tensor powers the action of  $g$  should transform single  $n \times n$  matrix factor with density matrix  $Id/n$  to a density matrix  $e_{11}$  of a pure state.

Obviously the number of degrees of freedom is affected and this can be interpreted in terms of appearance or disappearance of correlations. Quantization and emergence of non-commutativity indeed

implies the emergence of correlations and effective reduction of degrees of freedom. In particular, the fundamental quantum Clifford algebra has reduced dimension  $\mathcal{M} : \mathcal{N} = r \leq 4$  instead of  $r = 4$  since the replacement of complex valued matrix elements with  $\mathcal{N}$  valued ones implies non-commutativity and correlations.

The transformation would be induced by the shift of finite-dimensional state to right or left so that the number of matrix factors overlapping with  $I_\infty$  part increases or is reduced. Could it have interpretation in terms of quantum measurement for a quantum Clifford factor? Could quantum measurement for  $\mathcal{M}/\mathcal{N}$  degrees of freedom reducing the state in these degrees of freedom to a pure state be interpreted as a transformation of single finite-dimensional matrix factor to a type I factor inducing the scaling of the trace and could the scalings associated with automorphisms of HFFs of type *III* also be interpreted in terms of quantum measurement?

This interpretation does not as such say anything about HFF factors of type *III* since only a decomposition of  $II_1$  factor to  $I_2^k$  factor and  $II_1$  factor with a reduced trace of projector to the latter. However, one can ask whether the scaling of trace for HFFs of type *III* could correspond to a situation in which infinite number of finite-dimensional factors have been quantum measured. This would correspond to the inclusion  $\mathcal{N} \subset \mathcal{M}_\infty = \cup_n \mathcal{M}_n$  where  $\mathcal{N} \subset \mathcal{M} \subset \dots \mathcal{M}_n \dots$  defines the canonical inclusion sequence. Physicist can of course ask whether the presence of infinite number of  $I_2$ -, or more generally,  $I_n$ -factors is at all relevant to quantum measurement and it has already become clear that situation at the level of  $M$ -matrix reduces to  $I_n$ .

### Could the theory of HFFs of type *III* relate to the theory of Jones inclusions?

The idea about a connection of HFFs of type *III* and quantum measurement theory seems to be consistent with the basic facts about inclusions and HFFs of type  $III_1$ .

1. Quantum measurement would scale the trace by a factor  $2^k/\sqrt{\mathcal{M}:\mathcal{N}}$  since the trace would become a product for the trace of the projector to the newly born  $M(2, C)^{\otimes k}$  factor and the trace for the projection to  $\mathcal{N}$  given by  $1/\sqrt{\mathcal{M}:\mathcal{N}}$ . The continuous range of values  $\mathcal{M}:\mathcal{N} \geq 4$  gives good hopes that all values of  $\lambda$  are realized. The prediction would be that  $2^k\sqrt{\mathcal{M}:\mathcal{N}} \geq 1$  holds always true.
2. The values  $\mathcal{M}:\mathcal{N} \in \{r_n = 4\cos^2(\pi/n)\}$  for which the single  $M(2, C)$  factor emerges in state function reduction would define preferred values of the inverse of  $\lambda = \sqrt{\mathcal{M}:\mathcal{N}}/4$  parameterizing factors  $III_\lambda$ . These preferred values vary in the range  $[1/2, 1]$ .
3.  $\lambda = 1$  at the end of continuum would correspond to HFF  $III_1$  and to Jones inclusions defined by infinite cyclic subgroups dense in  $U(1) \subset SU(2)$  and this group combined with reflection. These groups correspond to the Dynkin diagrams  $A_\infty$  and  $D_\infty$ . Also the classical values of  $\mathcal{M}:\mathcal{N} = n^2$  characterizing the dimension of the quantum Clifford  $\mathcal{M}:\mathcal{N}$  are possible. In this case the scaling of trace would be trivial since the factor  $n$  to the trace would be compensated by the factor  $1/n$  due to the disappearance of  $\mathcal{M}/\mathcal{N}$  factor  $III_1$  factor.
4. Inclusions with  $\mathcal{M}:\mathcal{N} = \infty$  are also possible and they would correspond to  $\lambda = 0$  so that also  $III_0$  factor would also have a natural identification in this framework. These factors correspond to ergodic systems and one might perhaps argue that quantum measurement in this case would give infinite amount of information.
5. This picture makes sense also physically. p-Adic thermodynamics for the representations of super-conformal algebra could be formulated in terms of factors of type  $I_\infty$  and in excellent approximation using factors  $I_n$ . The generation of arbitrary number of type  $II_1$  factors in quantum measurement allow this possibility.

### The end points of spectrum of preferred values of $\lambda$ are physically special

The fact that the end points of the spectrum of preferred values of  $\lambda$  are physically special, supports the hopes that this picture might have something to do with reality.

1. The Jones inclusion with  $q = \exp(i\pi/n)$ ,  $n = 3$  (with principal diagram reducing to a Dynkin diagram of group  $SU(3)$ ) corresponds to  $\lambda = 1/2$ , which corresponds to HFF  $III_1$  differing in

essential manner from factors  $III_\lambda$ ,  $\lambda < 1$ . On the other hand,  $SU(3)$  corresponds to color group which appears as an isometry group and important subgroup of automorphisms of octonions thus differs physically from the ADE gauge groups predicted to be realized dynamically by the TGD based view about McKay correspondence [18].

2. For  $r = 4$   $SU(2)$  inclusion parameterized by extended ADE diagrams  $M(2, C)^{\otimes 2}$  would be created in the state function reduction and also this would give  $\lambda = 1/2$  and scaling by a factor of 2. Hence the end points of the range of discrete spectrum would correspond to the same scaling factor and same HFF of type III.  $SU(2)$  could be interpreted either as electro-weak gauge group, group of rotations of the geodesic sphere of  $\delta M_\pm^4$ , or a subgroup of  $SU(3)$ . In TGD interpretation for McKay correspondence a phase transition replacing gauge symmetry with Kac-Moody symmetry.
3. The scalings of trace by factor 2 seem to be preferred physically which should be contrasted with the fact that primes near prime powers of 2 and with the fact that quantum phases  $q = \exp(i\pi/n)$  with  $n$  equal to Fermat integer proportional to power of 2 and product of the Fermat primes (the known ones are 5, 17, 257, and  $2^{16} + 1$ ) are in a special role in TGD Universe.

### 11.6.3 What could one say about $II_1$ automorphism associated with the $II_\infty$ automorphism defining factor of type III?

An interesting question relates to the interpretation of the automorphisms of  $II_\infty$  factor inducing the scaling of trace.

1. If the automorphism for Jones inclusion involves the generator of cyclic automorphism sub-group  $Z_n$  of  $II_1$  factor then it would seem that for other values of  $\lambda$  this group cannot be cyclic.  $SU(2)$  has discrete subgroups generated by arbitrary phase  $q$  and these are dense in  $U(1) \subset SU(2)$  sub-group. If the interpretation in terms of Jones inclusion makes sense then the identification  $\lambda = \sqrt{\mathcal{M} : \mathcal{N}}/2^k$  makes sense.
2. If HFF of type  $II_1$  is realized as group algebra of infinite symmetric group [18], the outer automorphism induced by the diagonally imbedded finite Galois groups can induce only integer values of  $n$  and  $Z_n$  would correspond to cyclic subgroups. This interpretation conforms with the fact that the automorphisms in the completion of inner automorphisms of HFF of type  $II_1$  induce trivial scalings. Therefore only automorphisms which do not belong to this completion can define HFFs of type III.

### 11.6.4 What could be the physical interpretation of two kinds of invariants associated with HFFs type III?

TGD predicts two kinds of counterparts for  $S$ -matrix:  $M$ -matrix and  $U$ -matrix. Both are expected to be more or less universal.

There are also *two* kinds of invariants and automorphisms associated with HFFs of type III.

1. The first invariant corresponds to the scaling  $\lambda \in ]0, 1[$  of the trace associated with the automorphism of factor of  $II_\infty$ . Also the end points of the interval make sense. The inverse of this scaling accompanies the inverse of this automorphism.
2. Second invariant corresponds to the time scales  $t = T_0$  for which the outer automorphism  $\sigma_t$  reduces to inner automorphism. It turns out that  $T_0$  and  $\lambda$  are related by the formula  $\lambda^{iT_0} = 1$ , which gives the allowed values of  $T_0$  as  $T_0 = n2\pi/\log(\lambda)$  [62]. This formula can be understood intuitively by realizing that  $\lambda$  corresponds to the eigenvalue of the density matrix  $\Delta = e^H$  in the simplest possible realization of the state  $\phi$ .

The presence of two automorphisms and invariants brings in mind  $U$  matrix characterizing the unitary process occurring in quantum jump and  $M$ -matrix characterizing time like entanglement.

1. If one accepts the vision based on quantum measurement theory then  $\lambda$  corresponds to the scaling of the trace resulting when quantum Clifford algebra  $\mathcal{M}/\mathcal{N}$  reduces to a tensor power of  $M(2, C)$  factor in the state function reduction. The proposed interpretation for  $U$  process would be as the inverse of state function reduction transforming this factor back to  $\mathcal{M}/\mathcal{N}$ . Thus  $U$  process and state function reduction would correspond naturally to the scaling and its inverse. This picture might apply not only in single particle case but also for zero energy states which can be seen as states associated the a tensor power of HFFs of type  $II_1$  associated with partons.
2. The implication is that  $U$  process can occur only in the direction in which trace is reduced. This would suggest that the full  $III_1$  factor is not a physical notion and that one must restrict the group  $Z$  in the crossed product  $Z \times_{cr} II_\infty$  to the group  $N$  of non-negative integers. In this kind of situation the trace is well defined since the traces for the terms in the crossed product comes as powers  $\lambda^{-n}$  so that the net result is finite. This would mean a reduction to  $II_\infty$  factor.
3. Since time  $t$  is a natural parameter in elementary particle physics experiment, one could argue that  $\sigma_t$  could define naturally  $M$ -matrix. Time parameter would most naturally correspond to a parameter of scaling affecting all  $M_\pm^4$  coordinates rather than linear time. This conforms also with the fundamental role of conformal transformations and scalings in TGD framework.

The identification of the full  $M$ -matrix in terms of  $\sigma$  does not seem to make sense generally. It would however make sense for incoming and outgoing number theoretic braids so that  $\sigma$  could define universal braiding  $M$ -matrices. Inner automorphisms would bring in the dependence on experimental situation. The reduction of the braiding matrix to an inner automorphism for critical values of  $t$  which could be interpreted in terms of scaling by power of  $p$ . This trivialization would be a counterpart for the elimination of propagator legs from  $M$ -matrix element. Vertex itself could be interpreted as unitary isomorphism between tensor product of incoming and outgoing HFFs of type  $II_1$  would code all what is relevant about the particle reaction.

### 11.6.5 Does the time parameter $t$ represent time translation or scaling?

The connection  $T_n = n2\pi/\log(\lambda)$  would give a relationship between the scaling of trace and value of time parameter for which the outer automorphism represented by  $\sigma$  reduces to inner automorphism. It must be emphasized that the time parameter  $t$  appearing in  $\sigma$  need not have anything to do with time translation. The alternative interpretation is in terms of  $M_\pm^4$  scaling (implying also time scaling) but one cannot exclude even preferred Lorentz boosts in the direction of quantization axis of angular momentum.

#### Could the time parameter correspond to scaling?

The central role of conformal invariance in quantum TGD suggests that  $t$  parameterizes scaling rather than translation. In this case scalings would correspond to powers of  $(K\lambda)^n$ . The numerical factor  $K$  which cannot be excluded a priori, seems to reduce to  $K = 1$ .

1. The scalings by powers of  $p$  have a simple realization in terms of the representation of HFF of type  $II_\infty$  as infinite tensor power of  $M(p, C)$  with suitably chosen densities matrices in factors to get product of  $I_\infty$  and  $II_1$  factor. These matrix algebras have the remarkable property of defining prime tensor power factors of finite matrix algebras. Thus p-adic fractality would reflect directly basic properties of matrix algebras as suggested already earlier. That scalings by powers of  $p$  would correspond to automorphism reducing to inner automorphisms would conform with p-adic fractality.
2. Also scalings by powers  $[\sqrt{\mathcal{M} : \mathcal{N}/2^k}]^n$  would be physically preferred if one takes previous arguments about Jones inclusions seriously and if also in this case scalings are involved. For  $q = \exp(i\pi/n)$ ,  $n = 5$  the minimal value of  $n$  allowing universal topological quantum computation would correspond to a scaling by Golden Mean and these fractal scalings indeed play a key role in living matter. In particular, Golden Mean makes it visible in the geometry of DNA.

### Could the time parameter correspond to time translation?

One can consider also the interpretation of  $\sigma_t$  as time translation. TGD predicts a hierarchy of Planck constants parameterized by rational numbers such that integer multiples are favored. In particular, integers defining ruler and compass polygons are predicted to be in a very special role physically. Since the geometric time span associated with zero energy state should scale as Planck constant one expects that preferred values of time  $t$  associated with  $\sigma$  are quantized as rational multiples of some fundamental time scales, say the basic time scale defined by  $CP_2$  length or p-adic time scales.

1. For  $\lambda = 1/p$ ,  $p$  prime, the time scale would be  $T_n = nT_1$ ,  $T_1 = T_0 = 2\pi/\log(p)$  which is not what p-adic length scale hypothesis would suggest.
2. For Jones inclusions one would have  $T_n/T_0 = n2\pi/\log(2^{2k}/\mathcal{M} : \mathcal{N})$ . In the limit when  $\lambda$  becomes very small (the number  $k$  of reduced  $M(2, C)$  factors is large one obtains  $T_n = (n/k)t_1$ ,  $T_1 = T_0\pi/\log(2)$ . Approximate rational multiples of the basic length scale would be obtained as also predicted by the general quantization of Planck constant.

### p-Adic thermodynamics from first principles

Quantum field theory at non-zero temperature can be formulated in the functional integral formalism by replacing the time parameter associated with the unitary time evolution operator  $U(t)$  with a complexified time containing as imaginary part the inverse of the temperature:  $t \rightarrow t + i\hbar/T$ . In the framework of standard quantum field theory this is a mere computational trick but the time parameter associated with the automorphisms  $\sigma_t$  of HFF of type III is a temperature like parameter from the beginning, and its complexification would naturally lead to the analog of thermal QFT.

Thus thermal equilibrium state would be a genuine quantum state rather than fictive but useful auxiliary notion. Thermal equilibrium is defined separately for each incoming parton braid and perhaps even braid (partons can have arbitrarily large size). At elementary particle level p-adic thermodynamics could be in question so that particle massivation would have first principle description. p-Adic thermodynamics is under relatively mild conditions equivalent with its real counterpart obtained by the replacement of  $p^{L_0}$  interpreted as a p-adic number with  $p^{-L_0}$  interpreted as a real number.

### 11.6.6 Could HFFs of type III be associated with the dynamics in $M_{\pm}^4$ degrees of freedom?

HFFs of type III could be also assigned with the poorly understood dynamics in  $M_{\pm}^4$  degrees of freedom which should have a lot of to do with four-dimensional quantum field theory. Hyper-finite factors of type III<sub>1</sub> might emerge when one extends II<sub>1</sub> to a local algebra by multiplying it with hyper-octonions replaced as analog of matrix factor and considers hyper-quaternionic subalgebra. The resulting algebra would be the analog of local gauge algebra and the elements of algebra would be analogous to conformal fields with complex argument replaced with hyper-octonionic, -quaternionic, or -complex one. Since quantum field theory in  $M^4$  gives rise to hyper-finite III<sub>1</sub> factors one might guess that the hyper-quaternionic restriction indeed gives these factors.

The expansion of the local HFF II<sub>∞</sub> element as  $O(m) = \sum_n m^n O_n$ , where  $M^4$  coordinate  $m$  is interpreted as hyper-quaternion, could have interpretation as expansion in which  $O_n$  belongs to  $\mathcal{N}g^n$  in the crossed product  $\mathcal{N} \times_{cr} \{g^n, n \in \mathbb{Z}\}$ . The analogy with conformal fields suggests that the power  $g^n$  inducing  $\lambda^n$  fold scaling of trace increases the conformal weight by  $n$ .

One can ask whether the scaling of trace by powers of  $\lambda$  defines an inclusion hierarchy of sub-algebras of conformal sub-algebras as suggested by previous arguments. One such hierarchy would be the hierarchy of sub-algebras containing only the generators  $O_m$  with conformal weight  $m \geq n$ ,  $n \in \mathbb{Z}$ .

It has been suggested that the automorphism  $\Delta$  could correspond to scaling inside light-cone. This interpretation would fit nicely with Lorentz invariance and TGD in general. The factors III<sub>λ</sub> with  $\lambda$  generating semi-subgroups of integers (in particular powers of primes) could be of special physical importance in TGD framework. The values of  $t$  for which automorphism reduces to inner automorphism should be of special physical importance in TGD framework. These automorphisms correspond to scalings identifiable in terms of powers of p-adic prime  $p$  so that p-adic fractality would find an explanation at the fundamental level.

If the above mentioned expansion in powers of  $m^n$  of  $M_{\pm}^4$  coordinate makes sense then the action of  $\sigma^t$  representing a scaling by  $p^n$  would leave the elements  $O$  invariant or induce a mere inner automorphism. Conformal weight  $n$  corresponds naturally to  $n$ -ary  $p$ -adic length scale by uncertainty principle in  $p$ -adic mass calculations.

The basic question is the physical interpretation of the automorphism inducing the scaling of trace by  $\lambda$  and its detailed action in HFF. This scaling could relate to a scaling in  $M^4$  and to the appearance in the trace of an integral over  $M^4$  or subspace of it defining the trace. Fractal structures suggests itself strongly here. At the level of construction of physical states one always selects some minimum non-positive conformal weight defining the tachyonic ground state and physical states have non-negative conformal weights. The interpretation would be as a reduction to HFF of type  $II_{\infty}$  or even  $II_1$ .

### 11.6.7 Could the continuation of braidings to homotopies involve $\Delta^{it}$ automorphisms

The representation of braidings as special case of homotopies might lead from discrete automorphisms for HFFs type  $II_1$  to continuous outer automorphisms for HFFs of type  $III_1$ . The question is whether the periodic automorphism of  $II_1$  represented as a discrete sub-group of  $U(1)$  would be continued to  $U(1)$  in the transition.

The automorphism of  $II_{\infty}$  HFF associated with a given value of the scaling factor  $\lambda$  is unique. If Jones inclusions defined by the preferred values of  $\lambda$  as  $\lambda = \sqrt{\mathcal{M} : \mathcal{N}}/2^k$  (see the previous considerations), then this automorphism could involve a periodic automorphism of  $II_1$  factor defined by the generator of cyclic subgroup  $Z_n$  for  $\mathcal{M} : \mathcal{N} < 4$  besides additional shift transforming  $II_1$  factor to  $I_{\infty}$  factor and inducing the scaling.

### 11.6.8 HFFs of type $III$ as super-structures providing additional uniqueness?

If the braiding  $M$ -matrices are as such highly unique. One could however consider the possibility that they are induced from the automorphisms  $\sigma_t$  for the HFFs of type  $III$  restricted to HFFs of type  $II_{\infty}$ . If a reduction to inner automorphism in HFF of type  $III$  implies same with respect to HFF of type  $II_{\infty}$  and even  $II_1$ , they could be trivial for special values of time scaling  $t$  assignable to the partons and identifiable as a power of prime  $p$  characterizing the parton. This would allow to eliminate incoming and outgoing legs. This elimination would be the counterpart of the division of propagator legs in quantum field theories. Particle masses would however play no role in this process now although the power of  $p$ -adic prime would fix the mass scale of the particle.

## 11.7 The latest vision about the role of HFFs in TGD

It is clear that at least the hyper-finite factors of type  $II_1$  assignable to WCW spinors must have a profound role in TGD. Whether also HFFs of type  $III_1$  appearing also in relativistic quantum field theories emerge when WCW spinors are replaced with spinor fields is not completely clear. I have proposed several ideas about the role of hyper-finite factors in TGD framework. In particular, Connes tensor product is an excellent candidate for defining the notion of measurement resolution.

In the following this topic is discussed from the perspective made possible by zero energy ontology and the recent advances in the understanding of  $M$ -matrix using the notion of bosonic emergence. The conclusion is that the notion of state as it appears in the theory of factors is not enough for the purposes of quantum TGD. The reason is that state in this sense is essentially the counterpart of thermodynamical state. The construction of  $M$ -matrix might be understood in the framework of factors if one replaces state with its "complex square root" natural if quantum theory is regarded as a "complex square root" of thermodynamics. It is also found that the idea that Connes tensor product could fix  $M$ -matrix is too optimistic but an elegant formulation in terms of partial trace for the notion of  $M$ -matrix modulo measurement resolution exists and Connes tensor product allows interpretation as entanglement between sub-spaces consisting of states not distinguishable in the measurement resolution used. The partial trace also gives rise to non-pure states naturally.

### 11.7.1 Basic facts about factors

In this section basic facts about factors are discussed. My hope that the discussion is more mature than or at least complementary to the summary that I could afford when I started the work with factors for more than half decade ago. I of course admit that this just a humble attempt of a physicist to express physical vision in terms of only superficially understood mathematical notions.

#### Basic notions

First some standard notations. Let  $\mathcal{B}(\mathcal{H})$  denote the algebra of linear operators of Hilbert space  $\mathcal{H}$  bounded in the norm topology with norm defined by the supremum of for the length of the image of a point of unit sphere  $\mathcal{H}$ . This algebra has a lot of common with complex numbers in that the counterparts of complex conjugation, order structure and metric structure determined by the algebraic structure exist. This means the existence involution -that is \*- algebra property. The order structure determined by algebraic structure means following:  $A \geq 0$  defined as the condition  $(A\xi, \xi) \geq 0$  is equivalent with  $A = B^*B$ . The algebra has also metric structure  $\|AB\| \leq \|A\|\|B\|$  (Banach algebra property) determined by the algebraic structure. The algebra is also  $C^*$  algebra:  $\|A^*A\| = \|A\|^2$  meaning that the norm is algebraically like that for complex numbers.

A von Neumann algebra  $\mathcal{M}$  [40] is defined as a weakly closed non-degenerate \*-subalgebra of  $\mathcal{B}(\mathcal{H})$  and has therefore all the above mentioned properties. From the point of view of physicist it is important that a sub-algebra is in question.

In order to define factors one must introduce additional structure.

1. Let  $\mathcal{M}$  be subalgebra of  $\mathcal{B}(\mathcal{H})$  and denote by  $\mathcal{M}'$  its commutant defined as the sub-algebra of  $\mathcal{B}(\mathcal{H})$  commuting with it and allowing to express  $\mathcal{B}(\mathcal{H})$  as  $\mathcal{B}(\mathcal{H}) = \mathcal{M} \vee \mathcal{M}'$ .
2. A factor is defined as a von Neumann algebra satisfying  $\mathcal{M}'' = \mathcal{M}$  is called factor. The equality of double commutant with the original algebra is thus the defining condition so that also the commutant is a factor. An equivalent definition for factor is as the condition that the intersection of the algebra and its commutant reduces to a complex line spanned by a unit operator. The condition that the only operator commuting with all operators of the factor is unit operator corresponds to irreducibility in representation theory.
3. Some further basic definitions are needed.  $\Omega \in \mathcal{H}$  is cyclic if the closure of  $\mathcal{M}\Omega$  is  $\mathcal{H}$  and separating if the only element of  $\mathcal{M}$  annihilating  $\Omega$  is zero.  $\Omega$  is cyclic for  $\mathcal{M}$  if and only if it is separating for its commutant. In so called standard representation  $\Omega$  is both cyclic and separating.
4. For hyperfinite factors an inclusion hierarchy of finite-dimensional algebras whose union is dense in the factor exists. This roughly means that one can approximate the algebra in arbitrary accuracy with a finite-dimensional sub-algebra.

The definition of the factor might look somewhat artificial unless one is aware of the underlying physical motivations. The motivating question is what the decomposition of a physical system to non-interacting sub-systems could mean. The decomposition of  $\mathcal{B}(\mathcal{H})$  to  $\vee$  product realizes this decomposition.

1. Tensor product  $\mathcal{H} = \mathcal{H}_1 \otimes \mathcal{H}_2$  is the decomposition according to the standard quantum measurement theory and means the decomposition of operators in  $\mathcal{B}(\mathcal{H})$  to tensor products of mutually commuting operators in  $\mathcal{M} = \mathcal{B}(\mathcal{H}_1)$  and  $\mathcal{M}' = \mathcal{B}(\mathcal{H}_2)$ . The information about  $\mathcal{M}$  can be coded in terms of projection operators. In this case projection operators projecting to a complex ray of Hilbert space exist and arbitrary compact operator can be expressed as a sum of these projectors. For factors of type I minimal projectors exist. Factors of type  $I_n$  correspond to sub-algebras of  $\mathcal{B}(\mathcal{H})$  associated with infinite-dimensional Hilbert space and  $I_\infty$  to  $\mathcal{B}(\mathcal{H})$  itself. These factors appear in the standard quantum measurement theory where state function reduction can lead to a ray of Hilbert space.
2. For factors of type II no minimal projectors exists whereas finite projectors exist. For factors of type  $II_1$  all projectors have trace not larger than one and the trace varies in the range  $(0, 1]$ . In this case cyclic vectors  $\Omega$  exist. State function reduction can lead only to an infinite-dimensional

subspace characterized by a projector with trace smaller than 1 but larger than zero. The natural interpretation would be in terms of finite measurement resolution. The tensor product of  $\text{II}_1$  factor and  $\text{I}_\infty$  is  $\text{II}_\infty$  factor for which the trace for a projector can have arbitrarily large values.  $\text{II}_1$  factor has a unique finite tracial state and the set of traces of projections spans unit interval. There is uncountable number of factors of type II but hyper-finite factors of type  $\text{II}_1$  are the exceptional ones and physically most interesting.

3. Factors of type III correspond to an extreme situation. In this case the projection operators  $E$  spanning the factor have either infinite or vanishing trace and there exists an isometry mapping  $E\mathcal{H}$  to  $\mathcal{H}$  meaning that the projection operator spans almost all of  $\mathcal{H}$ . All projectors are also related to each other by isometry. Factors of type III are smallest if the factors are regarded as sub-algebras of a fixed  $\mathcal{B}(\mathcal{H})$  where  $\mathcal{H}$  corresponds to isomorphism class of Hilbert spaces. Situation changes when one speaks about concrete representations. Also now hyper-finite factors are exceptional.
4. Von Neumann algebras define a non-commutative measure theory. Commutative von Neumann algebras indeed reduce to  $L^\infty(X)$  for some measure space  $(X, \mu)$  and vice versa.

### Weights, states and traces

The notions of weight, state, and trace are standard notions in the theory of von Neumann algebras.

1. A weight of von Neumann algebra is a linear map from the set of positive elements (those of form  $a^*a$ ) to non-negative reals.
2. A positive linear functional is weight with  $\omega(1)$  finite.
3. A state is a weight with  $\omega(1) = 1$ .
4. A trace is a weight with  $\omega(aa^*) = \omega(a^*a)$  for all  $a$ .
5. A tracial state is a weight with  $\omega(1) = 1$ .

A factor has a trace such that the trace of a non-zero projector is non-zero and the trace of projection is infinite only if the projection is infinite. The trace is unique up to a rescaling. For factors that are separable or finite, two projections are equivalent if and only if they have the same trace. Factors of type  $\text{I}_n$  the values of trace are equal to multiples of  $1/n$ . For a factor of type  $\text{I}_\infty$  the value of trace are  $0, 1, 2, \dots$ . For factors of type  $\text{II}_1$  the values span the range  $[0, 1]$  and for factors of type  $\text{II}_\infty$  in the range  $[0, \infty)$ . For factors of type III the values of the trace are  $0$ , and  $\infty$ .

### Tomita-Takesaki theory

Tomita-Takesaki theory is a vital part of the theory of factors. First some definitions.

1. Let  $\omega(x)$  be a faithful state of von Neumann algebra so that one has  $\omega(xx^*) > 0$  for  $x > 0$ . Assume by Riesz lemma the representation of  $\omega$  as a vacuum expectation value:  $\omega = (\cdot\Omega, \Omega)$ , where  $\Omega$  is cyclic and separating state.
2. Let

$$L^\infty(\mathcal{M}) \equiv \mathcal{M} \quad , \quad L^2(\mathcal{M}) = \mathcal{H} \quad , \quad L^1(\mathcal{M}) = \mathcal{M}_* \quad , \quad (11.7.1)$$

where  $\mathcal{M}_*$  is the pre-dual of  $\mathcal{M}$  defined by linear functionals in  $\mathcal{M}$ . One has  $\mathcal{M}_*^* = \mathcal{M}$ .

3. The conjugation  $x \rightarrow x^*$  is isometric in  $\mathcal{M}$  and defines a map  $\mathcal{M} \rightarrow L^2(\mathcal{M})$  via  $x \rightarrow x\Omega$ . The map  $S_0; x\Omega \rightarrow x^*\Omega$  is however non-isometric.

4. Denote by  $S$  the closure of the anti-linear operator  $S_0$  and by  $S = J\Delta^{1/2}$  its polar decomposition analogous that for complex number and generalizing polar decomposition of linear operators by replacing (almost) unitary operator with anti-unitary  $J$ . Therefore  $\Delta = S^*S > 0$  is positive self-adjoint and  $J$  an anti-unitary involution. The non-triviality of  $\Delta$  reflects the fact that the state is not trace so that hermitian conjugation represented by  $S$  in the state space brings in additional factor  $\Delta^{1/2}$ .
5. What  $x$  can be is puzzling to physicists. The restriction fermionic Fock space and thus to creation operators would imply that  $\Delta$  would act non-trivially only vacuum state so that  $\Delta > 0$  condition would not hold true. The resolution of puzzle is the allowance of tensor product of Fock spaces for which vacua are conjugates: only this gives cyclic and separating state. This is natural in zero energy ontology.

The basic results of Tomita-Takesaki theory are following.

1. The basic result can be summarized through the following formulas

$$\Delta^{it}M\Delta^{-it} = \mathcal{M} \quad , \quad J\mathcal{M}J = \mathcal{M}' \quad .$$

2. The latter formula implies that  $\mathcal{M}$  and  $\mathcal{M}'$  are isomorphic algebras. The first formula implies that a one parameter group of modular automorphisms characterizes partially the factor. The physical meaning of modular automorphisms is discussed in [67, 130]  $\Delta$  is Hermitian and positive definite so that the eigenvalues of  $\log(\Delta)$  are real but can be negative.  $\Delta^{it}$  is however not unitary for factors of type II and III. Physically the non-unitarity must relate to the fact that the flow is contracting so that hermiticity as a local condition is not enough to guarantee unitarity.
3.  $\omega \rightarrow \sigma_t^\omega = Ad\Delta^{it}$  defines a canonical evolution -modular automorphism- associated with  $\omega$  and depending on it. The  $\Delta$ :s associated with different  $\omega$ :s are related by a unitary inner automorphism so that their equivalence classes define an invariant of the factor.

Tomita-Takesaki theory gives rise to a non-commutative measure theory which is highly non-trivial. In particular the spectrum of  $\Delta$  can be used to classify the factors of type II and III.

### Modular automorphisms

Modular automorphisms of factors are central for their classification.

1. One can divide the automorphisms to inner and outer ones. Inner automorphisms correspond to unitary operators obtained by exponentiating Hermitian Hamiltonian belonging to the factor and connected to identity by a flow. Outer automorphisms do not allow a representation as a unitary transformations although  $\log(\Delta)$  is formally a Hermitian operator.
2. The fundamental group of the type  $II_1$  factor defined as fundamental group group of corresponding  $II_\infty$  factor characterizes partially a factor of type  $II_1$ . This group consists real numbers  $\lambda$  such that there is an automorphism scaling the trace by  $\lambda$ . Fundamental group typically contains all reals but it can be also discrete and even trivial.
3. Factors of type III allow a one-parameter group of modular automorphisms, which can be used to achieve a partial classification of these factors. These automorphisms define a flow in the center of the factor known as flow of weights. The set of parameter values  $\lambda$  for which  $\omega$  is mapped to itself and the center of the factor defined by the identity operator (projector to the factor as a sub-algebra of  $\mathcal{B}(\mathcal{H})$ ) is mapped to itself in the modular automorphism defines the Connes spectrum of the factor. For factors of type  $III_\lambda$  this set consists of powers of  $\lambda < 1$ . For factors of type  $III_0$  this set contains only identity automorphism so that there is no periodicity. For factors of type  $III_1$  Connes spectrum contains all real numbers so that the automorphisms do not affect the identity operator of the factor at all.

The modules over a factor correspond to separable Hilbert spaces that the factor acts on. These modules can be characterized by M-dimension. The idea is roughly that complex rays are replaced by the sub-spaces defined by the action of  $\mathcal{M}$  as basic units. M-dimension is not integer valued in general. The so called standard module has a cyclic separating vector and each factor has a standard representation possessing antilinear involution  $J$  such that  $\mathcal{M}' = J\mathcal{M}J$  holds true (note that  $J$  changes the order of the operators in conjugation). The inclusions of factors define modules having interpretation in terms of a finite measurement resolution defined by  $\mathcal{M}$ .

### Crossed product as a manner to construct factors of type III

By using so called crossed product [9] for a group  $G$  acting in algebra  $A$  one can obtain new von Neumann algebras. One ends up with crossed product by a two-step generalization by starting from the semidirect product  $G \triangleleft H$  for groups defined as  $(g_1, h_1)(g_2, h_2) = (g_1 h_1(g_2), h_1 h_2)$  (note that Poincare group has interpretation as a semidirect product  $M^4 \triangleleft SO(3, 1)$  of Lorentz and translation groups). At the first step one replaces the group  $H$  with its group algebra. At the second step the the group algebra is replaced with a more general algebra. What is formed is the semidirect product  $A \triangleleft G$  which is sum of algebras  $Ag$ . The product is given by  $(a_1, g_1)(a_2, g_2) = (a_1 g_1(a_2), g_1 g_2)$ . This construction works for both locally compact groups and quantum groups. A not too highly educated guess is that the construction in the case of quantum groups gives the factor  $\mathcal{M}$  as a crossed product of the included factor  $\mathcal{N}$  and quantum group defined by the factor space  $\mathcal{M}/\mathcal{N}$ .

The construction allows to express factors of type III as crossed products of factors of type  $II_\infty$  and the 1-parameter group  $G$  of modular automorphisms assignable to any vector which is cyclic for both factor and its commutant. The ergodic flow  $\theta_\lambda$  scales the trace of projector in  $II_\infty$  factor by  $\lambda > 0$ . The dual flow defined by  $G$  restricted to the center of  $II_\infty$  factor does not depend on the choice of cyclic vector.

The Connes spectrum - a closed subgroup of positive reals - is obtained as the exponent of the kernel of the dual flow defined as set of values of flow parameter  $\lambda$  for which the flow in the center is trivial. Kernel equals to  $\{0\}$  for  $III_0$ , contains numbers of form  $\log(\lambda)Z$  for factors of type  $III_\lambda$  and contains all real numbers for factors of type  $III_1$  meaning that the flow does not affect the center.

### 11.7.2 Inclusions and Connes tensor product

Inclusions  $\mathcal{N} \subset \mathcal{M}$  of von Neumann algebras have physical interpretation as a mathematical description for sub-system-system relation. For type I algebras the inclusions are trivial and tensor product description applies as such. For factors of  $II_1$  and  $III$  the inclusions are highly non-trivial. The inclusion of type  $II_1$  factors were understood by Vaughan Jones [4] and those of factors of type  $III$  by Alain Connes [61].

Formally sub-factor  $\mathcal{N}$  of  $\mathcal{M}$  is defined as a closed \*-stable C-subalgebra of  $\mathcal{M}$ . Let  $\mathcal{N}$  be a sub-factor of type  $II_1$  factor  $\mathcal{M}$ . Jones index  $\mathcal{M} : \mathcal{N}$  for the inclusion  $\mathcal{N} \subset \mathcal{M}$  can be defined as  $\mathcal{M} : \mathcal{N} = \dim_{\mathcal{N}}(L^2(\mathcal{M})) = \text{Tr}_{\mathcal{N}'}(id_{L^2(\mathcal{M})})$ . One can say that the dimension of completion of  $\mathcal{M}$  as  $\mathcal{N}$  module is in question.

#### Basic findings about inclusions

What makes the inclusions non-trivial is that the position of  $\mathcal{N}$  in  $\mathcal{M}$  matters. This position is characterized in case of hyper-finite  $II_1$  factors by index  $\mathcal{M} : \mathcal{N}$  which can be said to the dimension of  $\mathcal{M}$  as  $\mathcal{N}$  module and also as the inverse of the dimension defined by the trace of the projector from  $\mathcal{M}$  to  $\mathcal{N}$ . It is important to notice that  $\mathcal{M} : \mathcal{N}$  does not characterize either  $\mathcal{M}$  or  $\mathcal{N}$ , only the imbedding.

The basic facts proved by Jones are following [4].

1. For pairs  $\mathcal{N} \subset \mathcal{M}$  with a finite principal graph the values of  $\mathcal{M} : \mathcal{N}$  are given by

$$\begin{aligned} a) \quad \mathcal{M} : \mathcal{N} &= 4\cos^2(\pi/h) \quad , \quad h \geq 3 \quad , \\ b) \quad \mathcal{M} : \mathcal{N} &\geq 4 \quad . \end{aligned} \tag{11.7.2}$$

the numbers at right hand side are known as Beraha numbers [111] . The comments below give a rough idea about what finiteness of principal graph means.

- As explained in [41] , for  $\mathcal{M} : \mathcal{N} < 4$  one can assign to the inclusion Dynkin graph of ADE type Lie-algebra  $g$  with  $h$  equal to the Coxeter number  $h$  of the Lie algebra given in terms of its dimension and dimension  $r$  of Cartan algebra  $r$  as  $h = (\dim g - r)/r$ . The Lie algebras of  $SU(n)$ ,  $E_7$  and  $D_{2n+1}$  are however not allowed. For  $\mathcal{M} : \mathcal{N} = 4$  one can assign to the inclusion an extended Dynkin graph of type ADE characterizing Kac Moody algebra. Extended ADE diagrams characterize also the subgroups of  $SU(2)$  and the interpretation proposed in [90] is following. The ADE diagrams are associated with the  $n = \infty$  case having  $\mathcal{M} : \mathcal{N} \geq 4$ . There are diagrams corresponding to infinite subgroups:  $SU(2)$  itself, circle group  $U(1)$ , and infinite dihedral groups (generated by a rotation by a non-rational angle and reflection. The diagrams corresponding to finite subgroups are extension of  $A_n$  for cyclic groups, of  $D_n$  dihedral groups, and of  $E_n$  with  $n=6,7,8$  for tetrahedron, cube, dodecahedron. For  $\mathcal{M} : \mathcal{N} < 4$  ordinary Dynkin graphs of  $D_{2n}$  and  $E_6, E_8$  are allowed.

### Connes tensor product

The inclusions The basic idea of Connes tensor product is that a sub-space generated sub-factor  $\mathcal{N}$  takes the role of the complex ray of Hilbert space. The physical interpretation is in terms of finite measurement resolution: it is not possible to distinguish between states obtained by applying elements of  $\mathcal{N}$ .

Intuitively it is clear that it should be possible to decompose  $\mathcal{M}$  to a tensor product of factor space  $\mathcal{M}/\mathcal{N}$  and  $\mathcal{N}$ :

$$\mathcal{M} = \mathcal{M}/\mathcal{N} \otimes \mathcal{N} . \tag{11.7.3}$$

One could regard the factor space  $\mathcal{M}/\mathcal{N}$  as a non-commutative space in which each point corresponds to a particular representative in the equivalence class of points defined by  $\mathcal{N}$ . The connections between quantum groups and Jones inclusions suggest that this space closely relates to quantum groups. An alternative interpretation is as an ordinary linear space obtained by mapping  $\mathcal{N}$  rays to ordinary complex rays. These spaces appear in the representations of quantum groups. Similar procedure makes sense also for the Hilbert spaces in which  $\mathcal{M}$  acts.

Connes tensor product can be defined in the space  $\mathcal{M} \otimes \mathcal{M}$  as entanglement which effectively reduces to entanglement between  $\mathcal{N}$  sub-spaces. This is achieved if  $\mathcal{N}$  multiplication from right is equivalent with  $\mathcal{N}$  multiplication from left so that  $\mathcal{N}$  acts like complex numbers on states. One can imagine variants of the Connes tensor product and in TGD framework one particular variant appears naturally as will be found.

In the finite-dimensional case Connes tensor product of Hilbert spaces has a rather simple representation. If the matrix algebra  $N$  of  $n \times n$  matrices acts on  $V$  from right,  $V$  can be regarded as a space formed by  $m \times n$  matrices for some value of  $m$ . If  $N$  acts from left on  $W$ ,  $W$  can be regarded as space of  $n \times r$  matrices.

- In the first representation the Connes tensor product of spaces  $V$  and  $W$  consists of  $m \times r$  matrices and Connes tensor product is represented as the product  $VW$  of matrices as  $(VW)_{mr} e^{mr}$ . In this representation the information about  $N$  disappears completely as the interpretation in terms of measurement resolution suggests. The sum over intermediate states defined by  $N$  brings in mind path integral.
- An alternative and more physical representation is as a state

$$\sum_n V_{mn} W_{nr} e^{mn} \otimes e^{nr}$$

in the tensor product  $V \otimes W$ .

3. One can also consider two spaces  $V$  and  $W$  in which  $N$  acts from right and define Connes tensor product for  $A^\dagger \otimes_N B$  or its tensor product counterpart. This case corresponds to the modification of the Connes tensor product of positive and negative energy states. Since Hermitian conjugation is involved, matrix product does not define the Connes tensor product now. For  $m = r$  case entanglement coefficients should define a unitary matrix commuting with the action of the Hermitian matrices of  $N$  and interpretation would be in terms of symmetry. HFF property would encourage to think that this representation has an analog in the case of HFFs of type  $II_1$ .
4. Also type  $I_n$  factors are possible and for them Connes tensor product makes sense if one can assign the inclusion of finite-D matrix algebras to a measurement resolution.

### 11.7.3 Factors in quantum field theory and thermodynamics

Factors arise in thermodynamics and in quantum field theories [98, 67, 130]. There are good arguments showing that in HFFS of  $III_1$  appear are relativistic quantum field theories. In non-relativistic QFTs the factors of type I appear so that the non-compactness of Lorentz group is essential. Factors of type  $III_1$  and  $III_\lambda$  appear also in relativistic thermodynamics.

The geometric picture about factors is based on open subsets of Minkowski space. The basic intuitive view is that for two subsets of  $M^4$ , which cannot be connected by a classical signal moving with at most light velocity, the von Neumann algebras commute with each other so that  $\vee$  product should make sense.

Some basic mathematical results of algebraic quantum field theory [130] deserve to be listed since they are suggestive also from the point of view of TGD.

1. Let  $\mathcal{O}$  be a bounded region of  $R^4$  and define the region of  $M^4$  as a union  $\cup_{|x|<\epsilon}(\mathcal{O} + x)$  where  $(\mathcal{O} + x)$  is the translate of  $\mathcal{O}$  and  $|x|$  denotes Minkowski norm. Then every projection  $E \in \mathcal{M}(\mathcal{O})$  can be written as  $WW^*$  with  $W \in \mathcal{M}(\mathcal{O}_\epsilon)$  and  $W^*W = 1$ . Note that the union is not a bounded set of  $M^4$ . This almost establishes the type III property.
2. Both the complement of light-cone and double light-cone define HFF of type  $III_1$ . Lorentz boosts induce modular automorphisms.
3. The so called split property suggested by the description of two systems of this kind as a tensor product in relativistic QFTs is believed to hold true. This means that the HFFs of type  $III_1$  associated with causally disjoint regions are sub-factors of factor of type  $I_\infty$ . This means

$$\mathcal{M}_1 \subset \mathcal{B}(\mathcal{H}_1) \times 1 \quad , \quad \mathcal{M}_2 \subset 1 \otimes \mathcal{B}(\mathcal{H}_2) \quad .$$

An infinite hierarchy of inclusions of HFFS of type  $III_1$ s is induced by set theoretic inclusions.

### 11.7.4 TGD and factors

The following vision about TGD and factors relies heavily on zero energy ontology, TGD inspired quantum measurement theory, basic vision about quantum TGD, and bosonic emergence.

#### The problems

Concerning the role of factors in TGD framework there are several problems of both conceptual and technical character.

#### 1. Conceptual problems

It is safest to start from the conceptual problems and take a role of skeptic.

1. Under what conditions the assumptions of Tomita-Takesaki formula stating the existence of modular automorphism and isomorphy of the factor and its commutant hold true? What is the physical interpretation of the formula  $\mathcal{M}' = J\mathcal{M}J$  relating factor and its commutant in TGD framework?

2. Is the identification  $M = \Delta^{it}$  sensible in quantum TGD and zero energy ontology, where M-matrix is "complex square root" of exponent of Hamiltonian defining thermodynamical state and the notion of unitary time evolution is given up? The notion of state  $\omega$  leading to  $\Delta$  is essentially thermodynamical and one can wonder whether one should take also a "complex square root" of  $\omega$  to get M-matrix giving rise to a genuine quantum theory.
3. TGD based quantum measurement theory involves both quantum fluctuating degrees of freedom assignable to light-like 3-surfaces and zero modes identifiable as classical degrees of freedom assignable to interior of the space-time sheet. Zero modes have also fermionic counterparts. State preparation should generate entanglement between the quantal and classical states. What this means at the level of von Neumann algebras?
4. What is the TGD counterpart for causal disjointness. At space-time level different space-time sheets could correspond to such regions whereas at imbedding space level causally disjoint  $CD$ s would represent such regions.

### 2. Technical problems

There are also more technical questions.

1. What is the von Neumann algebra needed in TGD framework? Does one have a direct integral over factors (at least a direct integral over zero modes labeling factors)? Which factors appear in it? Can one construct the factor as a crossed product of some group  $G$  with a direct physical interpretation and of naturally appearing factor  $A$ ? Is  $A$  a HFF of type  $II_\infty$ ? assignable to a fixed  $CD$ ? What is the natural Hilbert space  $\mathcal{H}$  in which  $A$  acts?
2. What are the geometric transformations inducing modular automorphisms of  $II_\infty$  inducing the scaling down of the trace? Is the action of  $G$  induced by the boosts in Lorentz group. Could also translations and scalings induce the action? What is the factor associated with the union of Poincare transforms of  $CD$ ?  $\log(\Delta)$  is Hermitian algebraically: what does the non-unitarity of  $\exp(\log(\Delta)it)$  mean physically?
3. Could  $\Omega$  correspond to a vacuum which in conformal degrees of freedom depends on the choice of the sphere  $S^2$  defining the radial coordinate playing the role of complex variable in the case of the radial conformal algebra. Does  $*$ -operation in  $\mathcal{M}$  correspond to Hermitian conjugation for fermionic oscillator operators and change of sign of super conformal weights?

The exponent of the modified Dirac action gives rise to the exponent of Kähler function as Dirac determinant and fermionic inner product defined by fermionic Feynman rules. It is implausible that this exponent could as such correspond to  $\omega$  or  $\Delta^{it}$  having conceptual roots in thermodynamics rather than QFT. If one assumes that the exponent of the modified Dirac action defines a "complex square root" of  $\omega$  the situation changes. This raises technical questions relating to the notion of square root of  $\omega$ .

1. Does the square root of  $\omega$  in the have a polar decomposition to a product of positive definite matrix (square root of the density matrix) and unitary matrix and does  $\omega^{1/2}$  correspond to the modulus in the decomposition? Does the square root of  $\Delta$  have similar decomposition with modulus equal equal to  $\Delta^{1/2}$  in standard picture so that modular automorphism, which is inherent property of von Neumann algebra, would not be affected?
2.  $\Delta^{it}$  or rather its generalization is defined modulo a unitary operator defined by some Hamiltonian and is therefore highly non-unique as such. This non-uniqueness applies also to  $|\Delta|$ . Could this non-uniqueness correspond to the thermodynamical degrees of freedom?

### Zero energy ontology and factors

The first question concerns the identification of the Hilbert space associated with the factors in zero energy ontology. As the positive or negative energy part of the zero energy state space or as the entire space of zero energy states? The latter option would look more natural physically and is forced by the condition that the vacuum state is cyclic and separating.

1. The commutant of HFF given as  $\mathcal{M}' = J\mathcal{M}J$ , where  $J$  is involution transforming fermionic oscillator operators and bosonic vector fields to their Hermitian conjugates. Also conformal weights would change sign in the map which conforms with the view that the light-like boundaries of  $CD$  are analogous to upper and lower hemispheres of  $S^2$  in conformal field theory. The presence of  $J$  representing essentially Hermitian conjugation would suggest that positive and zero energy parts of zero energy states are related by this formula so that state space decomposes to a tensor product of positive and negative energy states and  $M$ -matrix can be regarded as a map between these two sub-spaces.
2. The fact that HFF of type  $\text{II}_1$  has the algebra of fermionic oscillator operators as a canonical representation makes the situation puzzling for a novice. The assumption that the vacuum is cyclic and separating means that neither creation nor annihilation operators can annihilate it. Therefore Fermionic Fock space cannot appear as the Hilbert space in the Tomita-Takesaki theorem. The paradox is circumvented if the action of  $*$  transforms creation operators acting on the positive energy part of the state to annihilation operators acting on negative energy part of the state. If  $J$  permutes the two Fock vacuums in their tensor product, the action of  $S$  indeed maps permutes the tensor factors associated with  $\mathcal{M}$  and  $\mathcal{M}'$ .

It is far from obvious whether the identification  $M = \Delta^{it}$  makes sense in zero energy ontology.

1. In zero energy ontology  $M$ -matrix defines time-like entanglement coefficients between positive and negative energy parts of the state.  $M$ -matrix is essentially "complex square root" of the density matrix and quantum theory similar square root of thermodynamics. The notion of state as it appears in the theory of HFFS is however essentially thermodynamical. Therefore it is good to ask whether the "complex square root of state" could make sense in the theory of factors.
2. Quantum field theory suggests an obvious proposal concerning the meaning of the square root: one replaces exponent of Hamiltonian with imaginary exponential of action at  $T \rightarrow 0$  limit. In quantum TGD the exponent of modified Dirac action giving exponent of Kähler function as real exponent could be the manner to take this complex square root. Modified Dirac action can therefore be regarded as a "square root" of Kähler action.
3. The identification  $M = \Delta^{it}$  relies on the idea of unitary time evolution which is given up in zero energy ontology based on  $CD$ s? Is the reduction of the quantum dynamics to a flow a realistic idea? As will be found this automorphism could correspond to a time translation or scaling for either upper or lower light-cone defining  $CD$  and can ask whether  $\Delta^{it}$  corresponds to the exponent of scaling operator  $L_0$  defining single particle propagator as one integrates over  $t$ . Its complex square root would correspond to fermionic propagator.
4. In this framework  $J\Delta^{it}$  would map the positive energy and negative energy sectors to each other. If the positive and negative energy state spaces can identified by isometry then  $M = J\Delta^{it}$  identification can be considered but seems unrealistic.  $S = J\Delta^{1/2}$  maps positive and negative energy states to each other: could  $S$  or its generalization appear in  $M$ -matrix as a part which gives thermodynamics? The exponent of the modified Dirac action does not seem to provide thermodynamical aspect and p-adic thermodynamics suggests strongly the presence exponent of  $\exp(-L_0/T_p)$  with  $T_p$  chose in such manner that consistency with p-adic thermodynamics is obtained. Could the generalization of  $J\Delta^{n/2}$  with  $\Delta$  replaced with its "square root" give rise to p-adic thermodynamics and also ordinary thermodynamics at the level of density matrix? The minimal option would be that power of  $\Delta^{it}$  which imaginary value of  $t$  is responsible for thermodynamical degrees of freedom whereas everything else is dictated by the unitary  $S$ -matrix appearing as phase of the "square root" of  $\omega$ .

### Zero modes and factors

The presence of zero modes justifies quantum measurement theory in TGD framework and the relationship between zero modes and HFFS involves further conceptual problems.

1. The presence of zero modes means that one has a direct integral over HFFs labeled by zero modes which by definition do not contribute to the configuration space line element. The realization

of quantum criticality in terms of modified Dirac action [15] suggests that also fermionic zero mode degrees of freedom are present and correspond to conserved charges assignable to the critical deformations of the pace-time sheets. Induced Kähler form characterizes the values of zero modes for a given space-time sheet and the symplectic group of light-cone boundary characterizes the quantum fluctuating degrees of freedom. The entanglement between zero modes and quantum fluctuating degrees of freedom is essential for quantum measurement theory. One should understand this entanglement.

2. Physical intuition suggests that classical observables should correspond to longer length scale than quantal ones. Hence it would seem that the interior degrees of freedom outside  $CD$  should correspond to classical degrees of freedom correlating with quantum fluctuating degrees of freedom of  $CD$ .
3. Quantum criticality means that modified Dirac action allows an infinite number of conserved charges which correspond to deformations leaving metric invariant and therefore act on zero modes. Does this super-conformal algebra commute with the super-conformal algebra associated with quantum fluctuating degrees of freedom? Could the restriction of elements of quantum fluctuating currents to 3-D light-like 3-surfaces actually imply this commutativity. Quantum holography would suggest a duality between these algebras. Quantum measurement theory suggests even 1-1 correspondence between the elements of the two super-conformal algebras. The entanglement between classical and quantum degrees of freedom would mean that prepared quantum states are created by operators for which the operators in the two algebras are entangled in diagonal manner.
4. The notion of finite measurement resolution has become key element of quantum TGD and one should understand how finite measurement resolution is realized in terms of inclusions of hyper-finite factors for which sub-factor defines the resolution in the sense that its action creates states not distinguishable from each other in the resolution used. The notion of finite measurement resolution suggests that one should speak about entanglement between sub-factors and corresponding sub-spaces rather than between states. Connes tensor product would code for the idea that the action of sub-factors is analogous to that of complex numbers and tracing over sub-factor realizes this idea.
5. Just for fun one can ask whether the duality between zero modes and quantum fluctuating degrees of freedom representing quantum holography could correspond to  $\mathcal{M}' = J\mathcal{M}J$ ? This interpretation must be consistent with the interpretation forced by zero energy ontology. If this crazy guess is correct (very probably not!), both positive and negative energy states would be observed in quantum measurement but in totally different manner. Since this identity would simplify enormously the structure of the theory, it deserves therefore to be shown wrong.

### Crossed product construction in TGD framework

The identification of the von Neumann algebra by crossed product construction is the basic challenge. Consider first the question how HFFs of type  $II_\infty$  could emerge, how modular automorphisms act on them, and how one can understand the non-unitary character of the  $\Delta^{it}$  in an apparent conflict with the hermiticity and positivity of  $\Delta$ .

1. If the number of spinor modes is infinite, the Clifford algebra at a given point of  $WCW(CD)$  (light-like 3-surfaces with ends at the boundaries of  $CD$ ) defines HFF of type  $II_1$  or possibly a direct integral of them. For a given  $CD$  having compact isotropy group  $SO(3)$  leaving the rest frame defined by the tips of  $CD$  invariant the factor defined by Clifford algebra valued fields in  $WCW(CD)$  is most naturally HFF of type  $II_\infty$ . The Hilbert space in which this Clifford algebra acts, consists of spinor fields in  $WCW(CD)$ . Also the symplectic transformations of light-cone boundary leaving light-like 3-surfaces inside  $CD$  can be included to  $G$ . In fact all conformal algebras leaving  $CD$  invariant could be included in  $CD$ .
2. The downwards scalings of the radial coordinate  $r_M$  of the light-cone boundary applied to the basis of  $WCW(CD)$  spinor fields could induce modular automorphism. These scalings reduce the size of the portion of light-cone in which the  $WCW$  spinor fields are non-vanishing

and effectively scale down the size of  $CD$ .  $\exp(iL_0)$  as algebraic operator acts as a phase multiplication on eigen states of conformal weight and therefore as apparently unitary operator. The geometric flow however contracts the  $CD$  so that the interpretation of  $\exp(itL_0)$  as a unitary modular automorphism is not possible. The scaling down of  $CD$  reduces the value of the trace if it involves integral over the boundary of  $CD$ . A similar reduction is implied by the downward shift of the upper boundary of  $CD$  so that also time translations would induce modular automorphism. These shifts seem to be necessary to define rest energies of positive and negative energy parts of the zero energy state.

3. The non-triviality of the modular automorphisms of  $II_\infty$  factor reflects different choices of  $\omega$ . The degeneracy of  $\omega$  could be due to the non-uniqueness of conformal vacuum which is part of the definition of  $\omega$ . The radial Virasoro algebra of light-cone boundary is generated by  $L_n = L_{-n}^*$ ,  $n \neq 0$  and  $L_0 = L_0^*$  and negative and positive frequencies are in asymmetric position. The conformal gauge is fixed by the choice of  $SO(3)$  subgroup of Lorentz group defining the slicing of light-cone boundary by spheres and the tips of  $CD$  fix  $SO(3)$  uniquely. One can however consider also alternative choices of  $SO(3)$  and each corresponds to a slicing of the light-cone boundary by spheres but in general the sphere defining the intersection of the two light-cone does not belong to the slicing. Hence the action of Lorentz transformation inducing different choice of  $SO(3)$  can lead out from the preferred state space so that its representation must be non-unitary unless Virasoro generators annihilate the physical states. The non-vanishing of the conformal central charge  $c$  and vacuum weight  $h$  seems to be necessary and indeed can take place for super-symplectic algebra and Super Kac-Moody algebra since only the differences of the algebra elements are assumed to annihilate physical states.

The essential assumption in the above argument is that the number of modes  $D_K\Psi = 0$  for the induced spinor field is infinite. This assumption is highly non-trivial and need not hold true always as the detailed considerations of [28] demonstrate.

1. The Dirac determinant defining the vacuum functional is identified as the product of generalized eigenvalues of the 3-D dimensional reduction  $D_{K,3}$  of  $D_K$  to light-like 3-surfaces  $Y_1^3$ . A physical analogy for the modified Dirac equation is fermion in a magnetic field.
2. When the dimension  $D$  of the  $CP_2$  projection of the space-time sheet satisfies  $D > 2$ , the counterpart of the Schrödinger amplitude - call it  $R$ - can depend on single  $CP_2$  coordinate only. For  $D = 2$  (cosmic strings would be the basic example)  $R$  can depend on 2  $CP_2$  coordinates. In this case infinite number of modes are possible and are analogous to 2-D spherical harmonics in the cross section of the string like object. At least in the interior of cosmic strings this option seems to be realized so that in this case the Clifford algebra would be infinite-dimensional.
3. What is essential is that for string like objects the slicings by light-like 3-surfaces associated with the wormhole throats at the opposite ends of string like object can correspond to the same slicing. Hence the situation is expected to be the same for all string like objects irrespective of the value of  $D$ . The coordinate on which  $R$  depends could be analogous to cylindrical angle coordinate and one would have infinite number of rotational modes. For infinite-dimensional case zeta function regularization must be used in the definition of Dirac determinant and under rather general conditions on spectrum reduces to the analytic continuation used to define Riemann Zeta.
4. For  $D > 2$  and for objects which are not string like objects situation is different. The slicings by light-like 3-surfaces associated with different wormhole throats must be defined on finite-sized basins separated by boundaries at which the spinor modes associated with particular throat must vanish. The modes are therefore restricted to a finite region of space-time sheet with a boundary. If  $R$  is analogous to a radial mode in constant magnetic field, there is a natural cutoff in oscillator modes which are analogous harmonic oscillator wave functions and Dirac determinant is automatically finite. Thus for  $D > 2$  or at least for  $D = 4$ - a phase analogous to QFT in  $M^4$  - the number of modes would be finite meaning that the Clifford algebra is finite-dimensional and one obtains only factor of type  $I_n$ .

Modular automorphism of HFFs type  $III_1$  can be induced by several geometric transformations for HFFs of type  $III_1$  obtained using the crossed product construction from  $II_\infty$  factor by extending  $CD$  to a union of its Lorentz transforms.

1. The crossed product would correspond to an extension of  $II_\infty$  by allowing a union of some geometric transforms of  $CD$ . If one assumes that only  $CD$ s for which the distance between tips is quantized in powers of 2, then scalings of either upper or lower boundary of  $CD$  cannot correspond to these transformations. Same applies to time translations acting on either boundary but not to ordinary translations. As found, the modular automorphisms reducing the size of  $CD$  could act in HFF of type  $II_\infty$ .
2. The geometric counterparts of the modular transformations would most naturally correspond to any non-compact one parameter sub-group of Lorentz group as also QFT suggests. The Lorentz boosts would replace the radial coordinate  $r_M$  of the light-cone boundary associated with the radial Virasoro algebra with a new one so that the slicing of light-cone boundary with spheres would be affected and one could speak of a new conformal gauge. The temporal distance between tips of  $CD$  in the rest frame would not be affected. The effect would seem to be however unitary because the transformation does not only modify the states but also transforms  $CD$ .
3. Since Lorentz boosts affect the isotropy group  $SO(3)$  of  $CD$  and thus also the conformal gauge defining the radial coordinate of the light-cone boundary, they affect also the definition of the conformal vacuum so that also  $\omega$  is affected so that the interpretation as a modular automorphism makes sense. The simplistic intuition of the novice suggests that if one allows wave functions in the space of Lorentz transforms of  $CD$ , unitarity of  $\Delta^{it}$  is possible. Note that the hierarchy of Planck constants assigns to  $CD$  preferred  $M^2$  and thus direction of quantization axes of angular momentum and boosts in this direction would be in preferred role.
4. One can also consider the HFF of type  $III_\lambda$  if the radial scalings by negative powers of 2 correspond to the automorphism group of  $II_\infty$  factor as the vision about allowed  $CD$ s suggests.  $\lambda = 1/2$  would naturally hold true for the factor obtained by allowing only the radial scalings. Lorentz boosts would expand the factor to HFF of type  $III_1$ . Why scalings by powers of 2 would give rise to periodicity should be understood.

The identification of  $M$ -matrix as modular automorphism  $\Delta^{it}$ , where  $t$  is complex number having as its real part the temporal distance between tips of  $CD$  quantized as  $2^n$  and temperature as imaginary part, looks at first highly attractive, since it would mean that  $M$ -matrix indeed exists mathematically. The proposed interpretations of modular automorphisms do not support the idea that they could define the S-matrix of the theory. In any case, the identification as modular automorphism would not lead to a magic universal formula since arbitrary unitary transformation is involved.

### 11.7.5 Can one identify $M$ -matrix from physical arguments?

Consider next the identification of  $M$ -matrix from physical arguments.

#### Basic physical picture

The following physical picture could help in the attempt to guess what the complex square root of  $\omega$  is and also whether this idea makes sense at all. Consider first quantum TGD proper.

1. The exponent of Kähler function identified as Kähler action for preferred extremals defines the bosonic vacuum functional appearing in the functional integral over  $WCW(CD)$ . The exponent of Kähler function depends on the real part of  $t$  identified as Minkowski distance between the tips of  $CD$ . This dependence is not consistent with the dependence of  $\Delta^{it}$  on  $t$  and the natural interpretation is that the vacuum functional can be included in the definition of the inner product for spinors fields of  $WCW$ . More formally, the exponent of Kähler function defines  $\omega$  in bosonic degrees of freedom.
2. One can assign to the modified Dirac action Dirac determinant identified tentatively as the exponent of Kähler function. This determinant is defined as the product of the generalized eigenvalues of a 3-dimensional modified Dirac operator assignable to light-like 3-surfaces. The definition relies on quantum holography involving the slicing of space-time surface both by light-like 3-surfaces and by string world sheets. Hence also Kähler coupling strength follows as a prediction so that the theory involves therefore no free coupling parameters. Kähler function

is defined only apart from an additive term which is sum of holomorphic and anti-holomorphic functions of the configuration space and this would naturally correspond to the effect of the modular automorphism. I have proposed that the choices of a particular light-like 3-surface in the slicing of  $X^4$  by light-like 3-surfaces at which vacuum functional is defined as Dirac determinant can differ by this kind of term having therefore interpretation also as a modular automorphism for a factor of type  $\text{II}_\infty$ .

3. Quantum criticality -implied by the condition that the modified Dirac action gives rise to conserved currents assignable to the deformations of the space-time surface - means the vanishing of the second variation of Kähler action for these deformations. Preferred extremals correspond to these 4-surfaces and  $M^8 - M^4 \times CP_2$  duality allows to identify them also as hyper-quaternionic space-time surfaces.
4. Second quantized spinor fields are the only quantum fields appearing at the space-time level. This justifies to the notion of bosonic emergence [56] , which means that gauge bosons and possible counterpart of Higgs particle are identified as bound states of fermion and antifermion at opposite light-like throats of wormhole contact. This suggests that the  $M$ -matrix should allow a formulation solely in terms of the modified Dirac action.

### HFFs and the definition of Dirac determinant

The definition of the Dirac determinant -call it  $\det(D)$ - discussed in [15] involves two assumptions. First, finite measurement resolution is assumed to correspond to a replacement of light-like 3-surfaces with braids whose strands carry fermion number. Secondly, the quantum holography justifies the assumption about dimensional reduction to a determinant assignable to 3-D Dirac operator.

1. The finiteness of the trace for HFF of type  $\text{II}_1$  indeed encourages the question whether one could define  $\det(D)$  as the exponent of the trace of the logarithm of 3-D Dirac operator  $D_3$  even without the assumption of finite measurement resolution. The trace would be induced from the trace of the tensor product of hyper-finite factor of type  $\text{II}_1$  and factor of type I.
2. One might wonder whether holography could allow to define  $\det(D)$  also in terms of the 4-D modified Dirac operator. The basic problem is of course that only the spinor fields satisfying  $D_4\Psi = 0$  are allowed and eigenvalue equation in standard sense breaks baryon and lepton number conservation. The critical deformation representing zero modes might however allow to circumvent this difficulty. The modified Dirac equation  $D\Psi = 0$  holding true for the 4-surfaces obtained as critical deformations can be written in the form  $D_0\Psi = D_0\delta\Psi = -\delta D\Psi$ , where the subscript  $_0$  refers to the non-deformed surface and one has  $\delta\Psi = O\Psi_0$  which involves propagator defined by  $D_4$ . Maybe one could define  $\det(D)$  as the determinant of the operator  $-\delta D$  by identifying it as the exponent of the trace of the operator  $\log(-\delta D)$ . This would require a division by the deformation parameter  $\delta t$  at both sides of the modified Dirac equation and means only the elimination of an infinite proportionality factor from the determinant.

### Bosonic emergence and QFT limit of TGD

The QFT limit of TGD gives further valuable hints about the formulation of quantum TGD proper. In QFT limit Dirac action coupled to gauge potentials (and possibly the TGD counterpart of Higgs) defines the theory and bosonic propagators and vertices involving bosons as external particles emerge as radiative corrections [56] . There are no free coupling constants in the theory.

1. The construction involves at the first step the coupling of spinor fields  $\Psi$  to fermionic sources  $\xi$  leading to an expression of the effective action as a functional of gauge potentials and  $\xi$  containing the counterpart of YM action in the purely bosonic sector plus interaction terms representing N-boson vertices. Bosonic dynamics is therefore generated purely radiatively in accordance with the emergence idea. At the next step the coupling to external YM currents leads to Feynman rules in the standard manner.
2. The inverse of the bosonic propagator and N-boson vertices correspond to fermionic loops and coupling constants are predicted completely in terms of them provided one can define the loop integrals uniquely.

3. Fermionic loops do not make sense without cutoff in both mass squared and hyperbolic angle defining the maximum Lorentz boost which can be applied to a virtual fermion in the rest system of the virtual gauge boson. Zero energy ontology realized in terms of a hierarchy of *CDs* provides a physical justification for the hierarchy of hyperbolic cutoffs. p-Adic length scale hypothesis (the sizes of *CDs* come in powers of 2) allows to decompose momentum space to shells corresponding to mass squared intervals  $[n, n + 1)$  using  $CP_2$  mass squared as a unit. The hyperbolic cutoff can depend on p-adic mass scale and can differ for time-like and space-like momenta: the relationship between these cutoffs is fixed from the condition that gauge bosons do not generate mass radiatively. One can find a simple ansatz for the hyperbolic cutoff consistent with the coupling constant evolution in standard model. The vanishing of all on-mass-shell  $N > 2$ -boson vertices defined by the fermionic loops states their irreducibility to lower vertices and serves as a candidate for the condition fixing the hyperbolic cutoff as a function of the p-adic mass scale.

### A proposal for *M*-matrix

This picture can be taken as a template as one tries to imagine how the construction of *M*-matrix could proceed in quantum TGD proper.

1. Modified Dirac action should replace the ordinary Dirac action and define the theory. The linear couplings of spinors to fermionic external currents are needed. Also bosons represented as bound states of fermion and antifermion to the analogs of gauge currents are needed to construct the *M*-matrix and would correspond to an addition of quantum part to induced spinor connection. One can consider also the addition of quantum parts to the induced metric and induced gamma matrices.
2. The couplings of the induced spinor fields to external sources would be given as contractions of the fermionic sources with conformal super-currents. Conformal currents would couple to bosonic external currents analogous to external YM currents and *M*-matrix would result via the usual procedure leading to generalized Feynman diagrams for which sub-*CDs* would contain vertices.

One cannot however argue that everything would be crystal clear.

1. There are two kinds of super-conformal algebras corresponding to quantum fluctuating degrees of freedom and zero modes. The super-conformal algebra associated with the zero modes follows from quantum criticality guaranteeing the conservation of these currents. These currents are defined in the interior of the space-time surface. By quantum holography the quantum fluctuating super-conformal algebra is assigned with light-like 3-surfaces. Both these algebras form a hierarchy of inclusions identifiable as counterparts for inclusions of HFFs. Which of the two super-conformal algebras one should use? Does quantum holography - interpreted as possibility of 1-1 entanglement between the two kinds of conformal currents for prepared states- mean that one can use either of them to construct *M*-matrix? How the dimensional reduction could be understood in terms of this duality?
2. The bosonic conserved currents in the interior of  $X^4$  implied by quantum criticality involve a purely local pairing of the induced spinor field and its conjugate. The problem is that gauge bosons as wormhole throats appearing in the dimensionally reduced description correspond to a non-local (in  $CP_2$  scale) pairing of spinor field and its conjugate at opposite wormhole throats. Should one accept as a fact that dimensionally reduced quantum fluctuating counterparts for the purely local zero mode currents are bi-local?
3. Only few days after posing these questions a plausible answer to them came through a resolution of several problems related to the formulation of quantum TGD (see the section "Handful of problems with a common resolution" of [20]). One important outcome of the formulation allowing to understand how stringy fermionic propagators emerge from the theory was that gravitational coupling vanishes for purely local composites of fermion and antifermion represented by Kac-Moody algebra and super-conformal algebra associated with critical deformations. Hence the only sensible identification of bosons seems to be as wormhole throats.

4. The construction of the bosonic propagators in terms of fermionic loops [56] as functionals integral over Grassmann variables generalizes. Fermionic loops correspond geometrically to wormhole contacts having fermion and anti-fermion at their opposite light-like throats. This implies a cutoff for momentum squared and hyperbolic angle of the virtual fermion in the rest system of boson crucial for the absence of loop divergences. Hence bosonic propagation is emergent as is also fermionic propagation which can be seen as induced by the measurement interaction for momentum. This justifies the cutoffs due to the finite measurement resolution.
5. It is essential that one first functionally integrates over the fermionic degrees of freedom and over the small deformations of light-like 3-surfaces and only after that constructs diagrams from tree diagrams with bosonic and fermionic lines by using generalized Cutkosky rules. Here the generalization of twistors to 8-D context allowing to regard massive particles as massless particles in 8-D framework is expected to be a crucial technical tool possibly allowing to achieve summations over large classes of generalized Feynman diagrams. Also the hierarchy of *CDs* is expected to be crucial in the construction.

The key idea is the addition of measurement interaction term to the modified Dirac action coupling to the conserved currents defined by quantum critical deformations for which the second variation of Kähler action vanishes. There remains a considerable freedom in choosing the precise form of the measurement interaction but there is a long list of arguments supporting the identification of the measurement interaction as the one defined by 3-D Chern-Simons term assignable with wormhole throats so that the dynamics in the interior of space-time sheet is not affected. This means that 3-D light-like wormhole throats carry induced spinor field which can be regarded as independent degrees of freedom having the spinor fields at partonic 2-surfaces as sources and acting as 3-D sources for the 4-D induced spinor field. The most general measurement interaction would involve the corresponding coupling also for Kähler action but is not physically motivated. Here are the arguments in favor of Chern-Simons Dirac action and corresponding measurement interaction.

1. A correlation between 4-D geometry of space-time sheet and quantum numbers is achieved by the identification of exponent of Kähler function as Dirac determinant making possible the entanglement of classical degrees of freedom in the interior of space-time sheet with quantum numbers.
2. Cartan algebra plays a key role not only at quantum level but also at the level of space-time geometry since quantum critical conserved currents vanish for Cartan algebra of isometries and the measurement interaction terms giving rise to conserved currents are possible only for Cartan algebras. Furthermore, modified Dirac equation makes sense only for eigen states of Cartan algebra generators. The hierarchy of Planck constants realized in terms of the book like structure of the generalized imbedding space assigns to each *CD* (causal diamond) preferred Cartan algebra: in case of Poincare algebra there are two of them corresponding to linear and cylindrical  $M^4$  coordinates.
3. Quantum holography and dimensional reduction hierarchy in which partonic 2-surface defined fermionic sources for 3-D fermionic fields at light-like 3-surfaces  $Y_l^3$  in turn defining fermionic sources for 4-D spinors find an elegant realization. Effective 2-dimensionality is achieved if the replacement of light-like wormhole throat  $X_l^3$  with light-like 3-surface  $Y_l^3$  "parallel" with it in the definition of Dirac determinant corresponds to the  $U(1)$  gauge transformation  $K \rightarrow K + f + \bar{f}$  for Kähler function of WCW so that WCW Kähler metric is not affected. Here  $f$  is holomorphic function of WCW ("world of classical worlds") complex coordinates and arbitrary function of zero mode coordinates.
4. An elegant description of the interaction between super-conformal representations realized at partonic 2-surfaces and dynamics of space-time surfaces is achieved since the values of Cartan charges are fed to the 3-D Dirac equation which also receives mass term at the same time. Almost topological QFT at wormhole throats results at the limit when four-momenta vanish: this is in accordance with the original vision about TGD as almost topological QFT.
5. A detailed view about the physical role of quantum criticality results. Quantum criticality fixes the values of Kähler coupling strength as the analog of critical temperature. Quantum

criticality implies that second variation of Kähler action vanishes for critical deformations and the existence of conserved current except in the case of Cartan algebra of isometries. Quantum criticality allows to fix the values of couplings appearing in the measurement interaction by using the condition  $K \rightarrow K + f + \bar{f}$ . p-Adic coupling constant evolution can be understood also and corresponds to scale hierarchy for the sizes of causal diamonds (CDs). To achieve internal consistency the quantum critical deformations for Kähler action must be also quantum critical for Chern-Simons action which implies that the deformations are orthogonal to Kähler magnetic field at each light-like 3-surface in the slicing of space-time sheet by light-like 3-surfaces.

6. CP breaking, irreversibility and the space-time description of dissipation are closely related. Also the interpretation of preferred extremals of Kähler action in regions where  $[D_{C-S}, D_{C-S,int}] = 0$  as asymptotic self organization patterns makes sense. Here  $D_{C-S}$  denotes the 3-D modified Dirac operator associated with Chern-Simons action and  $D_{C-S,int}$  to the corresponding measurement interaction term expressible as superposition of couplings to various observables to critical conserved currents.
7. A radically new view about matter antimatter asymmetry based on zero energy ontology emerges and one could understand the experimental absence of antimatter as being due to the fact antimatter corresponds to negative energy states. The identification of bosons as wormhole contacts is the only possible option in this framework.
8. Almost stringy propagators and a consistency with the identification of wormhole throats as lines of generalized Feynman diagrams is achieved. The notion of bosonic emergence leads to a long sought general master formula for the  $M$ -matrix elements. The counterpart for fermionic loop defining bosonic inverse propagator at QFT limit is wormhole contact with fermion and cutoffs in mass squared and hyperbolic angle for loop momenta of fermion and antifermion in the rest system of emitting boson have precise geometric counterpart.

On basis of above considerations it seems that the idea about "complex square root" of  $\omega$  might make sense in quantum TGD and that different measurement interactions correspond to various choices of  $\omega$ . Also the modular automorphism would make sense and because of its non-uniqueness  $\Delta$  could bring in the flexibility needed one wants thermodynamics. Stringy picture forces to ask whether  $\Delta$  could in some situation be proportional  $exp(L_0)$ , where  $L_0$  represents as the infinitesimal scaling generator of either super-symplectic algebra or super Kac-Moody algebra (the choice does not matter since the differences of the generators annihilate physical states in coset construction). This would allow to reproduce real thermodynamics consistent with p-adic thermodynamics.

In string models  $exp(iL_0\tau)$  is identified as the time evolution operator at single particle level whose integral over  $\tau$  defines the propagator. The quantization for the sizes of CDs does not however allow integration over  $t$  in this sense. Could the integration over projectors with traces differing by scalings parameterized by  $t$  correspond to this integral? Or should one give up this idea since modified Dirac operator defines a propagator in any case?

### 11.7.6 Finite measurement resolution and HFFs

The finite resolution of quantum measurement leads in TGD framework naturally to the notion of quantum  $M$ -matrix for which elements have values in sub-factor  $\mathcal{N}$  of HFF rather than being complex numbers.  $M$ -matrix in the factor space  $\mathcal{M}/\mathcal{N}$  is obtained by tracing over  $\mathcal{N}$ . The condition that  $\mathcal{N}$  acts like complex numbers in the tracing implies that  $M$ -matrix elements are proportional to maximal projectors to  $\mathcal{N}$  so that  $M$ -matrix is effectively a matrix in  $\mathcal{M}/\mathcal{N}$  and situation becomes finite-dimensional. It is still possible to satisfy generalized unitarity conditions but in general case tracing gives a weighted sum of unitary  $M$ -matrices defining what can be regarded as a square root of density matrix.

#### About the notion of observable in zero energy ontology

Some clarifications concerning the notion of observable in zero energy ontology are in order.

1. As in standard quantum theory observables correspond to hermitian operators acting on either positive or negative energy part of the state. One can indeed define hermitian conjugation for positive and negative energy parts of the states in standard manner.

2. Also the conjugation  $A \rightarrow JAJ$  is analogous to hermitian conjugation. It exchanges the positive and negative energy parts of the states also maps the light-like 3-surfaces at the upper boundary of  $CD$  to the lower boundary and vice versa. The map is induced by time reflection in the rest frame of  $CD$  with respect to the origin at the center of  $CD$  and has a well defined action on light-like 3-surfaces and space-time surfaces. This operation cannot correspond to the sought for hermitian conjugation since  $JAJ$  and  $A$  commute. The formulation of quantum TGD in terms of the modified Dirac action requires the addition of CP and T breaking fermionic counterpart of instanton term to the modified Dirac action. An interesting question is what this term means from the point of view of the conjugation.
3. Zero energy ontology gives Cartan sub-algebra of the Lie algebra of symmetries a special status. Only Cartan algebra acting on either positive or negative states respects the zero energy property but this is enough to define quantum numbers of the state. In absence of symmetry breaking positive and negative energy parts of the state combine to form a state in a singlet representation of group. Since only the net quantum numbers must vanish zero energy ontology allows a symmetry breaking respecting a chosen Cartan algebra.
4. In order to speak about four-momenta for positive and negative energy parts of the states one must be able to define how the translations act on  $CD$ s. The most natural action is a shift of the upper (lower) tip of  $CD$ . In the scale of entire  $CD$  this transformation induced Lorentz boost fixing the other tip. The value of mass squared is identified as proportional to the average of conformal weight in p-adic thermodynamics for the scaling generator  $L_0$  for either super-symplectic or Super Kac-Moody algebra.

### Inclusion of HFFS as characterizer of finite measurement resolution at the level of $S$ -matrix

The inclusion  $\mathcal{N} \subset \mathcal{M}$  of factors characterizes naturally finite measurement resolution. This means following things.

1. Complex rays of state space resulting usually in an ideal state function reduction are replaced by  $\mathcal{N}$ -rays since  $\mathcal{N}$  defines the measurement resolution and takes the role of complex numbers in ordinary quantum theory so that non-commutative quantum theory results. Non-commutativity corresponds to a finite measurement resolution rather than something exotic occurring in Planck length scales. The quantum Clifford algebra  $\mathcal{M}/\mathcal{N}$  creates physical states modulo resolution. The fact that  $\mathcal{N}$  takes the role of gauge algebra suggests that it might be necessary to fix a gauge by assigning to each element of  $\mathcal{M}/\mathcal{N}$  a unique element of  $\mathcal{M}$ . Quantum Clifford algebra with fractal dimension  $\beta = \mathcal{M} : \mathcal{N}$  creates physical states having interpretation as quantum spinors of fractal dimension  $d = \sqrt{\beta}$ . Hence direct connection with quantum groups emerges.
2. The notions of unitarity, hermiticity, and eigenvalue generalize. The elements of unitary and hermitian matrices and  $\mathcal{N}$ -valued. Eigenvalues are Hermitian elements of  $\mathcal{N}$  and thus correspond entire spectra of Hermitian operators. The mutual non-commutativity of eigenvalues guarantees that it is possible to speak about state function reduction for quantum spinors. In the simplest case of a 2-component quantum spinor this means that second component of quantum spinor vanishes in the sense that second component of spinor annihilates physical state and second acts as element of  $\mathcal{N}$  on it. The non-commutativity of spinor components implies correlations between them and thus fractal dimension is smaller than 2.
3. The intuition about ordinary tensor products suggests that one can decompose  $\text{Tr}$  in  $\mathcal{M}$  as

$$\text{Tr}_{\mathcal{M}}(X) = \text{Tr}_{\mathcal{M}/\mathcal{N}} \times \text{Tr}_{\mathcal{N}}(X) . \quad (11.7.4)$$

Suppose one has fixed gauge by selecting basis  $|r_k\rangle$  for  $\mathcal{M}/\mathcal{N}$ . In this case one expects that operator in  $\mathcal{M}$  defines an operator in  $\mathcal{M}/\mathcal{N}$  by a projection to the preferred elements of  $\mathcal{M}$ .

$$\langle r_1|X|r_2\rangle = \langle r_1|\text{Tr}_{\mathcal{N}}(X)|r_2\rangle . \quad (11.7.5)$$

4. Scattering probabilities in the resolution defined by  $\mathcal{N}$  are obtained in the following manner. The scattering probability between states  $|r_1\rangle$  and  $|r_2\rangle$  is obtained by summing over the final states obtained by the action of  $\mathcal{N}$  from  $|r_2\rangle$  and taking the analog of spin average over the states created in the similar from  $|r_1\rangle$ .  $\mathcal{N}$  average requires a division by  $Tr(P_{\mathcal{N}}) = 1/\mathcal{M} : \mathcal{N}$  defining fractal dimension of  $\mathcal{N}$ . This gives

$$p(r_1 \rightarrow r_2) = \mathcal{M} : \mathcal{N} \times \langle r_1 | Tr_{\mathcal{N}}(SP_{\mathcal{N}}S^\dagger) | r_2 \rangle . \quad (11.7.6)$$

This formula is consistent with probability conservation since one has

$$\sum_{r_2} p(r_1 \rightarrow r_2) = \mathcal{M} : \mathcal{N} \times Tr_{\mathcal{N}}(SS^\dagger) = \mathcal{M} : \mathcal{N} \times Tr(P_{\mathcal{N}}) = 1 . \quad (11.7.7)$$

5. Unitarity at the level of  $\mathcal{M}/\mathcal{N}$  can be achieved if the unit operator  $Id$  for  $\mathcal{M}$  can be decomposed into an analog of tensor product for the unit operators of  $\mathcal{M}/\mathcal{N}$  and  $\mathcal{N}$  and  $M$  decomposes to a tensor product of unitary  $M$ -matrices in  $\mathcal{M}/\mathcal{N}$  and  $\mathcal{N}$ . For HFFs of type II projection operators of  $\mathcal{N}$  with varying traces are present and one expects a weighted sum of unitary  $M$ -matrices to result from the tracing having interpretation in terms of square root of thermodynamics.
6. This argument assumes that  $\mathcal{N}$  is HFF of type II<sub>1</sub> with finite trace. For HFFs of type III<sub>1</sub> this assumption must be given up. This might be possible if one compensates the trace over  $\mathcal{N}$  by dividing with the trace of the infinite trace of the projection operator to  $\mathcal{N}$ . This probably requires a limiting procedure which indeed makes sense for HFFs.

### Quantum $M$ -matrix

The description of finite measurement resolution in terms of inclusion  $\mathcal{N} \subset \mathcal{M}$  seems to boil down to a simple rule. Replace ordinary quantum mechanics in complex number field  $C$  with that in  $\mathcal{N}$ . This means that the notions of unitarity, hermiticity, Hilbert space ray, etc.. are replaced with their  $\mathcal{N}$  counterparts.

The full  $M$ -matrix in  $\mathcal{M}$  should be reducible to a finite-dimensional quantum  $M$ -matrix in the state space generated by quantum Clifford algebra  $\mathcal{M}/\mathcal{N}$  which can be regarded as a finite-dimensional matrix algebra with non-commuting  $\mathcal{N}$ -valued matrix elements. This suggests that full  $M$ -matrix can be expressed as  $M$ -matrix with  $\mathcal{N}$ -valued elements satisfying  $\mathcal{N}$ -unitarity conditions.

Physical intuition also suggests that the transition probabilities defined by quantum  $S$ -matrix must be commuting hermitian  $\mathcal{N}$ -valued operators inside every row and column. The traces of these operators give  $\mathcal{N}$ -averaged transition probabilities. The eigenvalue spectrum of these Hermitian matrices gives more detailed information about details below experimental resolution.  $\mathcal{N}$ -hermicity and commutativity pose powerful additional restrictions on the  $M$ -matrix.

Quantum  $M$ -matrix defines  $\mathcal{N}$ -valued entanglement coefficients between quantum states with  $\mathcal{N}$ -valued coefficients. How this affects the situation? The non-commutativity of quantum spinors has a natural interpretation in terms of fuzzy state function reduction meaning that quantum spinor corresponds effectively to a statistical ensemble which cannot correspond to pure state. Does this mean that predictions for transition probabilities must be averaged over the ensemble defined by "quantum quantum states"?

### Quantum fluctuations and inclusions

Inclusions  $\mathcal{N} \subset \mathcal{M}$  of factors provide also a first principle description of quantum fluctuations since quantum fluctuations are by definition quantum dynamics below the measurement resolution. This gives hopes for articulating precisely what the important phrase "long range quantum fluctuations around quantum criticality" really means mathematically.

1. Phase transitions involve a change of symmetry. One might hope that the change of the symmetry group  $G_a \times G_b$  could universally code this aspect of phase transitions. This need not always mean a change of Planck constant but it means always a leakage between sectors of imbedding space. At quantum criticality 3-surfaces would have regions belonging to at least two sectors of  $H$ .
2. The long range of quantum fluctuations would naturally relate to a partial or total leakage of the 3-surface to a sector of imbedding space with larger Planck constant meaning zooming up of various quantal lengths.
3. For  $M$ -matrix in  $\mathcal{M}/\mathcal{N}$  regarded as  $calN$  module quantum criticality would mean a special kind of eigen state for the transition probability operator defined by the  $M$ -matrix. The properties of the number theoretic braids contributing to the  $M$ -matrix should characterize this state. The strands of the critical braids would correspond to fixed points for  $G_a \times G_b$  or its subgroup.

### **$M$ -matrix in finite measurement resolution**

The following arguments relying on the proposed identification of the space of zero energy states give a precise formulation for  $M$ -matrix in finite measurement resolution and the Connes tensor product involved. The original expectation that Connes tensor product could lead to a unique  $M$ -matrix is wrong. The replacement of  $\omega$  with its complex square root could lead to a unique hierarchy of  $M$ -matrices with finite measurement resolution and allow completely finite theory despite the fact that projectors have infinite trace for HFFs of type  $III_1$ .

1. In zero energy ontology the counterpart of Hermitian conjugation for operator is replaced with  $\mathcal{M} \rightarrow J\mathcal{M}J$  permuting the factors. Therefore  $N \in \mathcal{N}$  acting to positive (negative) energy part of state corresponds to  $N \rightarrow N' = JN$  acting on negative (positive) energy part of the state.
2. The allowed elements of  $N$  must be such that zero energy state remains zero energy state. The superposition of zero energy states involved can however change. Hence one must have that the counterparts of complex numbers are of form  $N = JN_1J \vee N_2$ , where  $N_1$  and  $N_2$  have same quantum numbers. A superposition of terms of this kind with varying quantum numbers for positive energy part of the state is possible.
3. The condition that  $N_{1i}$  and  $N_{2i}$  act like complex numbers in  $\mathcal{N}$ -trace means that the effect of  $JN_{1i}J \vee N_{2i}$  and  $JN_{2i}J \vee N_{1i}$  to the trace are identical and correspond to a multiplication by a constant. If  $\mathcal{N}$  is HFF of type  $II_1$  this follows from the decomposition  $\mathcal{M} = \mathcal{M}/\mathcal{N} \otimes \mathcal{N}$  and from  $Tr(AB) = Tr(BA)$  assuming that  $M$  is of form  $M = M_{\mathcal{M}/\mathcal{N}} \times P_{\mathcal{N}}$ . Contrary to the original hopes that Connes tensor product could fix the  $M$ -matrix there are no conditions on  $M_{\mathcal{M}/\mathcal{N}}$  which would give rise to a finite-dimensional  $M$ -matrix for Jones inclusions. One can replace the projector  $P_{\mathcal{N}}$  with a more general state if one takes this into account in  $*$  operation.
4. In the case of HFFs of type  $III_1$  the trace is infinite so that the replacement of  $Tr_N$  with a state  $\omega_N$  in the sense of factors looks more natural. This means that the counterpart of  $*$  operation exchanging  $N_1$  and  $N_2$  represented as  $SA\Omega = A^*\Omega$  involves  $\Delta$  via  $S = J\Delta^{1/2}$ . The exchange of  $N_1$  and  $N_2$  gives altogether  $\Delta$ . In this case the KMS condition  $\omega_N(AB) = \omega_N(\Delta A)$  guarantees the effective complex number property [17].
5. Quantum TGD more or less requires the replacement of  $\omega$  with its "complex square root" so that also a unitary matrix  $U$  multiplying  $\Delta$  is expected to appear in the formula for  $S$  and guarantee the symmetry. One could speak of a square root of KMS condition [17] in this case. The QFT counterpart would be a cutoff involving path integral over the degrees of freedom below the measurement resolution. In TGD framework it would mean a cutoff in the functional integral over WCW and for the modes of the second quantized induced spinor fields and also cutoff in sizes of causal diamonds. Discretization in terms of braids replacing light-like 3-surfaces should be the counterpart for the cutoff.
6. If one has  $M$ -matrix in  $\mathcal{M}$  expressible as a sum of  $M$ -matrices of form  $M_{\mathcal{M}/\mathcal{N}} \times M_{\mathcal{N}}$  with coefficients which correspond to the square roots of probabilities defining density matrix the tracing operation gives rise to square root of density matrix in  $M$ .

### Is universal M-matrix possible?

The realization of the finite measurement resolution could apply only to transition probabilities in which  $\mathcal{N}$ -trace or its generalization in terms of state  $\omega_{\mathcal{N}}$  is needed. One might however dream of something more.

1. Maybe there exists a universal M-matrix in the sense that the same M-matrix gives the M-matrices in finite measurement resolution for all inclusions  $\mathcal{N} \subset \mathcal{M}$ . This would mean that one can write

$$M = M_{\mathcal{M}/\mathcal{N}} \otimes M_{\mathcal{N}} \quad (11.7.8)$$

for any physically reasonable choice of  $\mathcal{N}$ . This would formally express the idea that  $M$  is as near as possible to M-matrix of free theory. Also fractality suggests itself in the sense that  $M_{\mathcal{N}}$  is essentially the same as  $M_{\mathcal{M}}$  in the same sense as  $\mathcal{N}$  is same as  $\mathcal{M}$ . It might be that the trivial solution  $M = 1$  is the only possible solution to the condition.

2.  $M_{\mathcal{M}/\mathcal{N}}$  would be obtained by the analog of  $Tr_{\mathcal{N}}$  or  $\omega_{\mathcal{N}}$  operation involving the "complex square root" of the state  $\omega$  in case of HFFs of type III<sub>1</sub>. The QFT counterpart would be path integration over the degrees of freedom below cutoff to get effective action.
3. Universality probably requires assumptions about the thermodynamical part of the universal M-matrix. A possible alternative form of the condition is that it holds true only for canonical choice of "complex square root" of  $\omega$  or for the S-matrix part of  $M$ :

$$S = S_{\mathcal{M}/\mathcal{N}} \otimes S_{\mathcal{N}} \quad (11.7.9)$$

for any physically reasonable choice  $\mathcal{N}$ .

4. In TGD framework the condition would say that the M-matrix defined by the modified Dirac action gives M-matrices in finite measurement resolution via the counterpart of integration over the degrees of freedom below the measurement resolution.

An objection against the universality is that if the M-matrix is "complex square root of state" cannot be unique and there are infinitely many choices related by a unitary transformation induced by the flows representing modular automorphism giving rise to new choices. This would actually be a well-come result and make possible quantum measurement theory. In the section "Handful of problems with a common resolution" of [19] it was found that one must add to the modified Dirac action a measurement interaction term characterizing the measured observables. This implies stringy propagation as well as space-time correlates for quantum numbers characterizing the partonic states. These different modified Dirac actions would give rise to different Kähler functions. The corresponding Kähler metrics would not however differ if the real parts of the Kähler functions associated with the two choices differ by a term  $f(Z) + \bar{f}(\bar{Z})$ , where  $Z$  denotes complex coordinates of WCW, the Kähler metric remains the same. The function  $f$  can depend also on zero modes. If this is the case then one can allow in given CD superpositions of WCW spinor fields for which the measurement interactions are different.

### Connes tensor product and space-like entanglement

Ordinary linear Connes tensor product makes sense also in positive/negative energy sector and also now it makes sense to speak about measurement resolution. Hence one can ask whether Connes tensor product should be posed as a constraint on space-like entanglement. The interpretation could be in terms of the formation of bound states. The reducibility of HFFs and inclusions means that the tensor product is not uniquely fixed and ordinary entanglement could correspond to this kind of entanglement.

Also the counterpart of p-adic coupling constant evolution would makes sense. The interpretation of Connes tensor product would be as the variance of the states with respect to some subgroup of  $U(n)$  associated with the measurement resolution: the analog of color confinement would be in question.

## 2-vector spaces and entanglement modulo measurement resolution

John Baez and collaborators [45] are playing with very formal looking formal structures obtained by replacing vectors with vector spaces. Direct sum and tensor product serve as the basic arithmetic operations for the vector spaces and one can define category of  $n$ -tuples of vector spaces with morphisms defined by linear maps between vectors spaces of the tuple.  $n$ -tuples allow also element-wise product and sum. They obtain results which make them happy. For instance, the category of linear representations of a given group forms 2-vector spaces since direct sums and tensor products of representations as well as  $n$ -tuples make sense. The 2-vector space however looks more or less trivial from the point of physics.

The situation could become more interesting in quantum measurement theory with finite measurement resolution described in terms of inclusions of hyper-finite factors of type  $\text{II}_1$ . The reason is that Connes tensor product replaces ordinary tensor product and brings in interactions via irreducible entanglement as a representation of finite measurement resolution. The category in question could give Connes tensor products of quantum state spaces and describing interactions. For instance, one could multiply  $M$ -matrices via Connes tensor product to obtain category of  $M$ -matrices having also the structure of 2-operator algebra.

1. The included algebra represents measurement resolution and this means that the infinite-D sub-Hilbert spaces obtained by the action of this algebra replace the rays. Sub-factor takes the role of complex numbers in generalized QM so that one obtains non-commutative quantum mechanics. For instance, quantum entanglement for two systems of this kind would not be between rays but between infinite-D subspaces corresponding to sub-factors. One could build a generalization of QM by replacing rays with sub-spaces and it would seem that quantum group concept does more or less this: the states in representations of quantum groups could be seen as infinite-dimensional Hilbert spaces.
2. One could speak about both operator algebras and corresponding state spaces modulo finite measurement resolution as quantum operator algebras and quantum state spaces with fractal dimension defined as factor space like entities obtained from HFF by dividing with the action of included HFF. Possible values of the fractal dimension are fixed completely for Jones inclusions. Maybe these quantum state spaces could define the notions of quantum 2-Hilbert space and 2-operator algebra via direct sum and tensor production operations. Fractal dimensions would make the situation interesting both mathematically and physically.

Suppose one takes the fractal factor spaces as the basic structures and keeps the information about inclusion.

1. Direct sums for quantum vectors spaces would be just ordinary direct sums with HFF containing included algebras replaced with direct sum of included HFFs.
2. The tensor products for quantum state spaces and quantum operator algebras are not anymore trivial. The condition that measurement algebras act effectively like complex numbers would require Connes tensor product involving irreducible entanglement between elements belonging to the two HFFs. This would have direct physical relevance since this entanglement cannot be reduced in state function reduction. The category would defined interactions in terms of Connes tensor product and finite measurement resolution.
3. The sequences of super-conformal symmetry breakings identifiable in terms of inclusions of super-conformal algebras and corresponding HFFs could have a natural description using the 2-Hilbert spaces and quantum 2-operator algebras.

### 11.7.7 Questions about quantum measurement theory in zero energy ontology

In the following some questions about quantum measurement theory are posed. First however a result about the relationship between  $U$ -matrix and  $M$ -matrix not known when the questions were made will be represented. The background allowing a deeper understanding of this result can be found from [44] discussing Negentropy Maximization Principle, which is the basic dynamical principle of

TGD inspired theory of consciousness and states that the information content of conscious experience is maximal.

### The relationship between $U$ -matrix and $M$ -matrix

Before proceeding it is a good idea to clarify the relationship between the notions of  $U$ -matrix and  $M$ -matrix. If state function reduction associated with time-like entanglement leads always to a product of positive and negative energy states (so that there is no counterpart of bound state entanglement and negentropic entanglement possible for zero energy states: these notions are discussed below)  $U$ -matrix and can be regarded as a collection of  $M$ -matrices

$$U_{m_+n_-,r_+,s_-} = M(m_+,n_-)_{r_+,s_-} \quad (11.7.10)$$

labeled by the pairs  $(m_+,n_-)$  labelling zero energy states assumed to reduced to pairs of positive and negative energy states.  $M$ -matrix element is the counterpart of S-matrix element  $S_{r,s}$  in positive energy ontology. Unitarity conditions for  $U$ -matrix read as

$$\begin{aligned} (UU^\dagger)_{m_+n_-,r_+,s_-} &= \sum_{k_+,l_-} M(m_+,n_-)_{k_+,l_-} \overline{M}(r_+,s_-)_{k_+,l_-} = \delta_{m_+r_+,n_-s_-} \ , \\ (U^\dagger U)_{m_+n_-,r_+,s_-} &= \sum_{k_+,l_-} \overline{M}(k_+,l_-)_{m_+,n_-} M(k_+,l_-)_{r_+,s_-} = \delta_{m_+r_+,n_-s_-} \ . \end{aligned} \quad (11.7.11)$$

The conditions state that the zero energy states associated with different labels are orthogonal as zero energy states and also that the zero energy states defined by the dual  $M$ -matrix

$$M^\dagger(m_+,n_-)_{k_+,l_-} \equiv \overline{M}(k_+,l_-)_{m_+,n_-} \quad (11.7.12)$$

-perhaps identifiable as phase conjugate states- define an orthonormal basis of zero energy states.

When time-like binding and negentropic entanglement are allowed also zero energy states with a label not implying a decomposition to a product state are involved with the unitarity condition but this does not affect the situation dramatically. As a matter fact, the situation is mathematically the same as for ordinary S-matrix in the presence of bound states. Here time-like bound states are analogous to space-like bound states and by definition are unable to decay to product states (free states). Negentropic entanglement makes sense only for entanglement probabilities, which are rationals or belong to their algebraic extensions. This is possible in what might be called the intersection of real and p-adic worlds (partonic surfaces in question have representation making sense for both real and p-adic numbers). Number theoretic entropy is obtained by replacing in the Shannon entropy the logarithms of probabilities with the logarithms of their p-adic norms. They satisfy the same defining conditions as ordinary Shannon entropy but can be also negative. One can always find prime  $p$  for which the entropy is maximally negative. The interpretation of negentropic entanglement is in terms of formations of rule or association. Schrödinger cat knows that it is better to not open the bottle: open bottle-dead cat, closed bottle-living cat and negentropic entanglement measures this information.

### Fractal hierarchy of state function reductions

In accordance with fractality, the conditions for the Connes tensor product at a given time scale imply the conditions at shorter time scales. On the other hand, in shorter time scales the inclusion would be deeper and would give rise to a larger reducibility of the representation of  $\mathcal{N}$  in  $\mathcal{M}$ . Formally, as  $\mathcal{N}$  approaches to a trivial algebra, one would have a square root of density matrix and trivial  $S$ -matrix in accordance with the idea about asymptotic freedom.

$M$ -matrix would give rise to a matrix of probabilities via the expression  $P(P_+ \rightarrow P_-) = Tr[P_+ M^\dagger P_- M]$ , where  $P_+$  and  $P_-$  are projectors to positive and negative energy energy  $\mathcal{N}$ -rays. The projectors give rise to the averaging over the initial and final states inside  $\mathcal{N}$  ray. The reduction could continue step by step to shorter length scales so that one would obtain a sequence of inclusions. If the  $U$ -process of

the next quantum jump can return the  $M$ -matrix associated with  $\mathcal{M}$  or some larger HFF, U process would be kind of reversal for state function reduction.

Analytic thinking proceeding from vision to details; human life cycle proceeding from dreams and wild actions to the age when most decisions relate to the routine daily activities; the progress of science from macroscopic to microscopic scales; even biological decay processes: all these have an intriguing resemblance to the fractal state function reduction process proceeding to shorter and shorter time scales. Since this means increasing thermality of  $M$ -matrix, U process as a reversal of state function reduction might break the second law of thermodynamics.

The conservative option would be that only the transformation of intentions to action by U process giving rise to new zero energy states can bring in something new and is responsible for evolution. The non-conservative option is that the biological death is the  $U$ -process of the next quantum jump leading to a new life cycle. Breathing would become a universal metaphor for what happens in quantum Universe. The 4-D body would be lived again and again.

### How quantum classical correspondence is realized at parton level?

Quantum classical correspondence must assign to a given quantum state the most probable space-time sheet depending on its quantum numbers. The space-time sheet  $X^4(X^3)$  defined by the Kähler function depends however only on the partonic 3-surface  $X^3$ , and one must be able to assign to a given quantum state the most probable  $X^3$  - call it  $X^3_{max}$  - depending on its quantum numbers.

$X^4(X^3_{max})$  should carry the gauge fields created by classical gauge charges associated with the Cartan algebra of the gauge group (color isospin and hypercharge and electromagnetic and  $Z^0$  charge) as well as classical gravitational fields created by the partons. This picture is very similar to that of quantum field theories relying on path integral except that the path integral is restricted to 3-surfaces  $X^3$  with exponent of Kähler function bringing in genuine convergence and that 4-D dynamics is deterministic apart from the delicacies due to the 4-D spin glass type vacuum degeneracy of Kähler action.

Stationary phase approximation selects  $X^3_{max}$  if the quantum state contains a phase factor depending not only on  $X^3$  but also on the quantum numbers of the state. A good guess is that the needed phase factor corresponds to either Chern-Simons type action or an action describing the interaction of the induced gauge field with the charges associated with the braid strand. This action would be defined for the induced gauge fields. YM action seems to be excluded since it is singular for light-like 3-surfaces associated with the light-like wormhole throats (not only  $\sqrt{\det(g_3)}$  but also  $\sqrt{\det(g_4)}$  vanishes).

The challenge is to show that this is enough to guarantee that  $X^4(X^3_{max})$  carries correct gauge charges. Kind of electric-magnetic duality should relate the normal components  $F_{ni}$  of the gauge fields in  $X^4(X^3_{max})$  to the gauge fields  $F_{ij}$  induced at  $X^3$ . An alternative interpretation is in terms of quantum gravitational holography. The difference between Chern-Simons action characterizing quantum state and the fundamental Chern-Simons type factor associated with the Kähler form would be that the latter emerges as the phase of the Dirac determinant.

One is forced to introduce gauge couplings and also electro-weak symmetry breaking via the phase factor. This is in apparent conflict with the idea that all couplings are predictable. The essential uniqueness of  $M$ -matrix in the case of HFFs of type  $II_1$  (at least) however means that their values as a function of measurement resolution time scale are fixed by internal consistency. Also quantum criticality leads to the same conclusion. Obviously a kind of bootstrap approach suggests itself.

### 11.7.8 How p-adic coupling constant evolution and p-adic length scale hypothesis emerge from quantum TGD proper?

What p-adic coupling constant evolution really means has remained for a long time more or less open. The progress made in the understanding of the S-matrix of theory has however changed the situation dramatically.

#### M-matrix and coupling constant evolution

The final breakthrough in the understanding of p-adic coupling constant evolution came through the understanding of S-matrix, or actually M-matrix defining entanglement coefficients between positive

and negative energy parts of zero energy states in zero energy ontology [19]. M-matrix has interpretation as a "complex square root" of density matrix and thus provides a unification of thermodynamics and quantum theory. S-matrix is analogous to the phase of Schrödinger amplitude multiplying positive and real square root of density matrix analogous to modulus of Schrödinger amplitude.

The notion of finite measurement resolution realized in terms of inclusions of von Neumann algebras allows to demonstrate that the irreducible components of M-matrix are unique and possesses huge symmetries in the sense that the hermitian elements of included factor  $\mathcal{N} \subset \mathcal{M}$  defining the measurement resolution act as symmetries of M-matrix, which suggests a connection with integrable quantum field theories.

It is also possible to understand coupling constant evolution as a discretized evolution associated with time scales  $T_n$ , which come as octaves of a fundamental time scale:  $T_n = 2^n T_0$ . Number theoretic universality requires that renormalized coupling constants are rational or at most algebraic numbers and this is achieved by this discretization since the logarithms of discretized mass scale appearing in the expressions of renormalized coupling constants reduce to the form  $\log(2^n) = n \log(2)$  and with a proper choice of the coefficient of logarithm  $\log(2)$  dependence disappears so that rational number results. Recall that also the weaker condition  $T_p = p T_0$ ,  $p$  prime, would assign secondary p-adic time scales to the size scale hierarchy of CDs:  $p \simeq 2^n$  would result as an outcome of some kind of "natural selection" for this option. The highly satisfactory feature would be that p-adic time scales would reflect directly the geometry of imbedding space and configuration space.

### p-Adic coupling constant evolution

An attractive conjecture is that the coupling constant evolution associated with CDs in powers of 2 implying time scale hierarchy  $T_n = 2^n T_0$  induces p-adic coupling constant evolution and explain why p-adic length scales correspond to  $L_p \propto \sqrt{p} R$ ,  $p \simeq 2^k$ ,  $R$   $CP_2$  length scale? This looks attractive but there seems to be a problem. p-Adic length scales come as powers of  $\sqrt{2}$  rather than 2 and the strongly favored values of  $k$  are primes and thus odd so that  $n = k/2$  would be half odd integer. This problem can be solved.

1. The observation that the distance traveled by a Brownian particle during time  $t$  satisfies  $r^2 = Dt$  suggests a solution to the problem. p-Adic thermodynamics applies because the partonic 3-surfaces  $X^2$  are as 2-D dynamical systems random apart from light-likeness of their orbit. For  $CP_2$  type vacuum extremals the situation reduces to that for a one-dimensional random light-like curve in  $M^4$ . The orbits of Brownian particle would now correspond to light-like geodesics  $\gamma_3$  at  $X^3$ . The projection of  $\gamma_3$  to a time=constant section  $X^2 \subset X^3$  would define the 2-D path  $\gamma_2$  of the Brownian particle. The  $M^4$  distance  $r$  between the end points of  $\gamma_2$  would be given  $r^2 = Dt$ . The favored values of  $t$  would correspond to  $T_n = 2^n T_0$  (the full light-like geodesic). p-Adic length scales would result as  $L^2(k) = DT(k) = D2^k T_0$  for  $D = R^2/T_0$ . Since only  $CP_2$  scale is available as a fundamental scale, one would have  $T_0 = R$  and  $D = R$  and  $L^2(k) = T(k)R$ .
2. p-Adic primes near powers of 2 would be in preferred position. p-Adic time scale would not relate to the p-adic length scale via  $T_p = L_p/c$  as assumed implicitly earlier but via  $T_p = L_p^2/R_0 = \sqrt{p} L_p$ , which corresponds to secondary p-adic length scale. For instance, in the case of electron with  $p = M_{127}$  one would have  $T_{127} = .1$  second which defines a fundamental biological rhythm. Neutrinos with mass around .1 eV would correspond to  $L(169) \simeq 5 \mu\text{m}$  (size of a small cell) and  $T(169) \simeq 1. \times 10^4$  years. A deep connection between elementary particle physics and biology becomes highly suggestive.
3. In the proposed picture the p-adic prime  $p \simeq 2^k$  would characterize the thermodynamics of the random motion of light-like geodesics of  $X^3$  so that p-adic prime  $p$  would indeed be an inherent property of  $X^3$ . For the weaker condition would be  $T_p = p T_0$ ,  $p$  prime,  $p \simeq 2^n$  could be seen as an outcome of some kind of "natural selection". In this case,  $p$  would a property of CD and all light-like 3-surfaces inside it and also that corresponding sector of configuration space.
4. The fundamental role of 2-adicity suggests that the fundamental coupling constant evolution and p-adic mass calculations could be formulated also in terms of 2-adic thermodynamics. With a suitable definition of the canonical identification used to map 2-adic mass squared values to real numbers this is possible, and the differences between 2-adic and p-adic thermodynamics

are extremely small for large values of for  $p \simeq 2^k$ . 2-adic temperature must be chosen to be  $T_2 = 1/k$  whereas p-adic temperature is  $T_p = 1$  for fermions. If the canonical identification is defined as

$$\sum_{n \geq 0} b_n 2^n \rightarrow \sum_{m \geq 1} 2^{-m+1} \sum_{(k-1)m \leq n < km} b_n 2^n ,$$

it maps all 2-adic integers  $n < 2^k$  to themselves and the predictions are essentially same as for p-adic thermodynamics. For large values of  $p \simeq 2^k$  2-adic real thermodynamics with  $T_R = 1/k$  gives essentially the same results as the 2-adic one in the lowest order so that the interpretation in terms of effective 2-adic/p-adic topology is possible.

### 11.7.9 Planar algebras and generalized Feynman diagrams

Planar algebras [27] are a very general notion due to Vaughan Jones and a special class of them is known to characterize inclusion sequences of hyper-finite factors of type  $II_1$  [50]. In the following an argument is developed that planar algebras might have interpretation in terms of planar projections of generalized Feynman diagrams (these structures are metrically 2-D by presence of one light-like direction so that 2-D representation is especially natural). In [13] the role of planar algebras and their generalizations is also discussed.

#### Planar algebra very briefly

First a brief definition of planar algebra.

1. One starts from planar  $k$ -tangles obtained by putting disks inside a big disk. Inner disks are empty. Big disk contains  $2k$  braid strands starting from its boundary and returning back or ending to the boundaries of small empty disks in the interior containing also even number of incoming lines. It is possible to have also loops. Disk boundaries and braid strands connecting them are different objects. A black-white coloring of the disjoint regions of  $k$ -tangle is assumed and there are two possible options (photo and its negative). Equivalence of planar tangles under diffeomorphisms is assumed.
2. One can define a product of  $k$ -tangles by identifying  $k$ -tangle along its outer boundary with some inner disk of another  $k$ -tangle. Obviously the product is not unique when the number of inner disks is larger than one. In the product one deletes the inner disk boundary but if one interprets this disk as a vertex-parton, it would be better to keep the boundary.
3. One assigns to the planar  $k$ -tangle a vector space  $V_k$  and a linear map from the tensor product of spaces  $V_{k_i}$  associated with the inner disks such that this map is consistent with the decomposition  $k$ -tangles. Under certain additional conditions the resulting algebra gives rise to an algebra characterizing multi-step inclusion of HFFs of type  $II_1$ .
4. It is possible to bring in additional structure and in TGD framework it seems necessary to assign to each line of tangle an arrow telling whether it corresponds to a strand of a braid associated with positive or negative energy parton. One can also wonder whether disks could be replaced with closed 2-D surfaces characterized by genus if braids are defined on partonic surfaces of genus  $g$ . In this case there is no topological distinction between big disk and small disks. One can also ask why not allow the strands to get linked (as suggested by the interpretation as planar projections of generalized Feynman diagrams) in which case one would not have a planar tangle anymore.

#### General arguments favoring the assignment of a planar algebra to a generalized Feynman diagram

There are some general arguments in favor of the assignment of planar algebra to generalized Feynman diagrams.

1. Planar diagrams describe sequences of inclusions of HFF:s and assign to them a multi-parameter algebra corresponding indices of inclusions. They describe also Connes tensor powers in the simplest situation corresponding to Jones inclusion sequence. Suppose that also general Connes tensor product has a description in terms of planar diagrams. This might be trivial.
2. Generalized vertices identified geometrically as partonic 2-surfaces indeed contain Connes tensor products. The smallest sub-factor  $N$  would play the role of complex numbers meaning that due to a finite measurement resolution one can speak only about  $N$ -rays of state space and the situation becomes effectively finite-dimensional but non-commutative.
3. The product of planar diagrams could be seen as a projection of 3-D Feynman diagram to plane or to one of the partonic vertices. It would contain a set of 2-D partonic 2-surfaces. Some of them would correspond vertices and the rest to partonic 2-surfaces at future and past directed light-cones corresponding to the incoming and outgoing particles.
4. The question is how to distinguish between vertex-partons and incoming and outgoing partons. If one does not delete the disk boundary of inner disk in the product, the fact that lines arrive at it from both sides could distinguish it as a vertex-parton whereas outgoing partons would correspond to empty disks. The direction of the arrows associated with the lines of planar diagram would allow to distinguish between positive and negative energy partons (note however line returning back).
5. One could worry about preferred role of the big disk identifiable as incoming or outgoing parton but this role is only apparent since by compactifying to say  $S^2$  the big disk exterior becomes an interior of a small disk.

#### A more detailed view

The basic fact about planar algebras is that in the product of planar diagrams one glues two disks with identical boundary data together. One should understand the counterpart of this in more detail.

1. The boundaries of disks would correspond to 1-D closed space-like stringy curves at partonic 2-surfaces along which fermionic anti-commutators vanish.
2. The lines connecting the boundaries of disks to each other would correspond to the strands of number theoretic braids and thus to braided time evolutions. The intersection points of lines with disk boundaries would correspond to the intersection points of strands of number theoretic braids meeting at the generalized vertex.  
[Number theoretic braid belongs to an algebraic intersection of a real parton 3-surface and its  $p$ -adic counterpart obeying same algebraic equations: of course, in time direction algebraicity allows only a sequence of snapshots about braid evolution].
3. Planar diagrams contain lines, which begin and return to the same disk boundary. Also "vacuum bubbles" are possible. Braid strands would disappear or appear in pairwise manner since they correspond to zeros of a polynomial and can transform from complex to real and vice versa under rather stringent algebraic conditions.
4. Planar diagrams contain also lines connecting any pair of disk boundaries. Stringy decay of partonic 2-surfaces with some strands of braid taken by the first and some strands by the second parton might bring in the lines connecting boundaries of any given pair of disks (if really possible!).
5. There is also something to worry about. The number of lines associated with disks is even in the case of  $k$ -tangles. In TGD framework incoming and outgoing tangles could have odd number of strands whereas partonic vertices would contain even number of  $k$ -tangles from fermion number conservation. One can wonder whether the replacement of boson lines with fermion lines could imply naturally the notion of half- $k$ -tangle or whether one could assign half- $k$ -tangles to the spinors of the configuration space ("world of classical worlds") whereas corresponding Clifford algebra defining HFF of type  $II_1$  would correspond to  $k$ -tangles.

### 11.7.10 Miscellaneous

The following considerations are somewhat out-of-date: hence the title 'Miscellaneous'.

#### Connes tensor product and fusion rules

One should demonstrate that Connes tensor product indeed produces an  $M$ -matrix with physically acceptable properties.

The reduction of the construction of vertices to that for  $n$ -point functions of a conformal field theory suggest that Connes tensor product is essentially equivalent with the fusion rules for conformal fields defined by the Clifford algebra elements of  $CH(CD)$  (4-surfaces associated with 3-surfaces at the boundary of causal diamond  $CD$  in  $M^4$ ), extended to local fields in  $M^4$  with gamma matrices acting on configuration space spinors assignable to the partonic boundary components.

Jones speculates that the fusion rules of conformal field theories can be understood in terms of Connes tensor product [90] and refers to the work of Wassermann about the fusion of loop group representations as a demonstration of the possibility to formula the fusion rules in terms of Connes tensor product [126].

Fusion rules are indeed something more intricate than the naive product of free fields expanded using oscillator operators. By its very definition Connes tensor product means a dramatic reduction of degrees of freedom and this indeed happens also in conformal field theories.

1. For non-vanishing  $n$ -point functions the tensor product of representations of Kac Moody group associated with the conformal fields must give singlet representation.
2. The ordinary tensor product of Kac Moody representations characterized by given value of central extension parameter  $k$  is not possible since  $k$  would be additive.
3. A much stronger restriction comes from the fact that the allowed representations must define integrable representations of Kac-Moody group [59]. For instance, in case of  $SU(2)_k$  Kac Moody algebra only spins  $j \leq k/2$  are allowed. In this case the quantum phase corresponds to  $n = k + 2$ .  $SU(2)$  is indeed very natural in TGD framework since it corresponds to both electro-weak  $SU(2)_L$  and isotropy group of particle at rest.

Fusion rules for localized Clifford algebra elements representing operators creating physical states would replace naive tensor product with something more intricate. The naivest approach would start from  $M^4$  local variants of gamma matrices since gamma matrices generate the Clifford algebra  $Cl$  associated with  $CH(CD)$ . This is certainly too naive an approach. The next step would be the localization of more general products of Clifford algebra elements elements of Kac Moody algebras creating physical states and defining free on mass shell quantum fields. In standard quantum field theory the next step would be the introduction of purely local interaction vertices leading to divergence difficulties. In the recent case one transfers the partonic states assignable to the light-cone boundaries  $\delta M_{\pm}^4(m_i) \times CP_2$  to the common partonic 2-surfaces  $X_V^2$  along  $X_{L,i}^3$  so that the products of field operators at the same space-time point do not appear and one avoids infinities.

The remaining problem would be the construction an explicit realization of Connes tensor product. The formal definition states that left and right  $\mathcal{N}$  actions in the Connes tensor product  $\mathcal{M} \otimes_{\mathcal{N}} \mathcal{M}$  are identical so that the elements  $nm_1 \otimes m_2$  and  $m_1 \otimes m_2n$  are identified. This implies a reduction of degrees of freedom so that free tensor product is not in question. One might hope that at least in the simplest choices for  $\mathcal{N}$  characterizing the limitations of quantum measurement this reduction is equivalent with the reduction of degrees of freedom caused by the integrability constraints for Kac-Moody representations and dropping away of higher spins from the ordinary tensor product for the representations of quantum groups. If fusion rules are equivalent with Connes tensor product, each type of quantum measurement would be characterized by its own conformal field theory.

In practice it seems safest to utilize as much as possible the physical intuition provided by quantum field theories. In [19] a rather precise vision about generalized Feynman diagrams is developed and the challenge is to relate this vision to Connes tensor product.

#### Connection with topological quantum field theories defined by Chern-Simons action

There is also connection with topological quantum field theories (TQFTs) defined by Chern-Simons action [128].

1. The light-like 3-surfaces  $X_l^3$  defining propagators can contain unitary matrix characterizing the braiding of the lines connecting fermions at the ends of the propagator line. Therefore the modular  $S$ -matrix representing the braiding would become part of propagator line. Also incoming particle lines can contain similar  $S$ -matrices but they should not be visible in the  $M$ -matrix. Also entanglement between different partonic boundary components of a given incoming 3-surface by a modular  $S$ -matrix is possible.
2. Besides  $CP_2$  type extremals MEs with light-like momenta can appear as brehmstrahlung like exchanges always accompanied by exchanges of  $CP_2$  type extremals making possible momentum conservation. Also light-like boundaries of magnetic flux tubes having macroscopic size could carry light-like momenta and represent similar brehmstrahlung like exchanges. In this case the modular  $S$ -matrix could make possible topological quantum computations in  $q \neq 1$  phase [81]. Notice the somewhat counter intuitive implication that magnetic flux tubes of macroscopic size would represent change in quantum jump rather than quantum state. These quantum jumps can have an arbitrary long geometric duration in macroscopic quantum phases with large Planck constant [24].

There is also a connection with topological QFT defined by Chern-Simons action allowing to assign topological invariants to the 3-manifolds [128]. If the light-like CDs  $X_{L,i}^3$  are boundary components, the 3-surfaces associated with particles are glued together somewhat like they are glued in the process allowing to construct 3-manifold by gluing them together along boundaries. All 3-manifold topologies can be constructed by using only torus like boundary components.

This would suggest a connection with 2+1-dimensional topological quantum field theory defined by Chern-Simons action allowing to define invariants for knots, links, and braids and 3-manifolds using surgery along links in terms of Wilson lines. In these theories one consider gluing of two 3-manifolds, say three-spheres  $S^3$  along a link to obtain a topologically non-trivial 3-manifold. The replacement of link with Wilson lines in  $S^3 \# S^3 = S^3$  reduces the calculation of link invariants defined in this manner to Chern-Simons theory in  $S^3$ .

In the recent situation more general structures are possible since arbitrary number of 3-manifolds are glued together along link so that a singular 3-manifolds with a book like structure are possible. The allowance of CDs which are not boundaries, typically 3-D light-like throats of wormhole contacts at which induced metric transforms from Minkowskian to Euclidian, brings in additional richness of structure. If the scaling factor of  $CP_2$  metric can be arbitrary large as the quantization of Planck constant predicts, this kind of structure could be macroscopic and could be also linked and knotted. In fact, topological condensation could be seen as a process in which two 4-manifolds are glued together by drilling light-like CDs and connected by a piece of  $CP_2$  type extremal.

## 11.8 Jones inclusions and cognitive consciousness

Configuration space spinors have a natural interpretation in terms of a quantum version of Boolean algebra. Beliefs of various kinds are the basic element of cognition and obviously involve a representation of the external world or part of it as states of the system defining the believer. Jones inclusions mediating unitary mappings between the spaces of configuration spaces spinors of two systems are excellent candidates for these maps, and it is interesting to find what one kind of model for beliefs this picture leads to.

The resulting quantum model for beliefs provides a cognitive interpretation for quantum groups and predicts a universal spectrum for the probabilities that a given belief is true. This spectrum depends only on the integer  $n$  characterizing the quantum phase  $q = \exp(i2\pi/n)$  characterizing the Jones inclusion. For  $n \neq \infty$  the logic is inherently fuzzy so that absolute knowledge is impossible.  $q = 1$  gives ordinary quantum logic with qbits having precise truth values after state function reduction.

### 11.8.1 Does one have a hierarchy of $U$ - and $M$ -matrices?

$U$ -matrix describes scattering of zero energy states and since zero energy states can be illustrated in terms of Feynman diagrams one can say that scattering of Feynman diagrams is in question. The initial and final states of the scattering are superpositions of Feynman diagrams characterizing the corresponding  $M$ -matrices which contain also the positive square root of density matrix as a factor.

The hypothesis that  $U$ -matrix is the tensor product of  $S$ -matrix part of  $M$ -matrix and its Hermitian conjugate would make  $U$ -matrix an object deducible by physical measurements. One cannot of course exclude that something totally new emerges. For instance, the description of quantum jumps creating zero energy state from vacuum might require that  $U$ -matrix does not reduce in this manner. One can assign to the  $U$ -matrix a square like structure with  $S$ -matrix and its Hermitian conjugate assigned with the opposite sides of a square.

One can imagine of constructing higher level physical states as composites of zero energy states by replacing the  $S$ -matrix with  $M$ -matrix in the square like structure. These states would provide a physical representation of  $U$ -matrix. One could define  $U$ -matrix for these states in a similar manner. This kind of hierarchy could be continued indefinitely and the hierarchy of higher level  $U$  and  $M$ -matrices would be labeled by a hierarchy of  $n$ -cubes,  $n = 1, 2, \dots$ . TGD inspired theory of consciousness suggests that this hierarchy can be interpreted as a hierarchy of abstractions represented in terms of physical states. This hierarchy brings strongly in mind also the hierarchies of  $n$ -algebras and  $n$ -groups and this forces to consider the possibility that something genuinely new emerges at each step of the hierarchy. A connection with the hierarchies of infinite primes [70] and Jones inclusions are suggestive.

### 11.8.2 Feynman diagrams as higher level particles and their scattering as dynamics of self consciousness

The hierarchy of inclusions of hyper-finite factors of  $II_1$  as counterpart for many-sheeted space-time lead inevitably to the idea that this hierarchy corresponds to a hierarchy of generalized Feynman diagrams for which Feynman diagrams at a given level become particles at the next level. Accepting this idea, one is led to ask what kind of quantum states these Feynman diagrams correspond, how one could describe interactions of these higher level particles, what is the interpretation for these higher level states, and whether they can be detected.

#### Jones inclusions as analogs of space-time surfaces

The idea about space-time as a 4-surface replicates itself at the level of operator algebra and state space in the sense that Jones inclusion can be seen as a representation of the operator algebra  $\mathcal{N}$  as infinite-dimensional linear sub-space (surface) of the operator algebra  $\mathcal{M}$ . This encourages to think that generalized Feynman diagrams could correspond to image surfaces in  $II_1$  factor having identification as kind of quantum space-time surfaces.

Suppose that the modular  $S$ -matrices are representable as the inner automorphisms  $\Delta(\mathcal{M}_k^{it})$  assigned to the external lines of Feynman diagrams. This would mean that  $\mathcal{N} \subset \mathcal{M}_k$  moves inside  $calM_k$  along a geodesic line determined by the inner automorphism. At the vertex the factors  $calM_k$  to fuse along  $\mathcal{N}$  to form a Connes tensor product. Hence the copies of  $\mathcal{N}$  move inside  $\mathcal{M}_k$  like incoming 3-surfaces in  $H$  and fuse together at the vertex. Since all  $\mathcal{M}_k$  are isomorphic to a universal factor  $\mathcal{M}$ , many-sheeted space-time would have a kind of quantum image inside  $II_1$  factor consisting of pieces which are  $d = \mathcal{M} : \mathcal{N}/2$ -dimensional quantum spaces according to the identification of the quantum space as subspace of quantum group to be discussed later. In the case of partonic Clifford algebras the dimension would be indeed  $d \leq 2$ .

#### The hierarchy of Jones inclusions defines a hierarchy of $S$ -matrices

It is possible to assign to a given Jones inclusion  $\mathcal{N} \subset \mathcal{M}$  an entire hierarchy of Jones inclusions  $\mathcal{M}_0 \subset \mathcal{M}_1 \subset \mathcal{M}_2 \dots$ ,  $\mathcal{M}_0 = \mathcal{N}$ ,  $\mathcal{M}_1 = \mathcal{M}$ . A possible interpretation for these inclusions would be as a sequence of topological condensations.

This sequence also defines a hierarchy of Feynman diagrams inside Feynman diagrams. The factor  $\mathcal{M}$  containing the Feynman diagram having as its lines the unitary orbits of  $\mathcal{N}$  under  $\Delta_{\mathcal{M}}$  becomes a parton in  $\mathcal{M}_1$  and its unitary orbits under  $\Delta_{\mathcal{M}_1}$  define lines of Feynman diagrams in  $\mathcal{M}_1$ . The concrete representation for  $M$ -matrix or projection of it to some subspace as entanglement coefficients of partons at the ends of a braid assignable to the space-like 3-surface representing a vertex of a higher level Feynman diagram. In this manner quantum dynamics would be coded and simulated by quantum states.

The outcome can be said to be a hierarchy of Feynman diagrams within Feynman diagrams, a fractal structure for which many particle scattering events at a given level become particles at the next

level. The particles at the next level represent dynamics at the lower level: they have the property of "being about" representing perhaps the most crucial element of conscious experience. Since net conserved quantum numbers can vanish for a system in TGD Universe, this kind of hierarchy indeed allows a realization as zero energy states. Crossing symmetry can be understood in terms of this picture and has been applied to construct a model for  $M$ -matrix at high energy limit [19].

One might perhaps say that quantum space-time corresponds to a double inclusion and that further inclusions bring in  $N$ -parameter families of space-time surfaces.

### Higher level Feynman diagrams

The lines of Feynman diagram in  $\mathcal{M}_{n+1}$  are geodesic lines representing orbits of  $\mathcal{M}_n$  and this kind of lines meet at vertex and scatter. The evolution along lines is determined by  $\Delta_{\mathcal{M}_{n+1}}$ . These lines contain within themselves  $\mathcal{M}_n$  Feynman diagrams with similar structure and the hierarchy continues down to the lowest level at which ordinary elementary particles are encountered.

For instance, the generalized Feynman diagrams at the second level are ribbon diagrams obtained by thickening the ordinary diagrams in the new time direction. The interpretation as ribbon diagrams crucial for topological quantum computation and suggested to be realizable in terms of zero energy states in [81] is natural. At each level a new time parameter is introduced so that the dimension of the diagram can be arbitrarily high. The dynamics is not that of ordinary surfaces but the dynamics induced by the  $\Delta_{\mathcal{M}_n}$ .

### Quantum states defined by higher level Feynman diagrams

The intuitive picture is that higher level quantum states corresponds to the self reflective aspect of existence and must provide representations for the quantum dynamics of lower levels in their own structure. This dynamics is characterized by  $M$ -matrix whose elements have representation in terms of Feynman diagrams.

1. These states correspond to zero energy states in which initial states have "positive energies" and final states have "negative energies". The net conserved quantum numbers of initial and final state partons compensate each other. Gravitational energies, and more generally gravitational quantum numbers defined as absolute values of the net quantum numbers of initial and final states do not vanish. One can say that thoughts have gravitational mass but no inertial mass.
2. States in sub-spaces of positive and negative energy states are entangled with entanglement coefficients given by  $M$ -matrix at the level below.

To make this more concrete, consider first the simplest non-trivial case. In this case the particles can be characterized as ordinary Feynman diagrams, or more precisely as scattering events so that the state is characterized by  $\hat{S} = P_{in} S P_{out}$ , where  $S$  is  $S$ -matrix and  $P_{in}$  resp.  $P_{out}$  is the projection to a subspace of initial resp. final states. An entangled state with the projection of  $S$ -matrix giving the entanglement coefficients is in question.

The larger the domains of projectors  $P_{in}$  and  $P_{out}$ , the higher the representative capacity of the state. The norm of the non-normalized state  $\hat{S}$  is  $Tr(\hat{S}\hat{S}^\dagger) \leq 1$  for  $II_1$  factors, and at the limit  $\hat{S} = S$  the norm equals to 1. Hence, by  $II_1$  property, the state always entangles infinite number of states, and can in principle code the entire  $S$ -matrix to entanglement coefficients.

The states in which positive and negative energy states are entangled by a projection of  $S$ -matrix might define only a particular instance of states for which conserved quantum numbers vanish. The model for the interaction of Feynman diagrams discussed below applies also to these more general states.

### The interaction of $\mathcal{M}_n$ Feynman diagrams at the second level of hierarchy

What constraints can one pose to the higher level reactions? How Feynman diagrams interact? Consider first the scattering at the second level of hierarchy ( $\mathcal{M}_1$ ), the first level  $\mathcal{M}_0$  being assigned to the interactions of the ordinary matter.

1. Conservation laws pose constraints on the scattering at level  $\mathcal{M}_1$ . The Feynman diagrams can transform to new Feynman diagrams only in such a manner that the net quantum numbers are

conserved separately for the initial positive energy states and final negative energy states of the diagram. The simplest assumption is that positive energy matter and negative energy matter know nothing about each other and effectively live in separate worlds. The scattering matrix form Feynman diagram like states would thus be simply the tensor product  $S \otimes S^\dagger$ , where  $S$  is the  $S$ -matrix characterizing the lowest level interactions and identifiable as unitary factor of  $M$ -matrix for zero energy states. Reductionism would be realized in the sense that, apart from the new elements brought in by  $\Delta_{\mathcal{M}_n}$  defining single particle free dynamics, the lowest level would determine in principle everything occurring at the higher level providing representations about representations about... for what occurs at the basic level. The lowest level would represent the physical world and higher levels the theory about it.

2. The description of hadronic reactions in terms of partons serves as a guide line when one tries to understand higher level Feynman diagrams. The fusion of hadronic space-time sheets corresponds to the vertices  $\mathcal{M}_1$ . In the vertex the analog of parton plasma is formed by a process known as parton fragmentation. This means that the partonic Feynman diagrams belonging to disjoint copies of  $\mathcal{M}_0$  find themselves inside the same copy of  $\mathcal{M}_0$ . The standard description would apply to the scattering of the initial *resp.* final state partons.
3. After the scattering of partons hadronization takes place. The analog of hadronization in the recent case is the organization of the initial and final state partons to groups  $I_i$  and  $F_i$  such that the net conserved quantum numbers are same for  $I_i$  and  $F_i$ . These conditions can be satisfied if the interactions in the plasma phase occur only between particles belonging to the clusters labeled by the index  $i$ . Otherwise only single particle states in  $\mathcal{M}_1$  would be produced in the reactions in the generic case. The cluster decomposition of  $S$ -matrix to a direct sum of terms corresponding to partitions of the initial state particles to clusters which do not interact with each other obviously corresponds to the "hadronization". Therefore no new dynamics need to be introduced.
4. One cannot avoid the question whether the parton picture about hadrons indeed corresponds to a higher level physics of this kind. This would require that hadronic space-time sheets carry the net quantum numbers of hadrons. The net quantum numbers associated with the initial state partons would be naturally identical with the net quantum numbers of hadron. Partons and their negative energy conjugates would provide in this picture a representation of hadron about hadron. This kind of interpretation of partons would make understandable why they cannot be observed directly. A possible objection is that the net gravitational mass of hadron would be three times the gravitational mass deduced from the inertial mass of hadron if partons feed their gravitational fluxes to the space-time sheet carrying Earth's gravitational field.
5. This picture could also relate to the suggested duality between string and parton pictures [72]. In parton picture hadron is formed from partons represented by space-like 2-surfaces  $X_i^2$  connected by join along boundaries bonds. In string picture partonic 2-surfaces are replaced with string orbits. If one puts positive and negative energy particles at the ends of string diagram one indeed obtains a higher level representation of hadron. If these pictures are dual then also in parton picture positive and negative energies should compensate each other. Interestingly, light-like 3-D causal determinants identified as orbits of partons could be interpreted as orbits of light like string world sheets with "time" coordinate varying in space-like direction.

### Scattering of Feynman diagrams at the higher levels of hierarchy

This picture generalizes to the description of higher level Feynman diagrams.

1. Assume that higher level vertices have recursive structure allowing to reduce the Feynman diagrams to ordinary Feynman diagrams by a procedure consisting of finite steps.
2. The lines of diagrams are classified as incoming or outgoing lines according to whether the time orientation of the line is positive or negative. The time orientation is associated with the time parameter  $t_n$  characterizing the automorphism  $\Delta_{\mathcal{M}_n}^{it_n}$ . The incoming and outgoing net quantum numbers compensate each other. These quantum numbers are basically the quantum numbers of the state at the lowest level of the hierarchy.

3. In the vertices the  $\mathcal{M}_{n+1}$  particles fuse and  $\mathcal{M}_n$  particles form the analog of quark gluon plasma. The initial and final state particles of  $\mathcal{M}_n$  Feynman diagram scatter independently and the  $S$ -matrix  $S_{n+1}$  describing the process is tensor product  $S_n \otimes S_n^\dagger$ . By the clustering property of  $S$ -matrix, this scattering occurs only for groups formed by partons formed by the incoming and outgoing particles  $\mathcal{M}_n$  particles and each outgoing  $\mathcal{M}_{n+1}$  line contains and irreducible  $\mathcal{M}_n$  diagram. By continuing the recursion one finally ends down with ordinary Feynman diagrams.

### 11.8.3 Logic, beliefs, and spinor fields in the world of classical worlds

Beliefs can be characterized as Boolean value maps  $\beta_i(p)$  telling whether  $i$  believes in proposition  $p$  or not. Additional structure is brought in by introducing the map  $\lambda_i(p)$  telling whether  $p$  is true or not in the environment of  $i$ . The task is to find quantum counterpart for this model.

#### Configuration space spinors as logic statements

In TGD framework the infinite-dimensional configuration space (CH) spinor fields defined in CH, the "world of classical worlds", describe quantum states of the Universe [15]. CH spinor field can be regarded as a state in infinite-dimensional Fock space and are labeled by a collection of various two valued indices like spin and weak isospin. The interpretation is as a collection of truth values of logic statements one for each fermionic oscillator operator in the state. For instance, spin up and down would correspond to two possible truth values of a proposition characterized by other quantum numbers of the mode.

The hierarchy of space-time sheet could define a physical correlate for the hierarchy of higher order logics (statements about statements about...). The space-time sheet containing  $N$  fermions topologically condensed at a larger space-time sheet behaves as a fermion or boson depending on whether  $N$  is odd or even. This hierarchy has also a number theoretic counterpart: the construction of infinite primes [70] corresponds to a repeated second quantization of a super-symmetric quantum field theory.

#### Quantal description of beliefs

The question is whether TGD inspired theory of consciousness allows a fundamental description of beliefs.

1. Beliefs define a model about some subsystem of universe constructed by the believer. This model can be understood as some kind of representation of real word in the state space representing the beliefs.
2. One can wonder what is the difference between real and p-adic variants of CH spinor fields and whether they could represent reality and beliefs about reality. CH spinors (as opposed to spinor fields) are constructible in terms of fermionic oscillator operators and seem to be universal in the sense that one cannot speak about p-adic and real CH spinors as different objects. Real/ p-adic spinor fields however have real/p-adic space-time sheets as arguments. This would suggest that there is no fundamental difference between the logic statements represented by p-adic and real CH spinors.

These observations suggest a more concrete view about how beliefs emerge physically.

The idea that p-adic CH spinor fields could serve as representations of beliefs and real CH spinor fields as representations of reality looks very nice but the fact that the outcomes of p-adic-to-real phase transition and its reversal are highly non-predictable does not support it as such.

Quantum statistical determinism could however come into rescue. Belief could be represented as an ensemble of p-adic mental images resulting in transitions of real mental images representing reality to p-adic states. p-Adic ensemble average would represent the belief.

It is not at all clear whether real-to-padic transitions can occur at high enough rate since p-adic-to-real transition are expected to be highly irreversible. The real initial states much have nearly vanishing quantum numbers emitted in the transition to p-adic state to guarantee conservation laws (p-adic conservation laws hold true only piecewise since conserved quantities are pseudo constants). The system defined by an ensemble of real Boolean mental images representing reality would automatically generate a p-adic variant representing a belief about reality.

p-Adic CH spinors can also represent the cognitive aspects of intention whereas p-adic space-time sheets would represent its geometric aspects reflected in sensory experience. p-Adic space-time sheet could also serve only as a space-time correlate for the fundamental representation of intention in terms of p-adic CH spinor field. This view is consistent with the proposed identification of beliefs since the transitions associated with intentions *resp.* beliefs would be p-adic-to-real *resp.* real-to-padic.

#### 11.8.4 Jones inclusions for hyperfinite factors of type $II_1$ as a model for symbolic and cognitive representations

Consider next a more detailed model for how cognitive representations and beliefs are realized at quantum level. This model generalizes trivially to symbolic representations.

The Clifford algebra of gamma matrices associated with CH spinor fields corresponds to a von Neumann algebra known as hyper-finite factor of type  $II_1$ . The mathematics of these algebras is extremely beautiful and reproduces basic mathematical structures of modern physics (conformal field theories, quantum groups, knot and braid groups,...) from the mere assumption that the world of classical worlds possesses infinite-dimensional Kähler geometry and allows spinor structure.

The almost defining feature is that the infinite-dimensional unit matrix of the Clifford algebra in question has by definition unit trace. Type  $II_1$  factors allow also what are known as Jones inclusions of Clifford algebras  $\mathcal{N} \subset \mathcal{M}$ . What is special to  $II_1$  factors is that the induced unitary mappings between spinor spaces are genuine inclusions rather than 1-1 maps.

The S-matrix associated with the real-to-p-adic quantum transition inducing belief from reality would naturally define Jones inclusion of CH Clifford algebra  $\mathcal{N}$  associated with the real space-time sheet to the Clifford algebra  $\mathcal{M}$  associated with the p-adic space-time sheet. The moduli squared of S-matrix elements would define probabilities for pairs or real and belief states.

In Jones inclusion  $\mathcal{N} \subset \mathcal{M}$  the factor  $\mathcal{N}$  is included in factor  $\mathcal{M}$  such that  $\mathcal{M}$  can be expressed as  $\mathcal{N}$ -module over quantum space  $\mathcal{M}/\mathcal{N}$  which has fractal dimension given by Jones index  $\mathcal{M} : \mathcal{N} = 4\cos^2(\pi/n) \leq 4$ ,  $n = 3, 4, \dots$  varying in the range  $[1, 4]$ . The interpretation is as the fractal dimension corresponding to a dimension of Clifford algebra acting in  $d = \sqrt{\mathcal{M} : \mathcal{N}}$ -dimensional spinor space:  $d$  varies in the range  $[1, 2]$ . The interpretation in terms of a quantal variant of logic is natural.

##### Probabilistic beliefs

For  $\mathcal{M} : \mathcal{N} = 4$  ( $n = \infty$ ) the dimension of spinor space is  $d = 2$  and one can speak about ordinary 2-component spinors with  $\mathcal{N}$ -valued coefficients representing generalizations of qubits. Hence the inclusion of a given  $\mathcal{N}$ -spinor as M-spinor can be regarded as a belief on the proposition and for the decomposition to a spinor in N-module  $\mathcal{M}/\mathcal{N}$  involves for each index a choice  $\mathcal{M}/\mathcal{N}$  spinor component selecting super-position of up and down spins. Hence one has a superposition of truth values in general and one can speak only about probabilistic beliefs. It is not clear whether one can choose the basis in such a manner that  $\mathcal{M}/\mathcal{N}$  spinor corresponds always to truth value 1. Since CH spinor field is in question and even if this choice might be possible for a single 3-surface, it need not be possible for deformations of it so that at quantum level one can only speak about probabilistic beliefs.

##### Fractal probabilistic beliefs

For  $d < 2$  the spinor space associated with  $\mathcal{M}/\mathcal{N}$  can be regarded as quantum plane having complex quantum dimension  $d$  with two non-commuting complex coordinates  $z^1$  and  $z^2$  satisfying  $z^1 z^2 = q z^2 z^1$  and  $\overline{z^1 z^2} = \overline{q} \overline{z^2 z^1}$ . These relations are consistent with hermiticity of the real and imaginary parts of  $z^1$  and  $z^2$  which define ordinary quantum planes. Hermiticity also implies that one can identify the complex conjugates of  $z^i$  as Hermitian conjugates.

The further commutation relations  $[z^1, z^2] = [z^2, \overline{z^1}] = 0$  and  $[z^1, \overline{z^1}] = [z^2, \overline{z^2}] = r$  give a closed algebra satisfying Jacobi identities. One could argue that  $r \geq 0$  should be a function  $r(n)$  of the quantum phase  $q = \exp(i2\pi/n)$  vanishing at the limit  $n \rightarrow \infty$  to guarantee that the algebra becomes commutative at this limit and truth values can be chosen to be non-fuzzy.  $r = \sin(\pi/n)$  would be the simplest choice. As will be found, the choice of  $r(n)$  does not however affect at all the spectrum for the probabilities of the truth values.  $n = \infty$  case corresponding to non-fuzzy quantum logic is also possible and must be treated separately: it corresponds to Kac Moody algebra instead of quantum groups.

The non-commutativity of complex spinor components means that  $z^1$  and  $z^2$  are not independent coordinates: this explains the reduction of the number of the effective number of truth values to  $d < 2$ . The maximal reduction occurs to  $d = 1$  for  $n = 3$  so that there is effectively only single truth value and one could perhaps speak about taboo or dogma or complete disappearance of the notions of truth and false (this brings in mind reports about meditative states: in fact  $n = 3$  corresponds to a phase in which Planck constant becomes infinite so that the system is maximally quantal).

As non-commuting operators the components of  $d$ -spinor are not simultaneously measurable for  $d < 2$ . It is however possible to measure simultaneously the operators describing the probabilities  $z^1 \overline{z^1}$  and  $z^2 \overline{z^2}$  for truth values since these operators commute. An inherently fuzzy Boolean logic would be in question with the additional feature that the spinorial counterparts of statement and its negation cannot be regarded as independent observables although the corresponding probabilities satisfy the defining conditions for commuting observables.

If one can speak of a measurement of probabilities for  $d < 2$ , it differs from the ordinary quantum measurement in the sense that it cannot involve a state function reduction to a pure qubit meaning irreducible quantal fuzziness. One could speak of fuzzy qbits or fqbits (or quantum qbits) instead of qbits. This picture would provide the long sought interpretation for quantum groups.

The previous picture applies to all representations  $M_1 \subset M_2$ , where  $M_1$  and  $M_2$  denote either real or p-adic Clifford algebras for some prime  $p$ . For instance, real-real Jones inclusion could be interpreted as symbolic representations assignable to a unitary mapping of the states of a subsystem  $M_1$  of the external world to the state space  $M_2$  of another real subsystem.  $p_1 \rightarrow p_2$  unitary inclusions would in turn map cognitive representations to cognitive representations. There is a strong temptation to assume that these Jones inclusions define unitary maps realizing universe as a universal quantum computer mimicking itself at all levels utilizing cognitive and symbolic representations. Subsystem-system inclusion would naturally define one example of Jones inclusion.

**The spectrum of probabilities of truth values is universal**

It is actually possible to calculate the spectrum of the probabilities of truth values with rather mild additional assumptions.

1. Since the Hermitian operators  $X_1 = (z^1 \overline{z^1} + \overline{z^1} z^1)/2$  and  $X_2 = (z^2 \overline{z^2} + \overline{z^2} z^2)/2$  commute, physical states can be chosen to be eigen states of these operators and it is possible to assign to the truth values probabilities given by  $p_1 = X_1/R^2$  and  $p_2 = X_2/R^2$ ,  $R^2 = X_1 + X_2$ .
2. By introducing the analog of the harmonic oscillator vacuum as a state  $|0\rangle$  satisfying  $z^1|0\rangle = z^2|0\rangle = 0$ , one obtains eigen states of  $X_1$  and  $X_2$  as states  $|n_1, n_2\rangle = \overline{z^1}^{n_1} \overline{z^2}^{n_2} |0\rangle$ ,  $n_1 \geq 0, n_2 \geq 0$ . The eigenvalues of  $X_1$  and  $X_2$  are given by a modified harmonic oscillator spectrum as  $(1/2 + n_1 q^{n_2})r$  and  $(1/2 + n_2 q^{n_1})r$ . The reality of eigenvalues (hermiticity) is guaranteed if one has  $n_1 = N_1 n$  and  $n_2 = N_2 n$  and implies that the spectrum of eigen states gets increasingly thinner for  $n \rightarrow \infty$ . This must somehow reflect the fractal dimension. The fact that large values of oscillator quantum numbers  $n_1$  and  $n_2$  correspond to the classical limit suggests that modulo condition guarantees approximate classicality of the logic for  $n \rightarrow \infty$ .
3. The probabilities  $p_1$  and  $p_2$  for the truth values given by  $(p_1, p_2) = (1/2 + N_1 n, 1/2 + N_2 n)/[1 + (N_1 + N_2)n]$  are rational and allow an interpretation as both real and p-adic numbers. All states are inherently fuzzy and only at the limits  $N_1 \gg N_2$  and  $N_2 \gg N_1$  non-fuzzy states result. As noticed,  $n = \infty$  must be treated separately and corresponds to an ordinary non-fuzzy qbit logic. At  $n \rightarrow \infty$  limit one has  $(p_1, p_2) = (N_1, N_2)/(N_1 + N_2)$ : at this limit  $N_1 = 0$  or  $N_2 = 0$  states are non-fuzzy.

**How to define variants of belief quantum mechanically?**

Probabilities of true and false for Jones inclusion characterize the plausibility of the belief and one can ask whether this description is enough to characterize states such as knowledge, misbelief, doubt, delusion, and ignorance. The truth value of  $\beta_i(p)$  is determined by the measurement of probability assignable to Jones inclusion on the p-adic side. The truth value of  $\lambda_i(p)$  is determined by a similar measurement on the real side.  $\beta$  and  $\lambda$  appear completely symmetrically and one can consider all kinds of triplets  $\mathcal{M}_1 \subset \mathcal{M}_2 \subset \mathcal{M}_3$  assuming that there exist unitary S-matrix like maps mediating a

sequence  $\mathcal{M}_1 \subset \mathcal{M}_2 \subset \mathcal{M}_3$  of Jones inclusions. Interestingly, the hierarchies of Jones inclusions are a key concept in the theory of hyper-finite factors of type  $II_1$  and pair of inclusions plays a fundamental role.

Let us restrict the consideration to the situation when  $\mathcal{M}_1$  corresponds to a real subsystem of the external world,  $\mathcal{M}_2$  its real representation by a real subsystem, and  $\mathcal{M}_3$  to p-adic cognitive representation of  $\mathcal{M}_3$ . Assume that both real and p-adic sides involve a preferred state basis for qubits representing truth and false.

Assume first that both  $\mathcal{M}_1 \subset \mathcal{M}_2$  and  $\mathcal{M}_2 \subset \mathcal{M}_3$  correspond to  $d = 2$  case for which ordinary quantum measurement or truth value is possible giving outcome true or false. Assume further that the truth values have been measured in both  $\mathcal{M}_2$  and  $\mathcal{M}_3$ .

1. Knowledge corresponds to the proposition  $\beta_i(p) \wedge \lambda_i(p)$ .
2. Misbelief to the proposition  $\beta_i(p) \wedge \neq \lambda_i(p)$ .  
Knowledge and misbelief would involve both the measurement of real and p-adic probabilities .
3. Assume next that one has  $d < 2$  form  $\mathcal{M}_2 \subset \mathcal{M}_3$ . Doubt can be regarded neither belief or disbelief:  $\beta_i(p) \wedge \neq \beta_i(\neq p)$ : belief is inherently fuzzy although proposition can be non-fuzzy.  
Assume next that truth values in  $\mathcal{M}_1 \subset \mathcal{M}_2$  inclusion corresponds to  $d < 2$  so that the basic propositions are inherently fuzzy.
4. Delusion is a belief which cannot be justified:  $\beta_i(p) \wedge \lambda_i(p) \wedge \neq \lambda(\neq p)$ . This case is possible if  $d = 2$  holds true for  $\mathcal{M}_2 \subset \mathcal{M}_3$ . Note that also misbelief that cannot be shown wrong is possible.  
In this case truth values cannot be quantum measured for  $\mathcal{M}_1 \subset \mathcal{M}_2$  but can be measured for  $\mathcal{M}_2 \subset \mathcal{M}_3$ . Hence the states are products of pure  $\mathcal{M}_3$  states with fuzzy  $\mathcal{M}_2$  states.
5. Ignorance corresponds to the proposition  $\beta_i(p) \wedge \neq \beta_i(\neq p) \wedge \lambda_i(p) \wedge \neq \lambda(\neq p)$ . Both real representational states and belief states are inherently fuzzy.

Quite generally, only for  $d_1 = d_2 = 2$  ideal knowledge and ideal misbelief are possible. Fuzzy beliefs and logics approach to ordinary one at the limit  $n \rightarrow \infty$ , which according to the proposal of [64] corresponds to the ordinary value of Planck constant. For other cases these notions are only approximate and quantal approach allows to characterize the goodness of the approximation. A new kind of inherent quantum uncertainty of knowledge is in question and one could speak about a Uncertainty Principle for cognition and symbolic representations. Also the unification of symbolic and various kinds of cognitive representations deserves to be mentioned.

### 11.8.5 Intentional comparison of beliefs by topological quantum computation?

Intentional comparison would mean that for a given initial state also the final state of the quantum jump is fixed. This requires the ability to engineer S-matrix so that it leads from a given state to single state only. Any S-matrix representing permutation of the initial states fulfills these conditions. This condition is perhaps unnecessarily strong.

Quantum computation is basically the engineering of S-matrix so that it represents a superposition of parallel computations. In TGD framework topological quantum computation based on the braiding of magnetic flux tubes would be represented as an evolution characterized by braid [81]. The dynamical evolution would be associated with light-like boundaries of braids. This evolution has dual interpretations either as a limit of time evolution of quantum state (program running) or a quantum state satisfying conformal invariance constraints (program code).

The dual interpretation would mean that conformally invariant states are equivalent with engineered time evolutions and topological computation realized as braiding connecting the quantum states to be compared (beliefs represented as many-fermion states at the boundaries of magnetic flux tubes) could give rise to conscious computational comparison of beliefs. The complexity of braiding would give a measure for how much the states to be compared differ.

Note that quantum computation is defined by a unitary map which could also be interpreted as symbolic representation of states of system  $M_1$  as states of system  $M_2$  mediated by the braid of

join along boundaries bonds connecting the two space-time sheets in question and having light-like boundaries. These considerations suggest that the idea about S-matrix of the Universe should be generalized so that the dynamics of the Universe is dynamics of mimicry described by an infinite collection of fermionic S-matrices representable in terms of Jones inclusions.

### 11.8.6 The stability of fuzzy qbits and quantum computation

The stability of fqbts against state function reduction might have deep implications for quantum computation since quantum spinors would be stable against state function reduction induced by the perturbations inducing de-coherence in the normal situation. If this is really true, and if the only dangerous perturbations are those inducing the phase transition to qbits, the implications for quantum computation could be dramatic. Of course, the rigidity of qbits could be just another way to say that topological quantum computations are stable against thermal perturbations not destroying anyons [81] .

The stability of fqbts could also be another manner to state the stability of rational, or more generally algebraic, bound state entanglement against state function reduction, which is one of the basic hypothesis of TGD inspired theory of consciousness [43] . For sequences of Jones inclusions or equivalently, for multiple Connes tensor products, one would obtain tensor products of quantum spinors making possible arbitrary complex configurations of fqbts. Anyonic braids in topological quantum computation would have interpretation as representations for this kind of tensor products.

### 11.8.7 Fuzzy quantum logic and possible anomalies in the experimental data for the EPR-Bohm experiment

The experimental data for EPR-Bohm experiment [2] excluding hidden variable interpretations of quantum theory. What is less known that the experimental data indicates about possibility of an anomaly challenging quantum mechanics [3] . The obvious question is whether this anomaly might provide a test for the notion of fuzzy quantum logic inspired by the TGD based quantum measurement theory with finite measurement resolution.

#### The anomaly

The experimental situation involves emission of two photons from spin zero system so that photons have opposite spins. What is measured are polarizations of the two photons with respect to polarization axes which differ from standard choice of this axis by rotations around the axis of photon momentum characterized by angles  $\alpha$  and  $\beta$ . The probabilities for observing polarizations  $(i, j)$ , where  $i, j$  is taken  $Z_2$  valued variable for a convenience of notation are  $P_{ij}(\alpha, \beta)$ , are predicted to be  $P_{00} = P_{11} = \cos^2(\alpha - \beta)/2$  and  $P_{01} = P_{10} = \sin^2(\alpha - \beta)/2$ .

Consider now the discrepancies.

1. One has four identities  $P_{i,i} + P_{i,i+1} = P_{ii} + P_{i+1,i} = 1/2$  having interpretation in terms of probability conservation. Experimental data of [2] are not consistent with this prediction [1] and this is identified as the anomaly.
2. The QM prediction  $E(\alpha, \beta) = \sum_i (P_{i,i} - P_{i,i+1}) = \cos(2(\alpha - \beta))$  is not satisfied neither: the maxima for the magnitude of  $E$  are scaled down by a factor  $\simeq .9$ . This deviation is not discussed in [1] .

Both these findings raise the possibility that QM might not be consistent with the data. It turns out that fuzzy quantum logic predicted by TGD and implying that the predictions for the probabilities and correlation must be replaced by ensemble averages, can explain anomaly b) but not anomaly a). A "mundane" explanation for anomaly a) is proposed.

#### Predictions of fuzzy quantum logic for the probabilities and correlations

1. *The description of fuzzy quantum logic in terms statistical ensemble*

The fuzzy quantum logic implies that the predictions  $P_{i,j}$  for the probabilities should be replaced with ensemble averages over the ensembles defined by fuzzy quantum logic. In practice this means that following replacements should be carried out:

$$P_{i,j} \rightarrow P^2 P_{i,j} + (1-P)^2 P_{i+1,j+1} + P(1-P)[P_{i,j+1} + P_{i+1,j}] . \quad (11.8.1)$$

Here  $P$  is one of the state dependent universal probabilities/fuzzy truth values for some value of  $n$  characterizing the measurement situation. The concrete predictions would be following

$$\begin{aligned} P_{0,0} = P_{1,1} &\rightarrow A \frac{\cos^2(\alpha - \beta)}{2} + B \frac{\sin^2(\alpha - \beta)}{2} \\ &= (A - B) \frac{\cos^2(\alpha - \beta)}{2} + \frac{B}{2} , \\ P_{0,1} = P_{1,0} &\rightarrow A \frac{\sin^2(\alpha - \beta)}{2} + B \frac{\cos^2(\alpha - \beta)}{2} \\ &= (A - B) \frac{\sin^2(\alpha - \beta)}{2} + \frac{B}{2} , \\ A &= P^2 + (1 - P)^2 , \quad B = 2P(1 - P) . \end{aligned} \quad (11.8.2)$$

The prediction is that the graphs of probabilities as a function as function of the angle  $\alpha - \beta$  are scaled by a factor  $1 - 4P(1 - P)$  and shifted upwards by  $P(1 - P)$ . The value of  $P$ , and one might hope even the value of  $n$  labeling Jones inclusion and the integer  $m$  labeling the quantum state might be deducible from the experimental data as the upward shift. The basic prediction is that the maxima of curves measuring probabilities  $P(i, j)$  have minimum at  $B/2 = P(1 - P)$  and maximum is scaled down to  $(A - B)/2 = 1/2 - 2P(1 - P)$ .

If the  $P$  is same for all pairs  $i, j$ , the correlation  $E = \sum_i (P_{ii} - P_{i,i+1})$  transforms as

$$E(\alpha, \beta) \rightarrow [1 - 4P(1 - P)] E(\alpha, \beta) . \quad (11.8.3)$$

Only the normalization of  $E(\alpha, \beta)$  as a function of  $\alpha - \beta$  reducing the magnitude of  $E$  occurs. In particular the maximum/minimum of  $E$  are scaled down from  $E = \pm 1$  to  $E = \pm(1 - 4P(1 - P))$ .

From the figure 1b) of [1] the scaling down indeed occurs for magnitudes of  $E$  with same amount for minimum and maximum. Writing  $P = 1 - \epsilon$  one has  $A - B \simeq 1 - 4\epsilon$  and  $B \simeq 2\epsilon$  so that the maximum is in the first approximation predicted to be at  $1 - 4\epsilon$ . The graph would give  $1 - P \simeq \epsilon \simeq .025$ . Thus the model explains the reduction of the magnitude for the maximum and minimum of  $E$  which was not however considered to be an anomaly in [3, 1] .

A further prediction is that the identities  $P(i, i) + P(i + 1, i) = 1/2$  should still hold true since one has  $P_{i,i} + P_{i,i+1} = (A - B)/2 + B = 1$ . This is implied also by probability conservation. The four curves corresponding to these identities do not however co-incide as the figure 6 of [1] demonstrates. This is regarded as the basic anomaly in [3, 1] . From the same figure it is also clear that below  $\alpha - \beta < 10$  degrees  $P_{++} = P_{--}$   $\Delta P_{+-} = -\Delta P_{-+}$  holds true in a reasonable approximation. After that one has also non-vanishing  $\Delta P_{ii}$  satisfying  $\Delta P_{++} = -\Delta P_{--}$ . This kind of splittings guarantee the identity  $\sum_{ij} P_{ij} = 1$ . These splittings are not visible in  $E$ .

Since probability conservation requires  $P_{ii} + P_{ii+1} = 1$ , a mundane explanation for the discrepancy could be that the failure of the conditions  $P_{i,i} + P_{ii+1} = 1$  means that the measurement efficiency is too low for  $P_{+-}$  and yields too low values of  $P_{+-} + P_{--}$  and  $P_{+-} + P_{++}$ . The constraint  $\sum_{ij} P_{ij} = 1$  would then yield too high value for  $P_{-+}$ . Similar reduction of measurement efficiency for  $P_{++}$  could explain the splitting for  $\alpha - \beta > 10$  degrees.

Clearly asymmetry with respect to exchange of photons or of detectors is in question.

1. The asymmetry of two photon state with respect to the exchange of photons could be considered as a source of asymmetry. This would mean that the photons are not maximally entangled. This could be seen as an alternative "mundane" explanation.

2. The assumption that the parameter  $P$  is different for the detectors does not change the situation as is easy to check.
3. One manner to achieve splittings which resemble observed splittings is to assume that the value of the probability parameter  $P$  depends on the *polarization pair*:  $P = P(i, j)$  so that one has  $(P(-, +), P(+, -)) = (P + \Delta, P - \Delta)$  and  $(P(-, -), P(+, +)) = (P + \Delta_1, P - \Delta_1)$ .  $\Delta \simeq .025$  and  $\Delta_1 \simeq \Delta/2$  could produce the observed splittings qualitatively. One would however always have  $P(i, i) + P(i, i + 1) \geq 1/2$ . Only if the procedure extracting the correlations uses the constraint  $\sum_{i,j} P_{ij} = 1$  effectively inducing a constant shift of  $P_{ij}$  downwards an asymmetry of observed kind can result. A further objection is that there are no special reason for the values of  $P(i, j)$  to satisfy the constraints.

2. *Is it possible to say anything about the value of  $n$  in the case of EPR-Bohm experiment?*

To explain the reduction of the maximum magnitudes of the correlation  $E$  from 1 to  $\sim .9$  in the experiment discussed above one should have  $p_1 \simeq .9$ . It is interesting to look whether this allows to deduce any information about the value of  $n$ . At the limit of large values of  $N_i n$  one would have  $(N_1 - N_2)/(N_1 + N_2) \simeq .4$  so that one cannot say anything about  $n$  in this case.  $(N_1, N_2) = (3, 1)$  satisfies the condition exactly. For  $n = 3$ , the smallest possible value of  $n$ , this would give  $p_1 \simeq .88$  and for  $n = 4$   $p_1 = .41$ . With high enough precision it might be possible to select between  $n = 3$  and  $n = 4$  options if small values of  $N_i$  are accepted.

### 11.8.8 Category theoretic formulation for quantum measurement theory with finite measurement resolution?

I have been trying to understand whether category theory might provide some deeper understanding about quantum TGD, not just as a powerful organizer of fuzzy thoughts but also as a tool providing genuine physical insights. Marni Dee Sheppard (or Kea in her blog Arcadian Functor at <http://keamonad.blogspot.com/>) is also interested in categories but in much more technical sense. Her dream is to find a category theoretical formulation of M-theory as something, which is not the 11-D something making me rather unhappy as a physicist with second foot still deep in the muds of low energy phenomenology.

#### Locales, frames, Sierpinski topologies and Sierpinski space

The ideas below popped up when Kea mentioned in M-theory lesson 51 the notions of locale and frame [12]. In Wikipedia I learned that complete Heyting algebras, which are fundamental to category theory, are objects of three categories with differing arrows. CHey, Loc and its opposite category Frm (arrows reversed). Complete Heyting algebras are partially ordered sets which are complete lattices. Besides the basic logical operations there is also algebra multiplication (I have considered the possible role of categories and Heyting algebras in TGD in [14]). From Wikipedia I also learned that locales and the dual notion of frames form the foundation of pointless topology [29]. These topologies are important in topos theory which does not assume axiom of choice.

The so called particular point topology [24] assumes a selection of single point but I have the physicist's feeling that it is otherwise rather near to pointless topology. Sierpinski topology [34] is this kind of topology. Sierpinski topology is defined in a simple manner: the set is open only if it contains a given preferred point  $p$ . The dual of this topology defined in the obvious sense exists also. Sierpinski space consisting of just two points 0 and 1 is the universal building block of these topologies in the sense that a map of an arbitrary space to Sierpinski space provides it with Sierpinski topology as the induced topology. In category theoretical terms Sierpinski space is the initial object in the category of frames and terminal object in the dual category of locales. This category theoretic reductionism looks highly attractive.

#### Particular point topologies, their generalization, and number theoretical braids

Pointless, or rather particular point topologies might be very interesting from physicist's point of view. After all, every classical physical measurement has a finite space-time resolution. In TGD framework discretization by number theoretic braids replaces partonic 2-surface with a discrete set consisting of

algebraic points in some extension of rationals: this brings in mind something which might be called a topology with a set of particular algebraic points. Could this preferred set belong to any open set in the particular point topology appropriate in this situation?

Perhaps the physical variant for the axiom of choice could be restricted so that only sets of algebraic points in some extension of rationals can be chosen freely and the choice is defined by the intersection of p-adic and real partonic 2-surfaces and in the framework of TGD inspired theory of consciousness would thus involve the interaction of cognition and intentionality with the material world. The extension would depend on the position of the physical system in the algebraic evolutionary hierarchy defining also a cognitive hierarchy. Certainly this would fit very nicely to the formulation of quantum TGD unifying real and p-adic physics by gluing real and p-adic number fields to single super-structure via common algebraic points.

### **Analogs of particular point topologies at the level of state space: finite measurement resolution**

There is also a finite measurement resolution in Hilbert space sense not taken into account in the standard quantum measurement theory based on factors of type I. In TGD framework one indeed introduces quantum measurement theory with a finite measurement resolution so that complex rays become included hyper-finite factors of type  $II_1$  (HFFs).

1. Could topology with particular algebraic points have a generalization allowing a category theoretic formulation of the quantum measurement theory without states identified as complex rays?
2. How to achieve this? In the transition of ordinary Boolean logic to quantum logic in the old fashioned sense (von Neuman again!) the set of subsets is replaced with the set of subspaces of Hilbert space. Perhaps this transition has a counterpart as a transition from Sierpinski topology to a structure in which sub-spaces of Hilbert space are quantum sub-spaces with complex rays replaced with the orbits of subalgebra defining the measurement resolution. Sierpinski space  $\{0,1\}$  would in this generalization be replaced with the quantum counterpart of the space of 2-spinors. Perhaps one should also introduce q-category theory with Heyting algebra being replaced with q-quantum logic.

### **Fuzzy quantum logic as counterpart for Sierpinski space**

The program formulated above might indeed make sense. The lucky association induced by Kea's blog was to the ideas about fuzzy quantum logic realized in terms of quantum 2-spinor that I had developed a couple of years ago. Fuzzy quantum logic would reflect the finite measurement resolution. I just list the pieces of the argument.

**Spinors and qbits:** Spinors define a quantal variant of Boolean statements, qbits. One can however go further and define the notion of quantum qbit, qqbit. I indeed did this for couple of years ago (the last section of this chapter).

**Q-spinors and qqbits:** For q-spinors the two components  $a$  and  $b$  are not commuting numbers but non-Hermitian operators:  $ab = qba$ ,  $q$  a root of unity. This means that one cannot measure both  $a$  and  $b$  simultaneously, only either of them.  $aa^\dagger$  and  $bb^\dagger$  however commute so that probabilities for bits 1 and 0 can be measured simultaneously. State function reduction is not possible to a state in which  $a$  or  $b$  gives zero. The interpretation is that one has q-logic is inherently fuzzy: there are no absolute truths or falsehoods. One can actually predict the spectrum of eigenvalues of probabilities for say 1. Obviously quantum spinors would be state space counterparts of Sierpinski space and for  $q \neq 1$  the choice of preferred spinor component is very natural. Perhaps this fuzzy quantum logic replaces the logic defined by the Heyting algebra.

**Q-locale:** Could one think of generalizing the notion of locale to quantum locale by using the idea that sets are replaced by sub-spaces of Hilbert space in the conventional quantum logic. Q-openness would be defined by identifying quantum spinors as the initial object,  $q$ -Sierpinski space.  $a$  (resp.  $b$  for the dual category) would define q-open set in this space. Q-open sets for other quantum spaces would be defined as inverse images of  $a$  (resp.  $b$ ) for morphisms to this space. Only for  $q=1$  one could have the q-counterpart of rather uninteresting topology in which all sets are open and every map is continuous.

**Q-locale and HFFs:** The q-Sierpinski character of q-spinors would conform with the very special role of Clifford algebra in the theory of HFFs, in particular, the special role of Jones inclusions to which one can assign spinor representations of  $SU(2)$ . The Clifford algebra and spinors of the world of classical worlds identifiable as Fock space of quark and lepton spinors is the fundamental example in which 2-spinors and corresponding Clifford algebra serves as basic building brick although tensor powers of any matrix algebra provides a representation of HFF.

**Q-measurement theory:** Finite measurement resolution (q-quantum measurement theory) means that complex rays are replaced by sub-algebra rays. This would force the Jones inclusions associated with  $SU(2)$  spinor representation and would be characterized by quantum phase q and bring in the q-topology and q-spinors. Fuzzyness of qqbits of course correlates with the finite measurement resolution.

**Q-n-logos:** For other q-representations of  $SU(2)$  and for representations of compact groups (Appendix) one would obtain something which might have something to do with quantum n-logos, quantum generalization of n-valued logic. All of these would be however less fundamental and induced by q-morphisms to the fundamental representation in terms of spinors of the world of classical worlds. What would be however very nice that if these q-morphisms are constructible explicitly it would become possible to build up q-representations of various groups using the fundamental physical realization - and as I have conjectured [61] - McKay correspondence and huge variety of its generalizations would emerge in this manner.

**The analogs of Sierpinski spaces:** The discrete subgroups of  $SU(2)$ , and quite generally, the groups  $Z_n$  associated with Jones inclusions and leaving the choice of quantization axes invariant, bring in mind the n-point analogs of Sierpinski space with unit element defining the particular point. Note however that  $n \geq 3$  holds true always so that one does not obtain Sierpinski space itself. If all these  $n$  preferred points belong to any open set it would not be possible to decompose this preferred set to two subsets belonging to disjoint open sets. Recall that the generalized imbedding space related to the quantization of Planck constant is obtained by gluing together coverings  $M^4 \times CP_2 \rightarrow M^4 \times CP_2/G_a \times G_b$  along their common points of base spaces. The topology in question would mean that if some point in the covering belongs to an open set, all of them do so. The interpretation would be that the points of fiber form a single inseparable quantal unit.

Number theoretical braids identified as subsets of the intersection of real and p-adic variants of algebraic partonic 2-surface define a second candidate for the generalized Sierpinski space with a set of preferred points.

## 11.9 Appendix: Inclusions of hyper-finite factors of type $II_1$

Many names have been assigned to inclusions: Jones, Wenzl, Ocneanu, Pimsner-Popa, Wasserman [60]. It would seem to me that the notion Jones inclusion includes them all so that various names would correspond to different concrete realizations of the inclusions conjugate under outer automorphisms.

1. According to [60] for inclusions with  $\mathcal{M} : \mathcal{N} \leq 4$  (with  $A_1^{(1)}$  excluded) there exists a countable infinity of sub-factors which are pairwise non inner conjugate but conjugate to  $\mathcal{N}$ .
2. Also for any finite group  $G$  and its outer action there exists uncountably many sub-factors which are pairwise non inner conjugate but conjugate to the fixed point algebra of  $G$  [60]. For any amenable group  $G$  the inclusion is also unique apart from outer automorphism [74].

Thus it seems that not only Jones inclusions but also more general inclusions are unique apart from outer automorphism.

Any \*-endomorphism  $\sigma$ , which is unit preserving, faithful, and weakly continuous, defines a sub-factor of type  $II_1$  factor [60]. The construction of Jones leads to a standard inclusion sequence  $\mathcal{N} \subset \mathcal{M} \subset \mathcal{M}^1 \subset \dots$ . This sequence means addition of projectors  $e_i$ ,  $i < 0$ , having visualization as an addition of braid strand in braid picture. This hierarchy exists for all factors of type II. At the limit  $\mathcal{M}^\infty = \cup_i \mathcal{M}^i$  the braid sequence extends from  $-\infty$  to  $\infty$ . Inclusion hierarchy can be understood as a hierarchy of Connes tensor powers  $\mathcal{M} \otimes_{\mathcal{N}} \mathcal{M} \dots \otimes_{\mathcal{N}} \mathcal{M}$ . Also the ordinary tensor powers of hyper-finite factors of type  $II_1$  (HFF) as well as their tensor products with finite-dimensional matrix algebras are isomorphic to the original HFF so that these objects share the magic of fractals.

Under certain assumptions the hierarchy can be continued also in opposite direction. For a finite index an infinite inclusion hierarchy of factors results with the same value of index.  $\sigma$  is said to be basic if it can be extended to \*-endomorphisms from  $\mathcal{M}^1$  to  $\mathcal{M}$ . This means that the hierarchy of inclusions can be continued in the opposite direction: this means elimination of strands in the braid picture. For finite factors (as opposed to hyper-finite ones) there are no basic \*-endomorphisms of  $\mathcal{M}$  having fixed point algebra of non-abelian  $G$  as a sub-factor [60].

### 11.9.1 Jones inclusions

For hyper-finite factors of type  $II_1$  Jones inclusions allow basic \*-endomorphism. They exist for all values of  $\mathcal{M} : \mathcal{N} = r$  with  $r \in \{4\cos^2(\pi/n) | n \geq 3\} \cap [4, \infty)$  [60]. They are defined for an algebra defined by projectors  $e_i, i \geq 1$ . All but nearest neighbor projectors commute.  $\lambda = 1/r$  appears in the relations for the generators of the algebra given by  $e_i e_j e_i = \lambda e_i, |i - j| = 1$ .  $\mathcal{N} \subset \mathcal{M}$  is identified as the double commutator of algebra generated by  $e_i, i \geq 2$ .

This means that principal graph and its dual are equivalent and the braid defined by projectors can be continued not only to  $-\infty$  but that also the dropping of arbitrary number of strands is possible [60]. It would seem that ADE property of the principal graph meaning single root length codes for the duality in the case of  $r \leq 4$  inclusions.

Irreducibility holds true for  $r < 4$  in the sense that the intersection of  $Q' \cap P = P' \cap P = C$ . For  $r \geq 4$  one has  $\dim(Q' \cap P) = 2$ . The operators commuting with  $Q$  contain besides identify operator of  $Q$  also the identify operator of  $P$ .  $Q$  would contain a single finite-dimensional matrix factor less than  $P$  in this case. Basic \*-endomorphisms with  $\sigma(P) = Q$  is  $\sigma(e_i) = e_{i+1}$ . The difference between genuine symmetries of quantum TGD and symmetries which can be mimicked by TGD could relate to the irreducibility for  $r < 4$  and raise these inclusions in a unique position. This difference could partially justify the hypothesis [27] that only the groups  $G_a \times G_b \subset SU(2) \times SU(2) \subset SL(2, C) \times SU(3)$  define orbifold coverings of  $H_{\pm} = M_{\pm}^4 \times CP_2 \rightarrow H_{\pm}/G_a \times G_b$ .

### 11.9.2 Wassermann's inclusion

Wasserman's construction of  $r = 4$  factors clarifies the role of the subgroup of  $G \subset SU(2)$  for these inclusions. Also now  $r = 4$  inclusion is characterized by a discrete subgroup  $G \subset SU(2)$  and is given by  $(1 \otimes \mathcal{M})^G \subset (M_2(C) \times \mathcal{M})^G$ . According to [60] Jones inclusions are irreducible also for  $r = 4$ . The definition of Wasserman inclusion for  $r = 4$  seems however to imply that the identity matrices of both  $\mathcal{M}^G$  and  $(M(2, C) \otimes \mathcal{M})^G$  commute with  $\mathcal{M}^G$  so that the inclusion should be reducible for  $r = 4$ .

Note that  $G$  leaves both the elements of  $\mathcal{N}$  and  $\mathcal{M}$  invariant whereas  $SU(2)$  leaves the elements of  $\mathcal{N}$  invariant.  $M(2, C)$  is effectively replaced with the orbifold  $M(2, C)/G$ , with  $G$  acting as automorphisms. The space of these orbits has complex dimension  $d = 4$  for finite  $G$ .

For  $r < 4$  inclusion is defined as  $M^G \subset M$ . The representation of  $G$  as outer automorphism must change step by step in the inclusion sequence  $\dots \subset \mathcal{N} \subset \mathcal{M} \subset \dots$  since otherwise  $G$  would act trivially as one proceeds in the inclusion sequence. This is true since each step brings in additional finite-dimensional tensor factor in which  $G$  acts as automorphisms so that although  $\mathcal{M}$  can be invariant under  $G_{\mathcal{M}}$  it is not invariant under  $G_{\mathcal{N}}$ .

These two inclusions might accompany each other in TGD based physics. One could consider  $r < 4$  inclusion  $\mathcal{N} = \mathcal{M}^G \subset \mathcal{M}$  with  $G$  acting non-trivially in  $\mathcal{M}/\mathcal{N}$  quantum Clifford algebra.  $\mathcal{N}$  would decompose by  $r = 4$  inclusion to  $\mathcal{N}_1 \subset \mathcal{N}$  with  $SU(2)$  taking the role of  $G$ .  $\mathcal{N}/\mathcal{N}_1$  quantum Clifford algebra would transform non-trivially under  $SU(2)$  but would be  $G$  singlet.

In TGD framework the  $G$ -invariance for  $SU(2)$  representations means a reduction of  $S^2$  to the orbifold  $S^2/G$ . The coverings  $H_{\pm} \rightarrow H_{\pm}/G_a \times G_b$  should relate to these double inclusions and  $SU(2)$  inclusion could mean Kac-Moody type gauge symmetry for  $\mathcal{N}$ . Note that the presence of the factor containing only unit matrix should relate directly to the generator  $d$  in the generator set of affine algebra in the McKay construction [18]. The physical interpretation of the fact that almost all ADE type extended diagrams ( $D_n^{(1)}$  must have  $n \geq 4$ ) are allowed for  $r = 4$  inclusions whereas  $D_{2n+1}$  and  $E_6$  are not allowed for  $r < 4$ , remains open.

### 11.9.3 Generalization from $SU(2)$ to arbitrary compact group

The inclusions with index  $\mathcal{M} : \mathcal{N} < 4$  have one-dimensional relative commutant  $\mathcal{N}' \cup \mathcal{M}$ . The most obvious conjecture that  $\mathcal{M} : \mathcal{N} \geq 4$  corresponds to a non-trivial relative commutant is wrong. The index for Jones inclusion is identifiable as the square of quantum dimension of the fundamental representation of  $SU(2)$ . This identification generalizes to an arbitrary representation of arbitrary compact Lie group.

In his thesis Wenzl [127] studied the representations of Hecke algebras  $H_n(q)$  of type  $A_n$  obtained from the defining relations of symmetric group by the replacement  $e_i^2 = (q-1)e_i + q$ .  $H_n$  is isomorphic to complex group algebra of  $S_n$  if  $q$  is not a root of unity and for  $q = 1$  the irreducible representations of  $H_n(q)$  reduce trivially to Young's representations of symmetric groups. For primitive roots of unity  $q = \exp(i2\pi/l)$ ,  $l = 4, 5, \dots$ , the representations of  $H_n(\infty)$  give rise to inclusions for which index corresponds to a quantum dimension of any irreducible representation of  $SU(k)$ ,  $k \geq 2$ . For  $SU(2)$  also the value  $l = 3$  is allowed for spin  $1/2$  representation.

The inclusions are obtained by dropping the first  $m$  generators  $e_k$  from  $H_\infty(q)$  and taking double commutant of both  $H_\infty$  and the resulting algebra. The relative commutant corresponds to  $H_m(q)$ . By reducing by the minimal projection to relative commutant one obtains an inclusion with a trivial relative commutant. These inclusions are analogous to a discrete states superposed in continuum. Thus the results of Jones generalize from the fundamental representation of  $SU(2)$  to all representations of all groups  $SU(k)$ , and in fact to those of general compact groups as it turns out.

The generalization of the formula for index to square of quantum dimension of an irreducible representation of  $SU(k)$  reads as

$$\mathcal{M} : \mathcal{N} = \prod_{1 \leq r < s \leq k} \frac{\sin^2((\lambda_r - \lambda_s + s - r)\pi/l)}{\sin^2((s - r)\pi/l)}. \tag{11.9.1}$$

Here  $\lambda_r$  is the number of boxes in the  $r^{th}$  row of the Yang diagram with  $n$  boxes characterizing the representations and the condition  $1 \leq k \leq l - 1$  holds true. Only Young diagrams satisfying the condition  $l - k = \lambda_1 - \lambda_{r_{max}}$  are allowed.

The result would allow to restrict the generalization of the imbedding space in such a manner that only cyclic group  $Z_n$  appears in the covering of  $M^4 \rightarrow M^4/G_a$  or  $CP_2 \rightarrow CP_2/G_b$  factor. Be as it may, it seems that quantum representations of any compact Lie group can be realized using the generalization of the imbedding space. In the case of  $SU(2)$  the interpretation of higher-dimensional quantum representations in terms of Connes tensor products of 2-dimensional fundamental representations is highly suggestive.

The groups  $SO(3, 1) \times SU(3)$  and  $SL(2, C) \times U(2)_{ew}$  have a distinguished position both in physics and quantum TGD and the vision about physics as a generalized number theory implies them. Also the general pattern for inclusions selects these groups, and one can say that the condition that all possible statistics are realized is guaranteed by the choice  $M^4 \times CP_2$ .

1.  $n > 2$  for the quantum counterparts of the fundamental representation of  $SU(2)$  means that braid statistics for Jones inclusions cannot give the usual fermionic statistics. That Fermi statistics cannot "emerge" conforms with the role of infinite- $D$  Clifford algebra as a canonical representation of HFF of type  $II_1$ .  $SO(3, 1)$  as isometries of  $H$  gives  $Z_2$  statistics via the action on spinors of  $M^4$  and  $U(2)$  holonomies for  $CP_2$  realize  $Z_2$  statistics in  $CP_2$  degrees of freedom.
2.  $n > 3$  for more general inclusions in turn excludes  $Z_3$  statistics as braid statistics in the general case.  $SU(3)$  as isometries induces a non-trivial  $Z_3$  action on quark spinors but trivial action at the imbedding space level so that  $Z_3$  statistics would be in question.

## Chapter 12

# Does TGD Predict a Spectrum of Planck Constants?

### 12.1 Introduction

The quantization of Planck constant has been the basic theme of TGD since 2005 and the perspective in the earlier version of this chapter reflected the situation for about year and one half after the basic idea stimulated by the finding of Nottale [10] that planetary orbits could be seen as Bohr orbits with enormous value of Planck constant given by  $\hbar_{gr} = GM_1M_2/v_0$ ,  $v_0 \simeq 2^{-11}$  for the inner planets. The general form of  $\hbar_{gr}$  is dictated by Equivalence Principle. This inspired the ideas that quantization is due to a condensation of ordinary matter around dark matter concentrated near Bohr orbits and that dark matter is in macroscopic quantum phase in astrophysical scales.

The second crucial empirical input were the anomalies associated with living matter. Mention only the effects of ELF radiation at EEG frequencies on vertebrate brain and anomalous behavior of the ionic currents through cell membrane. If the value of Planck constant is large, the energy of EEG photons is above thermal energy and one can understand the effects on both physiology and behavior. If ionic currents through cell membrane have large Planck constant the scale of quantum coherence is large and one can understand the observed low dissipation in terms of quantum coherence.

#### 12.1.1 The evolution of mathematical ideas

From the beginning the basic challenge -besides the need to deduce a general formula for the quantized Planck constant- was to understand how the quantization of Planck constant is mathematically possible. From the beginning it was clear that since particles with different values of Planck constant cannot appear in the same vertex, a generalization of space-time concept is needed to achieve this.

During last five years or so many deep ideas -both physical and mathematical- related to the construction of quantum TGD have emerged and this has led to a profound change of perspective in this and also other chapters. The overall view about TGD is described briefly in [6].

1. For more than five years ago I realized that von Neumann algebras known as hyperfinite factors of type  $II_1$  (HFFs) are highly relevant for quantum TGD since the Clifford algebra of configuration space ("world of classical worlds", WCW) is direct sum over HFFs. Jones inclusions are particular class of inclusions of HFFs and quantum groups are closely related to them. This led to a conviction that Jones inclusions can provide a detailed understanding of what is involved and predict very simple spectrum for Planck constants associated with  $M^4$  and  $CP_2$  degrees of freedom (later I replaced  $M^4$  by its light cone  $M^4_{\pm}$  and finally with the causal diamond  $CD$  defined as intersection of future and past light-cones of  $M^4$ ).
2. The notion of zero energy ontology replaces physical states with zero energy states consisting of pairs of positive and negative energy states at the light-like boundaries  $\delta M^4_{\pm} \times CP_2$  of  $CD$ s forming a fractal hierarchy containing  $CD$ s within  $CD$ s. In standard ontology zero energy state corresponds to a physical event, say particle reaction. This led to the generalization of S-matrix to M-matrix identified as Connes tensor product characterizing time like entanglement between

positive and negative energy states. M-matrix is product of square root of density matrix and unitary S-matrix just like Schrödinger amplitude is product of modulus and phase, which means that thermodynamics becomes part of quantum theory and thermodynamical ensembles are realized as single particle quantum states. This led also to a solution of long standing problem of understanding how geometric time of the physicist is related to the experienced time identified as a sequence of quantum jumps interpreted as moments of consciousness [4] in TGD inspired theory of consciousness which can be also seen as a generalization of quantum measurement theory [5] .

3. Another closely related idea was the emergence of measurement resolution as the basic element of quantum theory. Measurement resolution is characterized by inclusion  $\mathcal{M} \subset \mathcal{N}$  of HFFs with  $\mathcal{M}$  characterizing the measurement resolution in the sense that the action of  $\mathcal{M}$  creates states which cannot be distinguished from each other within measurement resolution used. Hence complex rays of state space are replaced with  $\mathcal{M}$  rays. One of the basic challenges is to define the nebulous factor space  $\mathcal{N}/\mathcal{M}$  having finite fractional dimension  $\mathcal{N} : \mathcal{M}$  given by the index of inclusion. It was clear that this space should correspond to quantum counterpart of Clifford algebra of world of classical worlds reduced to a finite-quantum dimensional algebra by the finite measurement resolution [15] .
4. The realization that light-like 3-surfaces at which the signature of induced metric of space-time surface changes from Minkowskian to Euclidian are ideal candidates for basic dynamical objects besides light-like boundaries of space-time surface was a further decisive step or progress. This led to vision that quantum TGD is almost topological quantum field theory ("almost" because light-likeness brings in induced metric) characterized by Chern-Simons action for induced Kähler gauge potential of  $CP_2$ . Together with zero energy ontology this led to the generalization of the notion of Feynman diagram to a light-like 3-surface for which lines correspond to light-like 3-surfaces and vertices to 2-D partonic surface at which these 3-D surface meet. This means a strong departure from string model picture. The interaction vertices should be given by N-point functions of a conformal field theory with second quantized induced spinor fields defining the basic fields in terms of which also the gamma matrices of world of classical worlds could be constructed as super generators of super conformal symmetries [15] .
5. By quantum classical correspondence finite measurement resolution should have a space-time correlate. The obvious guess was that this correlate is discretization at the level of construction of M-matrix. In almost-TQFT context the effective replacement of light-like 3-surface with braids defining basic objects of TQFTs is the obvious guess. Also number theoretic universality necessary for the p-adicization of quantum TGD by a process analogous to the completion of rationals to reals and various p-adic number fields requires discretization since only rational and possibly some algebraic points of the imbedding space (in suitable preferred coordinates) allow interpretation both as real and p-adic points. It was clear that the construction of M-matrix boils to the precise understanding of number theoretic braids [15] .
6. The interaction with M-theory dualities [68] led to a handful of speculations about dualities possible in TGD framework, and one of these dualities-  $M^8 - M^4 \times CP_2$  duality - eventually led to a unique identification of number theoretic braids. The dimensions of partonic 2-surface, space-time, and imbedding space strongly suggest that classical number fields, or more precisely their complexifications might help to understand quantum TGD. If the choice of imbedding space is unique because of uniqueness of infinite-dimensional Kähler geometric existence of world of classical worlds then standard model symmetries coded by  $M^4 \times CP_2$  should have some deeper meaning and the most obvious guess is that  $M^4 \times CP_2$  can be understood geometrically.  $SU(3)$  belongs to the automorphism group of octonions as well as hyper-octonions  $M^8$  identified by subspace of complexified octonions with Minkowskian signature of induced metric. This led to the discovery that hyper-quaternionic 4-surfaces in  $M^8$  can be mapped to  $M^4 \times CP_2$  provided their tangent space contains preferred  $M^2 \subset M^4 \subset M^4 \times E^4$ . Years later I realized that the map generalizes so that  $M^2$  can depend on the point of  $X^4$ . The interpretation of  $M^2(x)$  is both as a preferred hyper-complex (commutative) sub-space of  $M^8$  and as a local plane of non-physical polarizations so that a purely number theoretic interpretation of gauge conditions emerges in TGD framework. This led to a rapid progress in the construction of the quantum TGD. In

particular, the challenge of identifying the preferred extremal of Kähler action associated with a given light-like 3-surface  $X_l^3$  could be solved and the precise relation between  $M^8$  and  $M^4 \times CP_2$  descriptions was understood [15].

7. Also the challenge of reducing quantum TGD to the physics of second quantized induced spinor fields found a resolution recently [15]. For years ago it became clear that the vacuum functional of the theory must be the Dirac determinant associated with the induced spinor fields so that the theory would predict all coupling parameters from quantum criticality. Even more, the vacuum functional should correspond to the exponent of Kähler action for a preferred extremal. The problem was that the generalized eigenmodes of Chern-Simons Dirac operator allow a generalized eigenvalues to be arbitrary functions of two coordinates in the directions transversal to the light-like direction of  $X_l^3$ . The progress in the understanding of number theoretic compactification however allowed to understand how the information about the preferred extremal of Kähler action is coded to the spectrum of eigen modes.

The basic idea is simple and I actually discovered it for more than half decade ago but forgot! The generalized eigen modes of 3-D Chern-Simons Dirac operator  $D_{C-S}$  correspond to the zero modes of a 4-D modified Dirac operator defined by Kähler action localized to  $X_l^3$  so that induced spinor fields can be seen as 4-D spinorial shock waves. This led to a concrete interpretation of the eigenvalues as analogous to cyclotron energies of fermion in classical electro-weak magnetic fields defined by the induced spinor connection and a connection with anyon physics emerges by 2-dimensionality of the evolving system. Also it was possible to identify the boundary conditions for the preferred extremal of Kähler action -analog of Bohr orbit- at  $X_l^3$  and also to the vision about how general coordinate invariance allows to use any light-like 3-surface  $X^3 \subset X^4(X_l^3)$  instead of using only wormhole throat to second quantize induced spinor field.

8. It became as a total surprise that due to the huge vacuum degeneracy of induced spinor fields the number of generalized eigenmodes identified in this manner was finite. The good news was that the theory is manifestly finite and zeta function regularization is not needed to define the Dirac determinant. The manifest finiteness had been actually must-be-true from the beginning. The apparently bad news was that the Clifford algebra of WCW world constructed from the oscillator operators is bound to be finite-dimensional. The resolution of the paradox comes from the realization that this algebra represents the somewhat mysterious coset space  $\mathcal{N}/\mathcal{M}$  so that finite measurement resolution and the notion inclusion are coded by the vacuum degeneracy of Kähler action and the maximally economical description in terms of inclusions emerges automatically.
9. A unique identification of number theoretic braids became also possible and relates to the construction of the generalized imbedding space by gluing together singular coverings and factor spaces of  $CD \setminus M^2$  and  $CP_2 \setminus S_I^2$  to form a book like structure. Here  $M^2$  is preferred plane of  $M^4$  defining quantization axis of energy and angular momentum and  $S_I^2$  is one of the two geodesic spheres of  $CP_2$ . The interpretation of the selection of these sub-manifolds is as a geometric correlate for the selection of quantization axes and  $CD$  defining basic sector of world of classical worlds is replaced by a union corresponding to these choices. Number theoretic braids come in two variants dual to each other, and correspond to the intersection of  $M^2$  and  $M^4$  projection of  $X_l^3$  on one hand and  $S_I^2$  and  $CP_2$  projection of  $X_l^3$  on the other hand. This is simplest option and would mean that the points of number theoretic braid belong to  $M^2$  ( $S_I^2$ ) and are thus quantum critical although entire  $X^2$  at the boundaries of  $CD$  belongs to a fixed page of the Big Book. This means solution of a long standing problem of understanding in what sense TGD Universe is quantum critical. The phase transitions changing Planck constant correspond to tunneling represented geometrically by a leakage of partonic 2-surface from a page of Big Book to another one.
10. Many other steps of progress have occurred during the last years. Much earlier it had become clear that the basic difference between TGD and string models is that in TGD framework the super algebra generators are non-hermitian and carry quark or lepton number [15]. Super-space concept is unnecessary because super generators anticommute to Hamiltonians of bosonic symmetries rather than corresponding vector fields. This allows to avoid the Majorana condition of super string models fixing space-time dimension to 10 or 11. During last years a much more precise understanding of super-symplectic and super Kac-Moody symmetries has emerged. The

generalized coset representation for these two Super Virasoro algebras generalizes Equivalence Principle and predicts as a special case the equivalence of gravitational and inertial masses. Coset construction also provides justification for p-adic thermodynamics in apparent conflict with super-conformal invariance. The construction of the fusion rules of symplectic QFT as analog of conformal QFT led to the notion of number theoretic braid and to an explicit construction of a hierarchy of algebras realizing symplectic fusion rules and the notion of finite measurement resolution [13]. This approach led to the formulation of generalized Feynman diagrams and coupling constant evolution in terms of operads Taylor made for a mathematical realization of the notion of coupling constant evolution. One of the future challenges is to combine symplectic fusion algebras with the realization for the hierarchy of Planck constants.

### 12.1.2 The evolution of physical ideas

The evolution of physical ideas related to the hierarchy of Planck constants and dark matter as a hierarchy of phases of matter with non-standard value of Planck constants was much faster than the evolution of mathematical ideas and quite a number of applications have been developed during last five years.

1. The basic idea was that ordinary matter condenses around dark matter which is a phase of matter characterized by non-standard value of Planck constant.
2. The realization that non-standard values of Planck constant give rise to charge and spin fractionization and anyonization led to the precise identification of the prerequisites of anyonic phase [57]. If the partonic 2-surface, which can have even astrophysical size, surrounds the tip of  $CD$ , the matter at the surface is anyonic and particles are confined at this surface. Dark matter could be confined inside this kind of light-like 3-surfaces around which ordinary matter condenses. If the radii of the basic pieces of these nearly spherical anyonic surfaces - glued to a connected structure by flux tubes mediating gravitational interaction - are given by Bohr rules, the findings of Nottale [10] can be understood. Dark matter would resemble to a high degree matter in black holes replaced in TGD framework by light-like partonic 2-surfaces with minimum size of order Schwarzschild radius  $r_S$  of order scaled up Planck length:  $r_S \sim \sqrt{\hbar G}$ . Black hole entropy being inversely proportional to  $\hbar$  is predicted to be of order unity so that dramatic modification of the picture about black holes is implied.
3. Darkness is a relative concept and due to the fact that particles at different pages of book cannot appear in the same vertex of the generalized Feynman diagram. The phase transitions in which partonic 2-surface  $X^2$  during its travel along  $X_l^3$  leaks to different page of book are however possible and change Planck constant so that particle exchanges of this kind allow particles at different pages to interact. The interactions are strongly constrained by charge fractionization and are essentially phase transitions involving many particles. Classical interactions are also possible. This allows to conclude that we are actually observing dark matter via classical fields all the time and perhaps have even photographed it [75], [6].
4. Perhaps the most fascinating applications are in biology. The anomalous behavior ionic currents through cell membrane (low dissipation, quantal character, no change when the membrane is replaced with artificial one) has a natural explanation in terms of dark supra currents. This leads to a vision about how dark matter and phase transitions changing the value of Planck constant could relate to the basic functions of cell, functioning of DNA and aminoacids, and to the mysteries of bio-catalysis. This leads also a model for EEG interpreted as a communication and control tool of magnetic body containing dark matter and using biological body as motor instrument and sensory receptor. One especially shocking outcome is the emergence of genetic code of vertebrates from the model of dark nuclei as nuclear strings [47, 75], [47].

### 12.1.3 Brief summary about the generalization of the imbedding space concept

A brief summary of the basic vision in order might help reader to assimilate the more detailed representation about the generalization of imbedding space.

1. The hierarchy of Planck constants cannot be realized without generalizing the notions of imbedding space and space-time since particles with different values of Planck constant cannot appear in the same interaction vertex. This suggests some kind of book like structure for both  $M^4$  and  $CP_2$  factors of the generalized imbedding space is suggestive.
2. Schrödinger equation suggests that Planck constant corresponds to a scaling factor of  $M^4$  metric whose value labels different pages of the book. The scaling of  $M^4$  coordinate so that original metric results in  $M^4$  factor is possible so that the scaling of  $\hbar$  corresponds to the scaling of the size of causal diamond  $CD$  defined as the intersection of future and past directed light-cones. The light-like 3-surfaces having their 2-D and light-boundaries of  $CD$  are in a key role in the realization of zero energy states. The infinite-D spaces formed by these 3-surfaces define the fundamental sectors of the configuration space (world of classical worlds). Since the scaling of  $CD$  does not simply scale space-time surfaces, the coding of radiative corrections to the geometry of space-time sheets becomes possible and Kähler action can be seen as expansion in powers of  $\hbar/\hbar_0$ .
3. Quantum criticality of TGD Universe is one of the key postulates of quantum TGD. The most important implication is that Kähler coupling strength is analogous to critical temperature. The exact realization of quantum criticality would be in terms of critical sub-manifolds of  $M^4$  and  $CP_2$  common to all sectors of the generalized imbedding space. Quantum criticality would mean that the two kinds of number theoretic braids assignable to  $M^4$  and  $CP_2$  projections of the partonic 2-surface belong by the definition of number theoretic braids to these critical sub-manifolds. At the boundaries of  $CD$  associated with positive and negative energy parts of zero energy state in given time scale partonic two-surfaces belong to a fixed page of the Big Book whereas light-like 3-surface decomposes into regions corresponding to different values of Planck constant much like matter decomposes to several phases at thermodynamical criticality.
4. The connection with Jones inclusions was originally a purely heuristic guess based on the observation that the finite groups characterizing Jones inclusion characterize also pages of the Big Book. The key observation is that Jones inclusions are characterized by a finite subgroup  $G \subset SU(2)$  and that this group also characterizes the singular covering or factor spaces associated with  $CD$  or  $CP_2$  so that the pages of generalized imbedding space could indeed serve as correlates for Jones inclusions. The elements of the included algebra  $\mathcal{M}$  are invariant under the action of  $G$  and  $\mathcal{M}$  takes the role of complex numbers in the resulting non-commutative quantum theory.
5. The understanding of quantum TGD at parton level led to the realization that the dynamics of Kähler action realizes finite measurement resolution in terms of finite number of modes of the induced spinor field. This automatically implies cutoffs to the representations of various super-conformal algebras typical for the representations of quantum groups closely associated with Jones inclusions [7]. The Clifford algebra spanned by the fermionic oscillator operators would provide a realization for the factor space  $\mathcal{N}/\mathcal{M}$  of hyper-finite factors of type  $II_1$  identified as the infinite-dimensional Clifford algebra  $\mathcal{N}$  of the configuration space and included algebra  $\mathcal{M}$  determining the finite measurement resolution. The resulting quantum Clifford algebra has anti-commutation relations dictated by the fractionization of fermion number so that its unit becomes  $r = \hbar/\hbar_0$ .  $SU(2)$  Lie algebra transforms to its quantum variant corresponding to the quantum phase  $q = \exp(i2\pi/r)$ .
6. Jones inclusions appear as two variants corresponding to  $\mathcal{N} : \mathcal{M} < 4$  and  $\mathcal{N} : \mathcal{M} = 4$ . The tentative interpretation is in terms of singular  $G$ -factor spaces and  $G$ -coverings of  $M^4$  or  $CP_2$  in some sense. The alternative interpretation in terms of two geodesic spheres of  $CP_2$  would mean asymmetry between  $M^4$  and  $CP_2$  degrees of freedom.
7. Number theoretic Universality suggests an answer why the hierarchy of Planck constants is necessary. One must be able to define the notion of angle -or at least the notion of phase and of trigonometric functions- also in p-adic context. All that one can achieve naturally is the notion of phase defined as root of unity and introduced by allowing algebraic extension of p-adic number field by introducing the phase if needed. In the framework of TGD inspired theory of consciousness this inspires a vision about cognitive evolution as the gradual emergence of

increasingly complex algebraic extensions of p-adic numbers and involving also the emergence of improved angle resolution expressible in terms of phases  $\exp(i2\pi/n)$  up to some maximum value of  $n$ . The coverings and factor spaces would realize these phases geometrically and quantum phases  $q$  naturally assignable to Jones inclusions would realize them algebraically. Besides p-adic coupling constant evolution based on hierarchy of p-adic length scales there would be coupling constant evolution with respect to  $\hbar$  and associated with angular resolution.

## 12.2 Experimental input

In this section basic experimental inputs suggesting a hierarchy of Planck constants and the identification of dark matter as phases with non-standard value of Planck constant are discussed.

### 12.2.1 Hints for the existence of large $\hbar$ phases

Quantum classical correspondence suggests the identification of space-time sheets identifiable as quantum coherence regions. Since they can have arbitrarily large sizes, phases with arbitrarily large quantum coherence lengths and arbitrarily long de-coherence times seem to be possible in TGD Universe. In standard physics context this seems highly implausible. If Planck constant can have arbitrarily large values, the situation changes since Compton lengths and other quantum scales are proportional to  $\hbar$ . Dark matter is excellent candidate for large  $\hbar$  phases.

The expression for  $\hbar_{gr}$  in the model explaining the Bohr orbits for planets is of form  $\hbar_{gr} = GM_1M_2/v_0$  [64]. This suggests that the interaction is associated with some kind of interface between the systems, perhaps join along boundaries connecting the space-time sheets associated with systems possessing gravitational masses  $M_1$  and  $M_2$ . Also a large space-time sheet carrying the mutual classical gravitational field could be in question. This argument generalizes to the case  $\hbar/\hbar_0 = Q_1Q_2\alpha/v_0$  in case of generic phase transition to a strongly interacting phase with  $\alpha$  describing gauge coupling strength.

There exist indeed some experimental indications for the existence of phases with a large  $\hbar$ .

1. With inspiration coming from the finding of Nottale [10] I have proposed an explanation of dark matter as a macroscopic quantum phase with a large value of  $\hbar$  [64]. Any interaction, if sufficiently strong, can lead to this kind of phase. The increase of  $\hbar$  would make the fine structure constant  $\alpha$  in question small and guarantee the convergence of perturbation series.
2. Living matter could represent a basic example of large  $\hbar$  phase [23, 5]. Even ordinary condensed matter could be "partially dark" in many-sheeted space-time [25]. In fact, the realization of hierarchy of Planck constants leads to a considerably weaker notion of darkness stating that only the interaction vertices involving particles with different values of Planck constant are impossible and that the notion of darkness is relative notion. For instance, classical interactions and photon exchanges involving a phase transition changing the value of  $\hbar$  of photon are possible in this framework.
3. There is claim about a detection in RHIC (Relativistic Heavy Ion Collider in Brookhaven) of states behaving in some respects like mini black holes [13]. These states could have explanation as color flux tubes at Hagedorn temperature forming a highly tangled state and identifiable as stringy black holes of strong gravitation. The strings would carry a quantum coherent color glass condensate, and would be characterized by a large value of  $\hbar$  naturally resulting in confinement phase with a large value of  $\alpha_s$  [65]. The progress in hadronic mass calculations led to a concrete model of color glass condensate of single hadron as many-particle state of super-symplectic gluons [51, 45] - something completely new from the point of QCD - responsible for non-perturbative aspects of hadron physics. In RHIC events these color glass condensate would fuse to single large condensate. This condensate would be present also in ordinary black-holes and the blackness of black-hole would be darkness.
4. I have also discussed a model for cold fusion based on the assumption that nucleons can be in large  $\hbar$  phase. In this case the relevant strong interaction strength is  $Q_1Q_2\alpha_{em}$  for two nucleon clusters inside nucleus which can increase  $\hbar$  so large that the Compton length of protons becomes of order atomic size and nuclear protons form a macroscopic quantum phase [25, 23].

### 12.2.2 Quantum coherent dark matter and $\hbar$

The argument based on gigantic value of  $\hbar_{gr}$  explaining darkness of dark matter is attractive but one should be very cautious.

Consider first ordinary QED  $e = \sqrt{\alpha 4\pi\hbar}$  appears in vertices so that perturbation expansion in powers of  $\sqrt{\hbar}$  basically. This would suggest that large  $\hbar$  leads to large effects. All predictions are however in powers of alpha and large  $\hbar$  means small higher order corrections. What happens can be understood on basis of dimensional analysis. For instance, cross sections are proportional to  $(\hbar/m)^2$ , where  $m$  is the relevant mass and the remaining factor depends on  $\alpha = e^2/(4\pi\hbar)$  only. In the more general case tree amplitudes with  $n$  vertices are proportional to  $e^n$  and thus to  $\hbar^{n/2}$  and loop corrections give only powers of  $\alpha$  which get smaller when  $\hbar$  increases. This must relate to the powers of  $1/\hbar$  from the integration measure associated with the momentum loop integrals affected by the change of  $\alpha$ .

Consider now the effects of the scaling of  $\hbar$ . The scaling of Compton lengths and other quantum kinematical parameters is the most obvious effect. An obvious effect is due to the change of  $\hbar$  in the commutation relations and in the change of unit of various quantum numbers. In particular, the right hand side of oscillator operator commutation and anti-commutation relations is scaled. A further effect is due to the scaling of the eigenvalues of the modified Dirac operator  $\hbar\Gamma^\alpha D_\alpha$ .

The exponent  $exp(K)$  of Kähler function  $K$  defining perturbation series in the configuration space degrees of freedom is proportional to  $1/g_K^2$  and does not depend on  $\hbar$  at all if there is only single Planck constant. The propagator is proportional to  $g_K^2$ . This can be achieved also in QED by absorbing  $e$  from vertices to  $e^2$  in photon propagator. Hence it would seem that the dependence on  $\alpha_K$  (and  $\hbar$ ) must come from vertices which indeed involve Jones inclusions of the  $II_1$  factors of the incoming and outgoing lines.

This however suggests that the dependence of the scattering amplitudes on  $\hbar$  is purely kinematical so that all higher radiative corrections would be absent. This seems to leave only one option: the scale factors of covariant  $CD$  and  $CP_2$  metrics can vary and might have discrete spectrum of values.

1. The invariance of Kähler action with respect to overall scaling of metric however allows to keep  $CP_2$  metric fixed and consider only a spectrum for the scale factors of  $M^4$  metric.
2. The first guess motivated by Schrödinger equation is that the scaling factor of covariant  $CD$  metric corresponds the ratio  $r^2 = (\hbar/\hbar_0)^2$ . This would mean that the value of Kähler action depends on  $r^2$ . The scaling of  $M^4$  coordinate by  $r$  the metric reduces to the standard form but if causal diamonds with quantized temporal distance between their tips are the basic building blocks of the configuration space geometry as zero energy ontology requires, this scaling of  $\hbar$  scales the size of  $CD$  by  $r$  so that genuine effect results since  $M^4$  scalings are not symmetries of Kähler action.
3. In this picture  $r$  would code for radiative corrections to Kähler function and thus space-time physics. Even in the case that the radiative corrections to the configuration space functional integral vanish, as suggested by quantum criticality, they would be actually taken into account.

This kind of dynamics is not consistent with the original view about imbedding space and forces to generalize the notion of imbedding spaces since it is clear that particles with different Planck constants cannot appear in the same vertex of Feynman diagram. Somehow different values of Planck constant must be analogous to different pages of book having almost copies of imbedding space as pages. A possible resolution of the problem comes from the realization that the fundamental structure might be the inclusion hierarchy of number theoretical Clifford algebras from which entire TGD could emerge including generalization of the imbedding space concept.

### 12.2.3 The phase transition changing the value of Planck constant as a transition to non-perturbative phase

**A phase transition increasing  $\hbar$  as a transition guaranteeing the convergence of perturbation theory**

The general vision is that a phase transition increasing  $\hbar$  occurs when perturbation theory ceases to converge. Very roughly, this would occur when the parameter  $x = Q_1 Q_2 \alpha$  becomes larger than

one. The net quantum numbers for "spontaneously magnetized" regions provide new natural units for quantum numbers. The assumption that standard quantization rules prevail poses very strong restrictions on allowed physical states and selects a subspace of the original configuration space. One can of course, consider the possibility of giving up these rules at least partially in which case a spectrum of fractionally charged anyon like states would result with confinement guaranteed by the fractionization of charges.

The necessity of large  $\hbar$  phases has been actually highly suggestive since the first days of quantum mechanics. The classical looking behavior of macroscopic quantum systems remains still a poorly understood problem and large  $\hbar$  phases provide a natural solution of the problem.

In TGD framework quantum coherence regions correspond to space-time sheets. Since their sizes are arbitrarily large the conclusion is that macroscopic and macro-temporal coherence are possible in all scales. Standard quantum theory definitely fails to predict this and the conclusion is that large  $\hbar$  phases for which quantum length and time scales are proportional to  $\hbar$  and long are needed.

Somewhat paradoxically, large  $\hbar$  phases explain the effective classical behavior in long length and time scales. Quantum perturbation theory is an expansion in terms of gauge coupling strengths inversely proportional to  $\hbar$  and thus at the limit of large  $\hbar$  classical approximation becomes exact. Also the Coulombic contribution to the binding energies of atoms vanishes at this limit. The fact that we experience world as a classical only tells that large  $\hbar$  phase is essential for our sensory perception. Of course, this is not the whole story and the full explanation requires a detailed anatomy of quantum jump.

### The criterion for the occurrence of the phase transition increasing the value of $\hbar$

In the case of planetary orbits the large value of  $\hbar_{gr} = 2GM/v_0$  makes possible to apply Bohr quantization to planetary orbits. This leads to a more general idea that the phase transition increasing  $\hbar$  occurs when the system consisting of interacting units with charges  $Q_i$  becomes non-perturbative in the sense that the perturbation series in the coupling strength  $\alpha Q_i Q_j$ , where  $\alpha$  is the appropriate coupling strength and  $Q_i Q_j$  represents the maximum value for products of gauge charges, ceases to converge. Thus Mother Nature would resolve the problems of theoretician. A primitive formulation for this criterion is the condition  $\alpha Q_i Q_j \geq 1$ .

The first working hypothesis was the existence of dark matter hierarchies with  $\hbar = \lambda^k \hbar_0$ ,  $k = 0, 1, \dots$ ,  $\lambda = n/v_0$  or  $\lambda = 1/nv_0$ ,  $v_0 \simeq 2^{-11}$ . This rule turned out to be quite too specific. The mathematically plausible formulation predicts that in principle any rational value for  $r = \hbar(M^4)/\hbar(CP_2)$  is possible but there are certain number theoretically preferred values of  $r$  such as those coming powers of 2.

## 12.3 A generalization of the notion of imbedding space as a realization of the hierarchy of Planck constants

In the following the basic ideas concerning the realization of the hierarchy of Planck constants are summarized and after that a summary about generalization of the imbedding space is given. In [57] the important delicacies associated with the Kähler structure of generalized imbedding space are discussed. The background for the recent vision is quite different from that for half decade ago. Zero energy ontology and the notion of causal diamond, number theoretic compactification leading to the precise identification of number theoretic braids, the realization of number theoretic universality, and the understanding of the quantum dynamics at the level of modified Dirac action fix to a high degree the vision about generalized imbedding space.

### 12.3.1 Basic ideas

The first key idea in the geometric realization of the hierarchy of Planck constants emerges from the study of Schrödinger equation and states that Planck constant appears a scaling factor of  $M^4$  metric. Second key idea is the connection with Jones inclusions inspiring an explicit formula for Planck constants. For a long time this idea remained heuristic must-be-true feeling but the recent view about quantum TGD provide a justification for it.

### Scaling of Planck constant and scalings of $CD$ and $CP_2$ metrics

The key property of Schrödinger equation is that kinetic energy term depends on  $\hbar$  whereas the potential energy term has no dependence on it. This makes the scaling of  $\hbar$  a non-trivial transformation. If the contravariant metric scales as  $r = \hbar/\hbar_0$  the effect of scaling of Planck constant is realized at the level of imbedding space geometry provided it is such that it is possible to compare the regions of generalized imbedding space having different value of Planck constant.

In the case of Dirac equation same conclusion applies and corresponds to the minimal substitution  $p - eA \rightarrow i\hbar\nabla - eA$ . Consider next the situation in TGD framework.

1. The minimal substitution  $p - eA \rightarrow i\hbar\nabla - eA$  does not make sense in the case of  $CP_2$  Dirac operator since, by the non-triviality of spinor connection, one cannot choose the value of  $\hbar$  freely. In fact, spinor connection of  $CP_2$  is defined in such a manner that spinor connection corresponds to the quantity  $\hbar eQA$ , where denotes  $A$  gauge potential, and there is no natural manner to separate  $\hbar e$  from it.
2. The contravariant  $CD$  metric scales like  $\hbar^2$ . In the case of Dirac operator in  $M^4 \times CP_2$  one can assign separate Planck constants to Poincare and color algebras and the scalings of  $CD$  and  $CP_2$  metrics induce scalings of corresponding values of  $\hbar^2$ . As far as Kähler action is considered,  $CP_2$  metric could be always thought of being scaled to its standard form.
3. Dirac equation gives the eigenvalues of wave vector squared  $k^2 = k^i k_i$  rather than four-momentum squared  $p^2 = p^i p_i$  in  $CD$  degrees of freedom and its analog in  $CP_2$  degrees of freedom. The values of  $k^2$  are proportional to  $1/r^2$  so that  $p^2$  does not depend on it for  $p^i = \hbar k^i$ : analogous conclusion applies in  $CP_2$  degrees of freedom. This gives rise to the invariance of mass squared and the desired scaling of wave vector when  $\hbar$  changes.

This consideration generalizes to the case of the induced gamma matrices and induced metric in  $X^4$ , modified Dirac operator, and Kähler action which carry dynamical information about the ratio  $r = \hbar_{eff}/\hbar_0$ .

### Kähler function codes for a perturbative expansion in powers of $\hbar(CD)/\hbar(CP_2)$

Suppose that one accepts that the spectrum of  $CD$  resp.  $CP_2$  Planck constants is accompanied by a hierarchy of overall scalings of covariant  $CD$  (causal diamond) metric by  $(\hbar(M^4)/\hbar_0)^2$  and  $CP_2$  metric by  $(\hbar(CP_2)/\hbar_0)^2$  followed by overall scaling by  $r^2 = (\hbar_0/\hbar(CP_2))^2$  so that  $CP_2$  metric suffers no scaling and difficulties with isometric gluing procedure of sectors are avoided.

The first implication of this picture is that the modified Dirac operator determined by the induced metric and spinor structure depends on  $r$  in a highly nonlinear manner but there is no dependence on the overall scaling of the  $H$  metric. This in turn implies that the fermionic oscillator algebra used to define configuration space spinor structure and metric depends on the value of  $r$ . Same is true also for Kähler action and configuration space Kähler function. Hence Kähler function is analogous to an effective action expressible as infinite series in powers of  $r$ .

This interpretation allows to overcome the paradox caused by the hypothesis that loop corrections to the functional integral over configuration space defined by the exponent of Kähler function serving as vacuum functional vanish so that tree approximation is exact. This would imply that all higher order corrections usually interpreted in terms of perturbative series in powers of  $1/\hbar$  vanish. The paradox would result from the fact that scattering amplitudes would not receive higher order corrections and classical approximation would be exact.

The dependence of both states created by Super Kac-Moody algebra and the Kähler function and corresponding propagator identifiable as contravariant configuration space metric would mean that the expressions for scattering amplitudes indeed allow an expression in powers of  $r$ . What is so remarkable is that the TGD approach would be non-perturbative from the beginning and "semiclassical" approximation, which might be actually exact, automatically would give a full expansion in powers of  $r$ . This is in a sharp contrast to the usual quantization approach.

### Jones inclusions and hierarchy of Planck constants

From the beginning it was clear that Jones inclusions of hyper-finite factors of type  $II_1$  are somehow related to the hierarchy of Planck constants. The basic motivation for this belief has been that

configuration space Clifford algebra provides a canonical example of hyper-finite factor of type  $II_1$  and that Jones inclusion of these Clifford algebras is excellent candidate for a first principle description of finite measurement resolution.

Consider the inclusion  $\mathcal{N} \subset \mathcal{M}$  of hyper-finite factors of type  $II_1$  [83]. A deep result is that one can express  $\mathcal{M}$  as  $\mathcal{N} : \mathcal{M}$ -dimensional module over  $\mathcal{N}$  with fractal dimension  $\mathcal{N} : \mathcal{M} = B_n$ .  $\sqrt{b_n}$  represents the dimension of a space of spinor space renormalized from the value 2 corresponding to  $n = \infty$  down to  $\sqrt{b_n} = 2\cos(\pi/n)$  varying thus in the range  $[1, 2]$ .  $B_n$  in turn would represent the dimension of the corresponding Clifford algebra. The interpretation is that finite measurement resolution introduces correlations between components of quantum spinor implying effective reduction of the dimension of quantum spinors providing a description of the factor space  $\mathcal{N}/\mathcal{M}$ .

This would suggest that somehow the hierarchy of Planck constants must represent finite measurement resolution and since phase factors coming as roots of unity are naturally associated with Jones inclusions the natural guess was that angular resolution and coupling constant evolution associated with it is in question. This picture would suggest that the realization of the hierarchy of Planck constant in terms of a book like structure of generalized imbedding space provides also a geometric realization for a hierarchy of Jones inclusions.

The notion of number theoretic braid and realization that the modified Dirac operator has only finite number of generalized eigenmodes -thanks to the vacuum degeneracy of Kähler action- finally led to the understanding how the notion of finite measurement resolution is coded to the Kähler action and the realized in practice by second quantization of induced spinor fields and how these spinor fields endowed with q-anticommutation relations give rise to a representations of finite-quantum dimensional factor spaces  $\mathcal{N}/\mathcal{M}$  associated with the hierarchy of Jones inclusions having generalized imbedding space as space-time correlate. This means enormous simplification since infinite-dimensional spinor fields in infinite-dimensional world of classical worlds are replaced with finite-quantum-dimensional spinor fields in discrete points sets provided by number theoretic braids.

The study of a concrete model for Jones inclusions in terms of finite subgroups  $G$  of  $SU(2)$  defining sub-algebras of infinite-dimensional Clifford algebra as fixed point sub-algebras leads to what looks like a correct track concerning the understanding of quantization of Planck constants.

The ADE diagrams of  $A_n$  and  $D_{2n}$  characterize cyclic and dihedral groups whereas those of  $E_6$  and  $E_8$  characterize tetrahedral and icosahedral groups. This approach leads to the hypothesis that the scaling factor of Planck constant assignable to Poincare (color) algebra corresponds to the order of the maximal cyclic subgroup of  $G_b \subset SU(2)$  ( $G_a \subset SL(2, C)$ ) acting as symmetry of space-time sheet in  $CP_2$  ( $CD$ ) degrees of freedom. It predicts arbitrarily large  $CD$  and  $CP_2$  Planck constants in the case of  $A_n$  and  $D_{2n}$  under rather general assumptions.

There are two manners for how  $G_a$  and  $G_b$  can act as symmetries corresponding to  $G_i$  coverings and factor spaces. These coverings and factor spaces are singular and associated with spaces  $\hat{CD} \setminus M^2$  and  $CP_2 \setminus S_I^2$ , where  $S_I^2$  is homologically trivial geodesic sphere of  $CP_2$ . The physical interpretation is that  $M^2$  and  $S_I^2$  fix preferred quantization axes for energy and angular moment and color quantum numbers so that also a connection with quantum measurement theory emerges.

### 12.3.2 The vision

A brief summary of the basic vision behind the generalization of the imbedding space concept needed to realize the hierarchy of Planck constants is in order before going to the detailed representation.

1. The hierarchy of Planck constants cannot be realized without generalizing the notions of imbedding space and space-time because particles with different values of Planck constant cannot appear in the same interaction vertex. Some kind of book like structure for the generalized imbedding space forced also by p-adicization but in different sense is suggestive. Both  $M^4$  and  $CP_2$  factors would have the book like structure so that a Cartesian product of books would be in question.
2. The study of Schrödinger equation suggests that Planck constant corresponds to a scaling factor of  $CD$  metric whose value labels different pages of the book. The scaling of  $M^4$  coordinate so that original metric results in  $CD$  factor is possible so that the interpretation for scaled up value of  $\hbar$  is as scaling of the size of causal diamond  $CD$ .

3. The light-like 3-surfaces having their 2-D and light-boundaries of  $CD$  are in a key role in the realization of zero energy states, and the infinite-D spaces of light-like 3-surfaces inside scaled variants of  $CD$  define the fundamental building brick of the configuration space (world of classical worlds). Since the scaling of  $CD$  does not simply scale space-time surfaces the effect of scaling on classical and quantum dynamics is non-trivial and a coupling constant evolution results and the coding of radiative corrections to the geometry of space-time sheets becomes possible. The basic geometry of  $CD$  suggests that the allowed sizes of  $CD$  come in the basic sector  $\hbar = \hbar_0$  as powers of two. This predicts p-adic length scale hypothesis and lead to number theoretically universal discretized p-adic coupling constant evolution. Since the scaling is accompanied by a formation of singular coverings and factor spaces, different scales are distinguished at the level of topology. p-Adic length scale hierarchy affords similar characterization of length scales in terms of effective topology.
4. The idea that TGD Universe is quantum critical in some sense is one of the key postulates of quantum TGD. The basic ensuing prediction is that Kähler coupling strength is analogous to critical temperature. Quantum criticality in principle fixes the p-adic evolution of various coupling constants also the value of gravitational constant. The exact realization of quantum criticality would be in terms of critical sub-manifolds of  $M^4$  and  $CP_2$  common to all sectors of the generalized imbedding space. Quantum criticality of TGD Universe means that the two kinds of number theoretic braids assignable to  $M^4$  and  $CP_2$  projections of the partonic 2-surface belong by the very definition of number theoretic braids to these critical sub-manifolds. At the boundaries of  $CD$  associated with positive and negative energy parts of zero energy state in a given time scale partonic two-surfaces belong to a fixed page of the Big Book whereas light-like 3-surface decomposes to regions corresponding to different values of Planck constant much like matter decomposes to several phases at criticality.

The connection with Jones inclusions was originally a purely heuristic guess, and it took half decade to really understand why and how they are involved. The notion of measurement resolution is the key concept.

1. The key observation is that Jones inclusions are characterized by a finite subgroup  $G \subset SU(2)$  and the this group also characterizes the singular covering or factor spaces associated with  $CD$  or  $CP_2$  so that the pages of generalized imbedding space could indeed serve as correlates for Jones inclusions.
2. The dynamics of Kähler action realizes finite measurement resolution in terms of finite number of modes of the induced spinor field automatically implying cutoffs to the representations of various super-conformal algebras typical for the representations of quantum groups associated with Jones inclusions. The interpretation of the Clifford algebra spanned by the fermionic oscillator operators is as a realization for the concept of the factor space  $\mathcal{N}/\mathcal{M}$  of hyper-finite factors of type II<sub>1</sub> identified as the infinite-dimensional Clifford algebra  $\mathcal{N}$  of the configuration space and included algebra  $\mathcal{M}$  determining the finite measurement resolution for angle measurement in the sense that the action of this algebra on zero energy state has no detectable physical effects.  $\mathcal{M}$  takes the role of complex numbers in quantum theory and makes physics non-commutative. The resulting quantum Clifford algebra has anti-commutation relations dictated by the fractionization of fermion number so that unit becomes  $r = \hbar/\hbar_0$ .  $SU(2)$  Lie algebra transforms to its quantum variant corresponding to the quantum phase  $q = \exp(i2\pi/r)$ .
3.  $G$  invariance for the elements of the included algebra can be interpreted in terms of finite measurement resolution in the sense that action by  $G$  invariant Clifford algebra element has no detectable effects. Quantum groups realize this view about measurement resolution for angle measurement. The  $G$ -invariance of the physical states created by fermionic oscillator operators which by definition are not  $G$  invariant guarantees that quantum states as a whole have non-fractional quantum numbers so that the leakage between different pages is possible in principle. This hypothesis is consistent with the TGD inspired model of quantum Hall effect [57].
4. Concerning the formula for Planck constant in terms of the integers  $n_a$  and  $n_b$  characterizing orders of the maximal cyclic subgroups of groups  $G_a$  and  $G_b$  defining coverings and factor spaces associated with  $CD$  and  $CP_2$  the basic constraint is that the overall scaling of  $H$  metric has no

effect on physics. What matters is the ratio of Planck constants  $r = \hbar(M^4)/\hbar(CP_2)$  appearing as a scaling factor of  $M^4$  metric. This leaves two options if one requires that the Planck constant defines a homomorphism. The model for dark gravitons suggests a unique choice between these two options but one must keep still mind open for the alternative.

5. Jones inclusions appear as two variants corresponding to  $\mathcal{N} : \mathcal{M} < 4$  and  $\mathcal{N} : \mathcal{M} = 4$ . The tentative interpretation is in terms of singular  $G$ -factor spaces and  $G$ -coverings of  $M^4$  and  $CP_2$  in some sense. The alternative interpretation assigning the inclusions to the two different geodesic spheres of  $CP_2$  would mean asymmetry between  $M^4$  and  $CP_2$  degrees of freedom and is therefore not convincing.
6. The natural question is why the hierarchy of Planck constants is needed. Is it really necessary? Number theoretic Universality suggests that this is the case. One must be able to define the notion of angle -or at least the notion of phase and of trigonometric functions- also in the p-adic context. All that one can achieve naturally is the notion of phase defined as a root of unity and introduced by allowing algebraic extension of p-adic number field by introducing the phase. In the framework of TGD inspired theory of consciousness this inspires a vision about cognitive evolution as the gradual emergence of increasingly complex algebraic extensions of p-adic numbers and involving also the emergence of improved angle resolution expressible in terms of phases  $\exp(i2\pi/n)$  up to some maximum value of  $n$ . The coverings and factor spaces would realize these phases purely geometrically and quantum phases  $q$  assignable to Jones inclusions would realize them algebraically. Besides p-adic coupling constant evolution based on the hierarchy of p-adic length scales there would be coupling constant evolution with respect to  $\hbar$  and associated with angular resolution.

### 12.3.3 Hierarchy of Planck constants and the generalization of the notion of imbedding space

In the following the recent view about structure of imbedding space forced by the quantization of Planck constant is summarized. The question is whether it might be possible in some sense to replace  $H$  or its Cartesian factors by their necessarily singular multiple coverings and factor spaces. One can consider two options: either  $M^4$  or the causal diamond  $CD$ . The latter one is the more plausible option from the point of view of WCW geometry.

#### The evolution of physical ideas about hierarchy of Planck constants

The evolution of the physical ideas related to the hierarchy of Planck constants and dark matter as a hierarchy of phases of matter with non-standard value of Planck constants was much faster than the evolution of mathematical ideas and quite a number of applications have been developed during last five years.

1. The starting point was the proposal of Nottale [10] that the orbits of inner planets correspond to Bohr orbits with Planck constant  $\hbar_{gr} = GMm/v_0$  and outer planets with Planck constant  $\hbar_{gr} = 5GMm/v_0$ ,  $v_0/c \simeq 2^{-11}$ . The basic proposal [64] was that ordinary matter condenses around dark matter which is a phase of matter characterized by a non-standard value of Planck constant whose value is gigantic for the space-time sheets mediating gravitational interaction. The interpretation of these space-time sheets could be as magnetic flux quanta or as massless extremals assignable to gravitons.
2. Ordinary particles possibly residing at these space-time sheet have enormous value of Compton length meaning that the density of matter at these space-time sheets must be very slowly varying. The string tension of string like objects implies effective negative pressure characterizing dark energy so that the interpretation in terms of dark energy might make sense [65]. TGD predicted a one-parameter family of Robertson-Walker cosmologies with critical or over-critical mass density and the "pressure" associated with these cosmologies is negative.
3. The quantization of Planck constant does not make sense unless one modifies the view about standard space-time is. Particles with different Planck constant must belong to different worlds in the sense local interactions of particles with different values of  $\hbar$  are not possible. This inspires

the idea about the book like structure of the imbedding space obtained by gluing almost copies of  $H$  together along common "back" and partially labeled by different values of Planck constant.

4. Darkness is a relative notion in this framework and due to the fact that particles at different pages of the book like structure cannot appear in the same vertex of the generalized Feynman diagram. The phase transitions in which partonic 2-surface  $X^2$  during its travel along  $X_l^3$  leaks to another page of book are however possible and change Planck constant. Particle (say photon -) exchanges of this kind allow particles at different pages to interact. The interactions are strongly constrained by charge fractionization and are essentially phase transitions involving many particles. Classical interactions are also possible. It might be that we are actually observing dark matter via classical fields all the time and perhaps have even photographed it [75].
5. The realization that non-standard values of Planck constant give rise to charge and spin fractionization and anyonization led to the precise identification of the prerequisites of anyonic phase [57]. If the partonic 2-surface, which can have even astrophysical size, surrounds the tip of  $CD$ , the matter at the surface is anyonic and particles are confined at this surface. Dark matter could be confined inside this kind of light-like 3-surfaces around which ordinary matter condenses. If the radii of the basic pieces of these nearly spherical anyonic surfaces - glued to a connected structure by flux tubes mediating gravitational interaction - are given by Bohr rules, the findings of Nottale [10] can be understood. Dark matter would resemble a high degree matter in black holes replaced in TGD framework by light-like partonic 2-surfaces with a minimum size of order Schwarzschild radius  $r_S$  of order scaled up Planck length  $l_{Pl} = \sqrt{\hbar_{gr}G} = GM$ . Black hole entropy is inversely proportional to  $\hbar$  and predicted to be of order unity so that dramatic modification of the picture about black holes is implied.
6. Perhaps the most fascinating applications are in biology. The anomalous behavior ionic currents through cell membrane (low dissipation, quantal character, no change when the membrane is replaced with artificial one) has a natural explanation in terms of dark supra currents. This leads to a vision about how dark matter and phase transitions changing the value of Planck constant could relate to the basic functions of cell, functioning of DNA and aminoacids, and to the mysteries of bio-catalysis. This leads also a model for EEG interpreted as a communication and control tool of magnetic body containing dark matter and using biological body as motor instrument and sensory receptor. One especially amazing outcome is the emergence of genetic code of vertebrates from the model of dark nuclei as nuclear strings [47, 75], [47].

### The most general option for the generalized imbedding space

Simple physical arguments pose constraints on the choice of the most general form of the imbedding space.

1. The fundamental group of the space for which one constructs a non-singular covering space or factor space should be non-trivial. This is certainly not possible for  $M^4$ ,  $CD$ ,  $CP_2$ , or  $H$ . One can however construct singular covering spaces. The fixing of the quantization axes implies a selection of the sub-space  $H_4 = M^2 \times S^2 \subset M^4 \times CP_2$ , where  $S^2$  is geodesic sphere of  $CP_2$ .  $\hat{M}^4 = M^4 \setminus M^2$  and  $\hat{CP}_2 = CP_2 \setminus S^2$  have fundamental group  $Z$  since the codimension of the excluded sub-manifold is equal to two and homotopically the situation is like that for a punctured plane. The exclusion of these sub-manifolds defined by the choice of quantization axes could naturally give rise to the desired situation.
2.  $CP_2$  allows two geodesic spheres which left invariant by  $U(2)$  resp.  $SO(3)$ . The first one is homologically non-trivial. For homologically non-trivial geodesic sphere  $H_4 = M^2 \times S^2$  represents a straight cosmic string which is non-vacuum extremal of Kähler action (not necessarily preferred extremal). One can argue that the many-valuedness of  $\hbar$  is un-acceptable for non-vacuum extremals so that only homologically trivial geodesic sphere  $S^2$  would be acceptable. One could go even further. If the extremals in  $M^2 \times CP_2$  can be preferred non-vacuum extremals, the singular coverings of  $M^4$  are not possible. Therefore only the singular coverings and factor spaces of  $CP_2$  over the homologically trivial geodesic sphere  $S^2$  would be possible. This however looks a non-physical outcome.

- (a) The situation changes if the extremals of type  $M^2 \times Y^2$ ,  $Y^2$  a holomorphic surface of  $CP_3$ , fail to be hyperquaternionic. The tangent space  $M^2$  represents hypercomplex sub-space and the product of the modified gamma matrices associated with the tangent spaces of  $Y^2$  should belong to  $M^2$  algebra. This need not be the case in general.
  - (b) The situation changes also if one reinterprets the gluing procedure by introducing scaled up coordinates for  $M^4$  so that metric is continuous at  $M^2 \times CP_2$  but  $CD$ s with different size have different sizes differing by the ratio of Planck constants and would thus have only piece of lower or upper boundary in common.
3. For the more general option one would have four different options corresponding to the Cartesian products of singular coverings and factor spaces. These options can be denoted by  $C - C$ ,  $C - F$ ,  $F - C$ , and  $F - F$ , where  $C$  ( $F$ ) signifies for covering (factor space) and first (second) letter signifies for  $CD$  ( $CP_2$ ) and correspond to the spaces  $(\hat{C}D \hat{\times} G_a) \times (CP_2 \hat{\times} G_b)$ ,  $(\hat{C}D \hat{\times} G_a) \times CP_2/G_b$ ,  $\hat{C}D/G_a \times (CP_2 \hat{\times} G_b)$ , and  $\hat{C}D/G_a \times CP_2/G_b$ .
  4. The groups  $G_i$  could correspond to cyclic groups  $Z_n$ . One can also consider an extension by replacing  $M^2$  and  $S^2$  with its orbit under more general group  $G$  (say tetrahedral, octahedral, or icosahedral group). One expects that the discrete subgroups of  $SU(2)$  emerge naturally in this framework if one allows the action of these groups on the singular sub-manifolds  $M^2$  or  $S^2$ . This would replace the singular manifold with a set of its rotated copies in the case that the subgroups have genuinely 3-dimensional action (the subgroups which corresponds to exceptional groups in the ADE correspondence). For instance, in the case of  $M^2$  the quantization axes for angular momentum would be replaced by the set of quantization axes going through the vertices of tetrahedron, octahedron, or icosahedron. This would bring non-commutative homotopy groups into the picture in a natural manner.

### About the phase transitions changing Planck constant

There are several non-trivial questions related to the details of the gluing procedure and phase transition as motion of partonic 2-surface from one sector of the imbedding space to another one.

1. How the gluing of copies of imbedding space at  $M^2 \times CP_2$  takes place? It would seem that the covariant metric of  $CD$  factor proportional to  $\hbar^2$  must be discontinuous at the singular manifold since only in this manner the idea about different scaling factor of  $CD$  metric can make sense. On the other hand, one can always scale the  $M^4$  coordinates so that the metric is continuous but the sizes of  $CD$ s with different Planck constants differ by the ratio of the Planck constants.
2. One might worry whether the phase transition changing Planck constant means an instantaneous change of the size of partonic 2-surface in  $M^4$  degrees of freedom. This is not the case. Light-likeness in  $M^2 \times S^2$  makes sense only for surfaces  $X^1 \times D^2 \subset M^2 \times S^2$ , where  $X^1$  is light-like geodesic. The requirement that the partonic 2-surface  $X^2$  moving from one sector of  $H$  to another one is light-like at  $M^2 \times S^2$  irrespective of the value of Planck constant requires that  $X^2$  has single point of  $M^2$  as  $M^2$  projection. Hence no sudden change of the size  $X^2$  occurs.
3. A natural question is whether the phase transition changing the value of Planck constant can occur purely classically or whether it is analogous to quantum tunneling. Classical non-vacuum extremals of Chern-Simons action have two-dimensional  $CP_2$  projection to homologically non-trivial geodesic sphere  $S^2_I$ . The deformation of the entire  $S^2_I$  to homologically trivial geodesic sphere  $S^2_{II}$  is not possible so that only combinations of partonic 2-surfaces with vanishing total homology charge (Kähler magnetic charge) can in principle move from sector to another one, and this process involves fusion of these 2-surfaces such that  $CP_2$  projection becomes single homologically trivial 2-surface. A piece of a non-trivial geodesic sphere  $S^2_I$  of  $CP_2$  can be deformed to that of  $S^2_{II}$  using 2-dimensional homotopy flattening the piece of  $S^2$  to curve. If this homotopy cannot be chosen to be light-like, the phase transitions changing Planck constant take place only via quantum tunnelling. Obviously the notions of light-like homotopies (cobordisms) are very relevant for the understanding of phase transitions changing Planck constant.

**How one could fix the spectrum of Planck constants?**

The question how the observed Planck constant relates to the integers  $n_a$  and  $n_b$  defining the covering and factors spaces, is far from trivial and I have considered several options. The basic physical inputs are the condition that scaling of Planck constant must correspond to the scaling of the metric of  $CD$  (that is Compton lengths) on one hand and the scaling of the gauge coupling strength  $g^2/4\pi\hbar$  on the other hand.

1. One can assign to Planck constant to both  $CD$  and  $CP_2$  by assuming that it appears in the commutation relations of corresponding symmetry algebras. Algebraist would argue that Planck constants  $\hbar(CD)$  and  $\hbar(CP_2)$  must define a homomorphism respecting multiplication and division (when possible) by  $G_i$ . This requires  $r(X) = \hbar(X)\hbar_0 = n$  for covering and  $r(X) = 1/n$  for factor space or vice versa.
2. If one assumes that  $\hbar^2(X)$ ,  $X = M^4$ ,  $CP_2$  corresponds to the scaling of the covariant metric tensor  $g_{ij}$  and performs an over-all scaling of  $H$ -metric allowed by the Weyl invariance of Kähler action by dividing metric with  $\hbar^2(CP_2)$ , one obtains the scaling of  $M^4$  covariant metric by  $r^2 \equiv \hbar^2/\hbar_0^2 = \hbar^2(M^4)/\hbar^2(CP_2)$  whereas  $CP_2$  metric is not scaled at all.
3. The condition that  $\hbar$  scales as  $n_a$  is guaranteed if one has  $\hbar(CD) = n_a\hbar_0$ . This does not fix the dependence of  $\hbar(CP_2)$  on  $n_b$  and one could have  $\hbar(CP_2) = n_b\hbar_0$  or  $\hbar(CP_2) = \hbar_0/n_b$ . The intuitive picture is that  $n_b$ - fold covering gives in good approximation rise to  $n_a n_b$  sheets and multiplies YM action action by  $n_a n_b$  which is equivalent with the  $\hbar = n_a n_b \hbar_0$  if one effectively compresses the covering to  $CD \times CP_2$ . One would have  $\hbar(CP_2) = \hbar_0/n_b$  and  $\hbar = n_a n_b \hbar_0$ . Note that the descriptions using ordinary Planck constant and coverings and scaled Planck constant but contracting the covering would be alternative descriptions.

This gives the following formulas  $r \equiv \hbar/\hbar_0 = r(M^4)/r(CP_2)$  in various cases.

$C - C$	$F - C$	$C - F$	$F - F$
$r$	$n_a n_b$	$\frac{n_a}{n_b}$	$\frac{n_b}{n_a}$
			$\frac{1}{n_a n_b}$

**Preferred values of Planck constants**

Number theoretic considerations favor the hypothesis that the integers corresponding to Fermat polygons constructible using only ruler and compass and given as products  $n_F = 2^k \prod_s F_s$ , where  $F_s = 2^{2^s} + 1$  are distinct Fermat primes, are favored. The reason would be that quantum phase  $q = \exp(i\pi/n)$  is in this case expressible using only iterated square root operation by starting from rationals. The known Fermat primes correspond to  $s = 0, 1, 2, 3, 4$  so that the hypothesis is very strong and predicts that p-adic length scales have satellite length scales given as multiples of  $n_F$  of fundamental p-adic length scale.  $n_F = 2^{11}$  corresponds in TGD framework to a fundamental constant expressible as a combination of Kähler coupling strength,  $CP_2$  radius and Planck length appearing in the expression for the tension of cosmic strings, and the powers of  $2^{11}$  was proposed to define favored as values of  $n_a$  in living matter [24].

The hypothesis that Mersenne primes  $M_k = 2^k - 1$ ,  $k \in \{89, 107, 127\}$ , and Gaussian Mersennes  $M_{G,k} = (1 + i)k - 1$ ,  $k \in \{113, 151, 157, 163, 167, 239, 241.. \}$  (the number theoretical miracle is that all the four p-adic length scales with  $k \in \{151, 157, 163, 167\}$  are in the biologically highly interesting range 10 nm-2.5  $\mu$ m) define scaled up copies of electro-weak and QCD type physics with ordinary value of  $\hbar$  and that these physics are induced by dark variants of corresponding lower level physics leads to a prediction for the preferred values of  $r = 2^{k_d}$ ,  $k_d = k_i - k_j$ , and the resulting picture finds support from the ensuing models for biological evolution and for EEG [24]. This hypothesis - to be referred to as Mersenne hypothesis - replaces the rather ad hoc proposal  $r = \hbar/\hbar_0 = 2^{11k}$  for the preferred values of Planck constant.

**How Planck constants are visible in Kähler action?**

$\hbar(M^4)$  and  $\hbar(CP_2)$  appear in the commutation and anticommutation relations of various superconformal algebras. Only the ratio of  $M^4$  and  $CP_2$  Planck constants appears in Kähler action and is

due to the fact that the  $M^4$  and  $CP_2$  metrics of the imbedding space sector with given values of Planck constants are proportional to the corresponding Planck. This implies that Kähler function codes for radiative corrections to the classical action, which makes possible to consider the possibility that higher order radiative corrections to functional integral vanish as one might expect at quantum criticality. For a given p-adic length scale space-time sheets with all allowed values of Planck constants are possible. Hence the spectrum of quantum critical fluctuations could in the ideal case correspond to the spectrum of  $\hbar$  coding for the scaled up values of Compton lengths and other quantal lengths and times. If so, large  $\hbar$  phases could be crucial for understanding of quantum critical superconductors, in particular high  $T_c$  superconductors.

### A simple model for fractional quantum Hall effect

The generalization of the imbedding space suggests that it could possible to understand fractional quantum Hall effect [2] at the level of basic quantum TGD as integer QHE for non-standard value of Planck constant.

The formula for the quantized Hall conductance is given by

$$\begin{aligned}\sigma &= \nu \times \frac{e^2}{h} , \\ \nu &= \frac{n}{m} .\end{aligned}\tag{12.3.1}$$

Series of fractions in  $\nu = 1/3, 2/5, 3/7, 4/9, 5/11, 6/13, 7/15, \dots, 2/3, 3/5, 4/7, 5/9, 6/11, 7/13, \dots, 5/3, 8/5, 11/7, 14/9, \dots, 4/3, 7/5, 10/7, 13/9, \dots, 1/5, 2/9, 3/13, \dots, 2/7, 3/11, \dots, 1/7, \dots$  with odd denominator have been observed as are also  $\nu = 1/2$  and  $\nu = 5/2$  states with even denominator [2] .

The model of Laughlin [13] cannot explain all aspects of FQHE. The best existing model proposed originally by Jain is based on composite fermions resulting as bound states of electron and even number of magnetic flux quanta [11] . Electrons remain integer charged but due to the effective magnetic field electrons appear to have fractional charges. Composite fermion picture predicts all the observed fractions and also their relative intensities and the order in which they appear as the quality of sample improves.

Before proposing the TGD based model of FQHE as IQHE with non-standard value of Planck constant, it is good to represent a simple explanation of IQHE effect. Choose the coordinates of the current carrying slab so that  $x$  varies in the direction of Hall current and  $y$  in the direction of the main current. For IQHE the value of Hall conductivity is given by  $\sigma = j_y/E_x = n_e e v / v B = n_e e / B = N e^2 / h B S = N e^2 / m h$ , where  $m$  characterizes the value of magnetized flux and  $N$  is the total number of electrons in the current. In the Landau gauge  $A_y = x B$  one can assume that energy eigenstates are momentum eigenstates in the direction of current and harmonic oscillator Gaussians in x-direction in which Hall current runs. This gives

$$\Psi \propto \exp(i k y) H_n(x + k l^2) \exp\left(-\frac{(x + k l^2)^2}{2 l^2}\right) , \quad l^2 = \frac{\hbar}{e B} .\tag{12.3.2}$$

Only the states for which the oscillator Gaussian differs considerably from zero inside slab are important so that the momentum eigenvalues are in good approximation in the range  $0 \leq k \leq k_{max} = L_x / l^2$ . Using  $N = (L_y / 2\pi) \int_0^{k_{max}} dk$  one obtains that the total number of momentum eigenstates associated with the given value of  $n$  is  $N = e B d L_x L_y / h = n$ . If  $\nu$  Landau states are filled, the value of  $\sigma$  is  $\sigma = \nu e^2 / h$ .

The interpretation of FQHE as IQHE with non standard value of Planck constant could explain also the fractionization of charge, spin, and electron number. There are  $2 \times 2 = 4$  combinations of covering and factor spaces of  $CP_2$  and three of them can lead to the increase or at least fractionization of the Planck constant required by FQHE.

1. The prediction for the filling fraction in FQHE would be

$$\nu = \nu_0 \frac{\hbar_0}{\hbar} , \quad \nu_0 = 1, 2, \dots .\tag{12.3.3}$$

$\nu_0$  denotes the number of filled Landau levels.

2. Let us denote the options as C-C, C-F, F-C, F-F, where the first (second) letter tells whether a singular covering or factor space of  $CD$  ( $CP_2$ ) is in question. The observed filling fractions are consistent with options C-C, C-F, and F-C for which  $CD$  or  $CP_2$  or both correspond to a singular covering space. The values of  $\nu$  in various cases are given by the following table.

<i>Option</i>	$C - C$	$C - F$	$F - C$
$\nu$	$\frac{\nu_0}{n_a n_b}$	$\frac{\nu_0 n_b}{n_a}$	$\frac{\nu_0 n_a}{n_b}$

(12.3.4)

There is a complete symmetry under the exchange of  $CD$  and  $CP_2$  as far as values of  $\nu$  are considered.

3. All three options are consistent with observations. Charge fractionization allows only the options  $C - C$  and  $F - C$ . If one believes the general arguments stating that also spin is fractionized in FQHE then only the option  $C - C$ , for which charge and spin units are equal to  $1/n_b$  and  $1/n_a$  respectively, remains. For  $C - C$  option one must allow  $\nu_0 > 1$ .
4. Both  $\nu = 1/2$  and  $\nu = 5/2$  state has been observed [2, 8]. The fractionized charge is believed to be  $e/4$  in the latter case [16, 14]. This requires  $n_b = 4$  allowing only  $(C, C)$  and  $(F, C)$  options.  $n_i \geq 3$  holds true if coverings and factor spaces are correlates for Jones inclusions and this gives additional constraint. The minimal values of  $(\nu_0, n_a, n_b)$  are  $(2, 1, 4)$  for  $\nu = 1/2$  and  $(10, 1, 4)$  for  $\nu = 5/2$  for both  $C - C$  and  $F - C$  option. Filling fraction  $1/2$  corresponds in the composite fermion model and also experimentally to the limit of zero magnetic field [11].  $n_b = 2$  would be inconsistent with the observed fractionization of electric charge for  $\nu = 5/2$  and with the vision inspired by Jones inclusions implying  $n_i \geq 3$ .
5. A possible problematic aspect of the TGD based model is the experimental absence of even values of  $m$  except  $m = 2$  (Laughlin's model predicts only odd values of  $m$ ). A possible explanation is that by some symmetry condition possibly related to fermionic statistics (as in Laughlin model) both  $n_a$  and  $n_b$  must be odd. This would require that  $m = 2$  case differs in some manner from the remaining cases.
6. Large values of  $m$  in  $\nu = n/m$  emerge as  $B$  increases. This can be understood from flux quantization. One has  $e \int B dS = n\hbar$ . By using actual fractional charge  $e_F = e/n_b$  in the flux factor would give for  $(C, C)$  option  $e_F \int B dS = nn_a \hbar_0$ . The interpretation is that each of the  $n_b$  sheets contributes one unit to the flux for  $e$ . Note that the value of magnetic field at given sheet is not affected so that the build-up of multiple covering seems to keep magnetic field strength below critical value.
7. The understanding of the thermal stability is not trivial. The original FQHE was observed in 80 mK temperature corresponding roughly to a thermal energy of  $T \sim 10^{-5}$  eV. For graphene the effect is observed at room temperature. Cyclotron energy for electron is (from  $f_e = 6 \times 10^5$  Hz at  $B = .2$  Gauss) of order thermal energy at room temperature in a magnetic field varying in the range 1-10 Tesla. This raises the question why the original FQHE requires such a low temperature. A possible explanation is that since FQHE involves several values of Planck constant, it is quantum critical phenomenon and is characterized by a critical temperature. The differences of single particle energies associated with the phase with ordinary Planck constant and phases with different Planck constant would characterize the transition temperature.

### 12.3.4 Could the dynamics of Kähler action predict the hierarchy of Planck constants?

The original justification for the hierarchy of Planck constants came from the indications that Planck constant could have large values in both astrophysical systems involving dark matter and also in

biology. The realization of the hierarchy in terms of the singular coverings and possibly also factor spaces of  $CD$  and  $CP_2$  emerged from consistency conditions. The formula for the Planck constant involves heuristic guess work and physical plausibility arguments. There are good arguments in favor of the hypothesis that only coverings are possible. Only a finite number of pages of the Big Book correspond to a given value of Planck constant, biological evolution corresponds to a gradual dispersion to the pages of the Big Book with larger Planck constant, and a connection with the hierarchy of infinite primes and p-adicization program based on the mathematical realization of finite measurement resolution emerges.

One can however ask whether this hierarchy could emerge directly from the basic quantum TGD rather than as a separate hypothesis. The following arguments suggest that this might be possible. One finds also a precise geometric interpretation of preferred extremal property interpreted as criticality in zero energy ontology.

### 1-1 correspondence between canonical momentum densities and time derivatives fails for Kähler action

The basic motivation for the geometrization program was the observation that canonical quantization for TGD fails. To see what is involved let us try to perform a canonical quantization in zero energy ontology at the 3-D surfaces located at the light-like boundaries of  $CD \times CP_2$ .

1. In canonical quantization canonical momentum densities  $\pi_k^0 \equiv \pi_k = \partial L_K / \partial(\partial_0 h^k)$ , where  $\partial_0 h^k$  denotes the time derivative of imbedding space coordinate, are the physically natural quantities in terms of which to fix the initial values: once their value distribution is fixed also conserved charges are fixed. Also the weak form of electric-magnetic duality given by  $J^{03} \sqrt{g_4} = 4\pi\alpha_K J_{12}$  and a mild generalization of this condition to be discussed below can be interpreted as a manner to fix the values of conserved gauge charges (not Noether charges) to their quantized values since Kähler magnetic flux equals to the integer giving the homology class of the (wormhole) throat. This condition alone need not characterize criticality, which requires an infinite number of deformations of  $X^4$  for which the second variation of the Kähler action vanishes and implies infinite number conserved charges. This in fact gives hopes of replacing  $\pi_k$  with these conserved Noether charges.
2. Canonical quantization requires that  $\partial_0 h^k$  in the energy is expressed in terms of  $\pi_k$ . The equation defining  $\pi_k$  in terms of  $\partial_0 h^k$  is however highly non-linear although algebraic. By taking squares the equations reduces to equations for rational functions of  $\partial_0 h^k$ .  $\partial_0 h^k$  appears in contravariant and covariant metric at most quadratically and in the induced Kähler electric field linearly and by multiplying the equations by  $\det(g_4)^3$  one can transform the equations to a polynomial form so that in principle  $\partial_0 h^k$  can be obtained as a solution of polynomial equations.
3. One can always eliminate one half of the coordinates by choosing 4 imbedding space coordinates as the coordinates of the spacetime surface so that the initial value conditions reduce to those for the canonical momentum densities associated with the remaining four coordinates. For instance, for space-time surfaces representable as map  $M^4 \rightarrow CP_2$   $M^4$  coordinates are natural and the time derivatives  $\partial_0 s^k$  of  $CP_2$  coordinates are multivalued. One would obtain four polynomial equations with  $\partial_0 s^k$  as unknowns. In regions where  $CP_2$  projection is 4-dimensional -in particular for the deformations of  $CP_2$  vacuum extremals the natural coordinates are  $CP_2$  coordinates and one can regard  $\partial_0 m^k$  as unknowns. For the deformations of cosmic strings, which are of form  $X^4 = X^2 \times Y^2 \subset M^4 \times CP_2$ , one can use coordinates of  $M^2 \times S^2$ , where  $S^2$  is geodesic sphere as natural coordinates and regard as unknowns  $E^2$  coordinates and remaining  $CP_2$  coordinates.
4. One can imagine solving one of the four polynomial equations for time derivatives in terms of other obtaining  $N$  roots. Then one would substitute these roots to the remaining 3 conditions to obtain algebraic equations from which one solves then second variable. Obviously situation is very complex without additional symmetries. The criticality of the preferred extremals might however give additional conditions allowing simplifications. The reasons for giving up the canonical quantization program was following. For the vacuum extremals of Kähler action  $\pi_k$  are however identically vanishing and this means that there is an infinite number of value distributions for  $\partial_0 h^k$ . For small deformations of vacuum extremals one might however hope a finite

number of solutions to the conditions and thus finite number of space-time surfaces carrying same conserved charges.

If one assumes that physics is characterized by the values of the conserved charges one must treat the the many-valuedness of  $\partial_0 h^k$ . The most obvious guess is that one should replace the space of space-like 4-surfaces corresponding to different roots  $\partial_0 h^k = F^k(\pi_l)$  with four-surfaces in the covering space of  $CD \times CP_2$  corresponding to different branches of the many-valued function  $\partial_0 h^k = F(\pi_l)$  co-inciding at the ends of  $CD$ .

**Do the coverings forces by the many-valuedness of  $\partial_0 h^k$  correspond to the coverings associated with the hierarchy of Planck constants?**

The obvious question is whether this covering space actually corresponds to the covering spaces associated with the hierarchy of Planck constants. This would conform with quantum classical correspondence. The hierarchy of Planck constants and hierarchy of covering spaces was introduced to cure the failure of the perturbation theory at quantum level. At classical level the multivaluedness of  $\partial_0 h^k$  means a failure of perturbative canonical quantization and forces the introduction of the covering spaces. The interpretation would be that when the density of matter becomes critical the space-time surface splits to several branches so that the density at each branches is sub-critical. It is of course not at all obvious whether the proposed structure of the Big Book is really consistent with this hypothesis and one also consider modifications of this structure if necessary. The manner to proceed is by making questions.

1. The proposed picture would give only single integer characterizing the covering. Two integers assignable to  $CD$  and  $CP_2$  degrees of freedom are however needed. How these two coverings could emerge?
  - (a) One should fix also the values of  $\pi_k^n = \partial L_K / \partial h_n^k$ , where  $n$  refers to space-like normal coordinate at the wormhole throats. If one requires that charges do not flow between regions with different signatures of the metric the natural condition is  $\pi_k^n = 0$  and allows also multi-valued solution. Since wormhole throats carry magnetic charge and since weak form of electric-magnetic duality is assumed, one can assume that  $CP_2$  projection is four-dimensional so that one can use  $CP_2$  coordinates and regard  $\partial_0 m^k$  as un-knows. The basic idea about topological condensation in turn suggests that  $M^4$  projection can be assumed to be 4-D inside space-like 3-surfaces so that here  $\partial_0 s^k$  are the unknowns. At partonic 2-surfaces one would have conditions for both  $\pi_k^0$  and  $\pi_k^n$ . One might hope that the numbers of solutions are finite for preferred extremals because of their symmetries and given by  $n_a$  for  $\partial_0 m^k$  and by  $n_b$  for  $\partial_0 s^k$ . The optimistic guess is that  $n_a$  and  $n_b$  corresponds to the numbers of sheets for singular coverings of  $CD$  and  $CP_2$ . The covering could be visualized as replacement of space-time surfaces with space-time surfaces which have  $n_a n_b$  branches.  $n_b$  branches would degenerate to single branch at the ends of diagrams of the generated Feynman graph and  $n_a$  branches would degenerate to single one at wormhole throats.
  - (b) This picture is not quite correct yet. The fixing of  $\pi_k^0$  and  $\pi_k^n$  should relate closely to the effective 2-dimensionality as an additional condition perhaps crucial for criticality. One could argue that both  $\pi_k^0$  and  $\pi_k^n$  must be fixed at  $X^3$  and  $X_l^3$  in order to effectively bring in dynamics in two directions so that  $X^3$  could be interpreted as a an orbit of partonic 2-surface in space-like direction and  $X_l^3$  as its orbit in light-like direction. The additional conditions could be seen as gauge conditions made possible by symplectic and Kac-Moody type conformal symmetries. The conditions for  $\pi_k^0$  would give  $n_b$  branches in  $CP_2$  degrees of freedom and the conditions for  $\pi_k^n$  would split each of these branches to  $n_a$  branches.
  - (c) The existence of these two kinds of conserved charges (possibly vanishing for  $\pi_k^n$ ) could relate also very closely to the slicing of the space-time sheets by string world sheets and partonic 2-surfaces.
2. Should one then treat these branches as separate space-time surfaces or as a single space-time surface? The treatment as a single surface seems to be the correct thing to do. Classically the conserved changes would be  $n_a n_b$  times larger than for single branch. Kähler action need not

(but could!) be same for different branches but the total action is  $n_a n_b$  times the average action and this effectively corresponds to the replacement of the  $\hbar_0/g_K^2$  factor of the action with  $\hbar/g_K^2$ ,  $r \equiv \hbar/\hbar_0 = n_a n_b$ . Since the conserved quantum charges are proportional to  $\hbar$  one could argue that  $r = n_a n_b$  tells only that the charge conserved charge is  $n_a n_b$  times larger than without multi-valuedness.  $\hbar$  would be only effectively  $n_a n_b$  fold. This is of course poor man's argument but might catch something essential about the situation.

3. How could one interpret the condition  $J^{03}\sqrt{g_4} = 4\pi\alpha_K J_{12}$  and its generalization to be discussed below in this framework? The first observation is that the total Kähler electric charge is by  $\alpha_K \propto 1/(n_a n_b)$  same always. The interpretation would be in terms of charge fractionization meaning that each branch would carry Kähler electric charge  $Q_K = ng_K/n_a n_b$ . I have indeed suggested explanation of charge fractionization and quantum Hall effect based on this picture.
4. The vision about the hierarchy of Planck constants involves also assumptions about imbedding space metric. The assumption that the  $M^4$  covariant metric is proportional to  $\hbar^2$  follows from the physical idea about  $\hbar$  scaling of quantum lengths as what Compton length is. One can always introduce scaled  $M^4$  coordinates bringing  $M^4$  metric into the standard form by scaling up the  $M^4$  size of  $CD$ . It is not clear whether the scaling up of  $CD$  size follows automatically from the proposed scenario. The basic question is why the  $M^4$  size scale of the critical extremals must scale like  $n_a n_b$ ? This should somehow relate to the weak self-duality conditions implying that Kähler field at each branch is reduced by a factor  $1/r$  at each branch. Field equations should possess a dynamical symmetry involving the scaling of  $CD$  by integer  $k$  and  $J^{0\beta}\sqrt{g_4}$  and  $J^{n\beta}\sqrt{g_4}$  by  $1/k$ . The scaling of  $CD$  should be due to the scaling up of the  $M^4$  time interval during which the branched light-like 3-surface returns back to a non-branched one.
5. The proposed view about hierarchy of Planck constants is that the singular coverings reduce to single-sheeted coverings at  $M^2 \subset M^4$  for  $CD$  and to  $S^2 \subset CP_2$  for  $CP_2$ . Here  $S^2$  is any homologically trivial geodesic sphere of  $CP_2$  and has vanishing Kähler form. Weak self-duality condition is indeed consistent with any value of  $\hbar$  and implies that the vacuum property for the partonic 2-surface implies vacuum property for the entire space-time sheet as holography indeed requires. This condition however generalizes. In weak self-duality conditions the value of  $\hbar$  is free for any 2-D Lagrangian sub-manifold of  $CP_2$ .

The branching along  $M^2$  would mean that the branches of preferred extremals always collapse to single branch when their  $M^4$  projection belongs to  $M^2$ . Magnetically charged light-light-like throats cannot have  $M^4$  projection in  $M^2$  so that self-duality conditions for different values of  $\hbar$  do not lead to inconsistencies. For spacelike 3-surfaces at the boundaries of  $CD$  the condition would mean that the  $M^4$  projection becomes light-like geodesic. Straight cosmic strings would have  $M^2$  as  $M^4$  projection. Also  $CP_2$  type vacuum extremals for which the random light-like projection in  $M^4$  belongs to  $M^2$  would represent this of situation. One can ask whether the degeneration of branches actually takes place along any string like object  $X^2 \times Y^2$ , where  $X^2$  defines a minimal surface in  $M^4$ . For these the weak self-duality condition would imply  $\hbar = \infty$  at the ends of the string. It is very plausible that string like objects feed their magnetic fluxes to larger space-times sheets through wormhole contacts so that these conditions are not encountered.

### Connection with the criticality of preferred extremals

Also a connection with quantum criticality and the criticality of the preferred extremals suggests itself. Criticality for the preferred extremals must be a property of space-like 3-surfaces and light-like 3-surfaces with degenerate 4-metric and the degeneration of the  $n_a n_b$  branches of the space-time surface at the its ends and at wormhole throats is exactly what happens at criticality. For instance, in catastrophe theory roots of the polynomial equation giving extrema of a potential as function of control parameters co-incide at criticality. If this picture is correct the hierarchy of Planck constants would be an outcome of criticality and of preferred extremal property and preferred extremals would be just those multi-branched space-time surfaces for which branches co-incide at the the boundaries of  $CD \times CP_2$  and at the throats.

### 12.3.5 Realization of quantum criticality in terms of number theoretic braids

The long standing question has been how to define formally the vision that TGD Universe is quantum critical. The notion of number theoretical braid combined with hierarchy of Planck constant provide a solution to this question and also fixes the precise realization of the generalized imbedding space.

#### The notion of number theoretical braid

The notion of number theoretic braid is essential for the view about quantum TGD as almost topological quantum field theory. Its realization discretization as a space-time correlate for the finite measurement resolution. Number theoretical universality leads to this notion also and requires that the points in the intersection of the number theoretic braid with partonic 2-surface correspond to rational or at most algebraic points of  $H$  in preferred coordinates fixed by symmetry considerations. The challenge has been to find a unique identification of the number theoretic braid. Number theoretic vision indeed makes this possible.

The core element of number theoretic vision is that the laws of physics could be reduced to associativity conditions. One realization for associativity conditions is the level of  $M^8$  endowed with hyper-octonionic structure as a condition that the points sets possible as arguments of  $N$ -point function in  $X^4$  are associative and thus belong to hyper-quaternionic subspace  $M^4 \subset M^8$ . This decomposition must be consistent with the  $M^4 \times E^4$  decomposition implied by  $M^4 \times CP_2$  decomposition of  $H$ . What comes first in mind is that partonic 2-surfaces  $X^2$  belong to  $\delta M_{\pm}^4 \subset M^8$  defining the ends of the causal diamond and are thus associative. This boundary condition however freezes  $E^4$  degrees of freedom completely so that  $M^8$  configuration space geometry trivializes.

1. *Are the points of number theoretic braid commutative?*

One can also consider the commutativity condition by requiring that arguments belong to a preferred commutative hyper-complex sub-space  $M^2$  of  $M^8$  which can be regarded as a curve in complex plane. Fixing preferred real and imaginary units means a choice of  $M^2$  interpreted as a partial choice of quantization axes at the level of  $M^8$ . One must distinguish this choice from the hyper-quaternionicity of space-time surfaces and from the condition that each tangent space of  $X^4$  contains  $M^2(x) \subset M^4$  in its tangent space or normal space. Commutativity condition indeed implies the notion of number theoretic braid and fixes it uniquely once a global selection of  $M^2 \subset M^8$  is made. There is also an alternative identification of number theoretic braid based on the assumption that braids are light-like curves with tangent vector in  $M^2(x)$ .

1. The strong form of commutativity condition would require that the arguments of the  $n$ -point function at partonic 2-surface belong to the intersection  $X^2 \cap M_{\pm}$ . This however allows quite too few points since an intersection of 2-D and 1-D objects in 7-D space would be in question. Associativity condition would reduce cure the problem but would trivialize configuration space geometry.
2. The weaker condition that only  $\delta CD$  projections for the points of  $X^2$  commute is however sensible since the intersection of 1-D and 2-D surfaces of 3-D space results. This condition is also invariant under number theoretical duality. In the generic case this gives a discrete set of points as intersection of light-like radial geodesic and the projection  $P_{\delta M_{\pm}^4}(X^2)$ . This set is naturally identifiable in terms of points in the intersection of number theoretic braids with  $\delta CD \times E^4$ . One should show that this set of points consists of rational or at most algebraic points. Here the possibility to choose  $X^2$  to some degree could be essential. Any radial light ray from the tip of light-cone allows commutativity and one can consider the possibility of integrating over  $n$ -point functions with arguments at light ray to obtain maximal information.
3. For the pre-images of light-like 3-surfaces commutativity of the points in  $\delta M_{\pm}^4$  projection would allow the projections to be one-dimensional curves of  $M^2$  having thus interpretation as braid strands.  $M^2$  would play exactly the same role as the plane into which braid strands are projected in the construction of braid invariants. Therefore the plane of non-physical polarizations in gauge theories corresponds to the plane to which braids and knots are projected in braid and knot theories. A further constraint is that the braid strand connects algebraic points of  $M^8$  to

algebraic points of  $M^8$ . It seems that this can be guaranteed only by posing some additional conditions to the light-like 3-surfaces themselves which is of course possible since they are in the role of fundamental dynamical objects.

2. *Are number theoretic braids light-like curves with tangent in  $M^2(x)$ ?*

There are reasons why the identification of the number theoretic braid strand as a curve having hyper-complex light-like tangent looks more attractive.

1. An alternative identification of the number theoretic braid would give up commutativity condition for  $CD$  projection and assume braid strand to be as a light-like curve having light-like tangent belonging to the local hyper-complex tangent sub-space  $M^2(x)$  at point  $x$ . This definition would apply both in  $X^3 \subset \delta M_{\pm}^4 \times CP_2$  and in  $X_l^3$ . Also now one would have a continuous distribution of number theoretic braids, with one braid assignable to each light-like curve with tangent  $\delta M_{\pm}^4 \supset M_{\pm}(x) \subset M^2(x)$ . In this case each light-like curve at  $\delta M_{\pm}^4$  with tangent in  $M_{\pm}(x)$  would define a number theoretic braid so that the only difference would be the replacement of light-like ray with a more general light-like curve.
2. The preferred plane  $M^2(x)$  can be interpreted as the local plane of non-physical polarizations so that the interpretation as a number theoretic analog of gauge conditions posed in both quantum field theories and string models is possible. In TGD framework this would mean that super-conformal degrees of freedom are restricted to the orthogonal complement of  $M^2(x)$  and  $M^2(x)$  does not contribute to the configuration space metric. In Hamilton-Jacobi coordinates the pairs of light-like curves associated with coordinate lines can be interpreted as curved light rays. Hence the partonic planes  $M^2(x_i)$  associated with the points of the number theoretic braid could be also regarded as carriers four-momenta of fermions associated with the braid strands so that the standard gauge conditions  $\epsilon \cdot p = 0$  for polarization vector and four-momentum would be realized geometrically. The possibility of  $M^2$  to depend on point of  $X_l^3$  would be essential to have non-collinear momenta and for a classical description of interactions between braid strands.
3. One could also define analogs of string world sheets as sub-manifolds of  $P_{M_{\pm}^4}(X^4)$  having  $M^2(x) \subset M^4$  as their tangent space or being assignable to their tangent containing  $M_{\pm}(x)$  in the case that the distribution defined by the planes  $M^2(x)$  exists and is integrable. It must be emphasized that in the case of massless extremals one can assign only  $M_{\pm}(x) \subset M^4$  to  $T(X^4(x))$  so that only a foliation of  $X^4$  by light-like curves in  $CD$  is possible. For  $P_{M_{\pm}^4}(X^4)$  however a foliation by 2-D stringy surfaces is obtained. Integrability of this distribution and thus the duality with stringy description has been suggested to be a basic feature of the preferred extremals and is equivalent with the existence of Hamilton-Jacobi coordinates for a large class of extremals of Kähler action [8].
4. The possibility of dual descriptions based on integrable distribution of planes  $M^2(x)$  allowing identification as 2-dimensional stringy sub-manifolds of  $X^4(X^3)$  and the flexibility provided by the hyper-complex conformal invariance raise the hopes of achieving the lifting of super-symplectic algebra  $SS$  and super Kac-Moody algebra  $SKM$  to  $H$ . At the light-cone boundary the light-like radial coordinate could be lifted to a hyper-complex coordinate defining coordinate for  $M^2$ . At  $X_l^3$  one could fix the light-like coordinate varying along the braid strands and it can be lifted to a light-like hyper-complex coordinate in  $CD$  by requiring that the tangent to the coordinate curve is light-like line of  $M^2(x)$  at point  $x$ . The total four-momenta and color quantum numbers assignable to  $SS$  and  $SKM$  degrees of freedom are naturally identical since they can be identified as the four-momentum of the partonic 2-surface  $X^2 \subset X^3 \cap \delta M_{\pm}^4 \times CP_2$ . Equivalence Principle would emerge as an identity.

3. *Are also  $CP_2$  duals of number theoretic braids possible?*

This picture is probably not enough. From the beginning the idea that also the  $CP_2$  projections of points of  $X^2$  define number theoretic braids has been present. The dual role of the braids defined by  $M^2$  and  $CP_2$  projections of  $X^2$  is suggested both by the construction of the symplectic fusion algebras [13] and by the model of anyons [57].  $M^2$  and the geodesic sphere  $S_i^2 \subset CP_2$ , where one has

either  $i = I$  or  $i = II$ , where  $i = I/II$  corresponds to homologically trivial/non-trivial geodesic sphere, are in a key role in the geometric realization of the hierarchy of Planck constants in terms of the book like structure of the generalized imbedding space. The fact that  $S_I^2$  corresponds to vacuum extremals would suggest that only the intersection  $S_{II}^2 \cap P_{CP_2}(X^2)$  can define  $CP_2$  counterpart of the number theoretic braid.  $CD$  braid could be the proper description in the associative case (Minkowskian signature of induced metric) and  $CP_2$  braid in the co-associative case (Euclidian signature of induced metric). The duality of these descriptions would be reflected also by the fact that the physical Planck constant is given by  $\hbar = r\hbar_0$ ,  $r = \hbar(M^4)/\hbar(CP_2)$ , so that only the ratio of the two Planck constants matters in commutation relations.

### Number theoretic braids are quantum critical

The elegant manner to realized quantum criticality is as quantum criticality of number theoretic braids.

1. All particles, be their elementary particles or anyonic systems of astrophysical size, have light-like partonic 3-surfaces as space-time correlates. If the corresponding partonic 2-surfaces  $X^2$  are as a whole quantum critical their  $M^2$  projection belongs to  $M_+ \subset \delta M_{\pm}^4$  or  $CP_2$  projection to  $S_i^2$ ,  $i = I$  or  $II$  corresponding to homological trivial and non-trivial geodesic spheres. If  $X^2$  is fully quantum critical, it belongs  $M^2 \times S^2$  defining the intersection of all pages of the big book. This definition is quite too stringent. The geometric picture about phase transition implies that only a 1-D curves of partonic 2-surface correspond to exact quantum criticality so that 2-surface could consist of several parts having different values of Planck constant during transition. This would realize at the level of partonic 2-surfaces the geometric view about criticality as decomposition to regions consisting of different phases.
2. The construction of M-matrix utilizes only the data from the discrete number theoretic braids defined by the intersections of with  $M_{\pm} \cap P_{\delta M_{\pm}^4}(X^2)$  where one has  $M_{\pm} \subset M^2 \cap \delta M^4_{\pm}$  where  $M_{\pm} = M^2 \cap \delta M^4_{\pm}$  is light-like ray. The proposed dual description uses number theoretic braids defined by  $CP_2$  projection  $S_i^2 \cap P_{CP_2}(X^2)$ ,  $i = I$  or  $II$ . Quantum criticality of TGD Universe would mean that  $M^2$  and  $S_i^2$  defining the quantum measurement axis and quantum critical manifolds also define number theoretical braids.

### Which geodesic sphere?

There are two geodesic spheres in  $CP_2$ . Which one should choose or are both possible? It seems that it is not possible to make final conclusion yet.

1. For the homologically non-trivial geodesic sphere  $S_{II}^2$  corresponding to the simplest cosmic strings, the isometry group is  $U(2) \subset SU(3)$ . The homologically trivial geodesic sphere  $S_I^2$  has vanishing induced Kähler form and in maximal quantum criticality would correspond to vacuum extremals. It has isometry group  $SO(3) \subset SU(3)$ . One could argue that  $U(1)$  factor excludes  $S_{II}^2$  but there is actually no reason for restring the consideration to  $SU(2)$ . For  $SU(2)$  color isospin would be the quantum number involved and  $G$  would act as phase rotations for complex coordinates of  $CP_2$ . For  $SO(3)$   $SO(2)$  would mix complex coordinates like real coordinates of plane and  $SO(2)$  quantum number would not allow interpretation in terms of color.
2. One could also argue that for a quantum critical partonic 2-surface containing regions with different values of Planck constant these regions must correspond to different regions inside which induced Kähler form is non-vanishing since second quantization in this case would be done for a fixed value of Planck constant. This is not guaranteed in the case  $S_{II}^2$  but in the case of  $S_I^2$  there exists a 1-D curve separating the regions with different Planck constant from each other. Again one can however simply restrict the partonic two-surfaces at  $\delta CD \times CP_2$  to belong to single page of generalized imbedding space so that quantum criticality as decomposition to regions belonging to different pages would hold true only for  $X_I^3$  and quantum criticality would be purely dynamical phenomenon analogous to quantum tunneling. In particular, there would be no vertex characterizing the phase transition changing the page.

3. Quantum criticality corresponds to long range fluctuations and non-deterministic behavior and there is a strong temptation to assign with with the vacuum degeneracy of Kähler action implying also 4-D spin glass like character of TGD Universe. This would favor  $S_I^2$ . If  $S_I^2$  is chosen one can ask whether all surfaces  $M^2 \times Y^2$ ,  $Y^2$  Lagrangian sub-manifold of  $CP_2$  defining vacuum sectors of the theory should be allowed. The answer seems to be "No" since in the generic case  $SO(3)$  does not act as  $H$ -isometries of  $Y^2$ . If one allows these sub-manifolds or even sub-manifolds of form  $M^4 \times Y^2$  to appear as intersection of fractally scaled up variants, one must replace Cartan algebra as algebra associated with  $SO(3)$  subgroup of symplectic transformations of  $CP_2$  mapping  $Y^2$  to itself (if this kind of algebra exists).
4. If partonic 2-surfaces belong to single page of the Big book, there is no reason to exclude the option allowing both  $S_I^2$  and  $S_{II}^2$ . This raises the question whether the two kinds of Jones inclusions corresponding to  $\mathcal{M} : \mathcal{N} < 4$  and  $\mathcal{M} : \mathcal{N} = 4$  correspond to the two geodesic spheres.  $S_I^2$  would correspond to a phase obtained as small perturbations of vacuum extremals and  $S_{II}^2$  to string like objects (Kähler magnetic flux tubes) obtained as perturbations of cosmic strings. The objection is that there would be asymmetry between  $CD$  and  $CP_2$  degrees of freedom since for  $CD$  only  $M^2$  appears and would correspond to either  $\mathcal{M} : \mathcal{N} < 4$  or  $\mathcal{M} : \mathcal{N} = 4$ . If singular coverings and factor spaces correspond to the two kinds of Jones inclusions, the factors are in completely symmetric position.
5. An argument favoring  $S_I^2$  is that situation should be symmetric with respect to  $CD$  and  $CP_2$ . Since  $M^2$  corresponds to non-physical polarizations and  $S_I^2$  to vacuum extremals, one might argue that these are the correct choices.  $S_{II}^2$  corresponds also to a non-holomorphic sub-manifold of  $CP_2$  being given by  $\xi^2 = \bar{\xi}^2$  in Eguchi-Hanson coordinates. Symmetry argument suggests also that  $M^2(x) \oplus E^2(x)$  decomposition should have  $CP_2$  counter part and correspond to a slicing of  $CP_2$  to geodesic spheres. This slicing would be analogous to the slicing of sphere by geodesic circles labeled by the value of the coordinate  $\theta$  and intersecting at two diametrically opposite points at equator. The variation range  $\theta$  defines half-geodesic circle orthogonal to the slices. The spherical  $CP_2$  coordinate pairs  $(r, \Psi)$  and  $(r, \Phi)$  would label the slices of  $S_I^2$  and  $S_{II}^2$  slicings with three intersection points.  $(r, \Psi)$  and the complex coordinate for  $S_{II}^2$  would define the analog of Hamilton-Jacobi coordinates for  $CP_2$  and the analogy with sphere would suggest that the variation ranges of  $(r, \Psi)$  resp.  $(r, \Phi)$  define pieces of  $S_{II}^2$  resp.  $S_I^2$ . The dual geodesic spheres are not orthogonal to the geodesic spheres which they label as the expression of  $CP_2$  metric in Eguchi-Hanson coordinates shows [2] , [2] . In fact, orthogonality fails of longitudinal and transversal planes fails for Hamilton-Jacobi coordinates too.

### What are the correct anti-commutation relations for fermionic oscillator operators?

Quantum commutation relations make sense only for quantum version of the  $SU(2)$  Lie algebra. The reason is that the quantum commutation relations of form  $a^\dagger a + qaa^\dagger = \hbar$  are consistent with the hermiticity of the right hand side only for real values of  $q$ .

The vision about fractionization of various quantum numbers as being due to the fractionization of fermion number suggests that the correct anti-commutation relations are of form

$$\begin{aligned} a^\dagger a + aa^\dagger &= \hbar = r\hbar_0 , \\ r &= \frac{\hbar(CD)}{\hbar(CP_2)} . \end{aligned} \tag{12.3.5}$$

One cannot transform these relations to the standard form for all pages of the Big Book simultaneously by scaling the oscillator operators by  $1/\sqrt{r}$ . The unit of fermion number becomes  $r$  so that single fermion leakage between sectors with different value of  $r$  is not possible.

One can consider also a more delicate modification is based on the replacement of  $r$  with its  $q$ -counterpart  $r_q$ .

$$a^\dagger a + aa^\dagger = \hbar_q = r_q \hbar_0 . \tag{12.3.6}$$

It is however not completely clear what one means with q-rational. The counterpart  $n_q$  of integer  $n$  is  $n_q = (q^n - q^{-n})/(q - q^{-1})$ . The two alternative definitions of  $r_q$  for  $r = n_1/n_2$  would be

$$r_q = \frac{(q^r - q^{-r})}{q - q^{-1}}$$

and

$$r_q = \frac{m_q}{n_q} .$$

$q = \exp(i2\pi/r)$  however implies that  $r_q$  vanishes in both cases so that the modification does not make sense.

A good guess for the commutation relations of quantum  $SU(2)$  is as

$$\begin{aligned} [J_z, J_{\pm}] &= \pm J_{\pm} , \\ [J_+, J_-] &= r\hbar_0 \times \frac{q^{\frac{J_z}{r\hbar_0}} - q^{-r\frac{J_z}{r\hbar_0}}}{q - q^{-1}} , \\ q &= \exp(i\frac{2\pi}{r}) . \end{aligned} \tag{12.3.7}$$

For the eigenstates of  $J_z$  with  $J_z = mr\hbar_0$  the right hand side gives  $\exp(im2\pi/r) - \exp(-im2\pi/r)$  just as for the standard quantum group for which one has  $r = n$ .

One could criticize the appearance of  $\hbar(CP_2)$  in the denominator of  $r$  as something having no concrete interpretation: why the covering of  $CP_2$  should reduce the unit of fermion number? The interpretation in terms of the scaling of metric does not leave however leave any other option and one should find some elegant interpretation for the formula before one can accept it. A possible interpretation in the case of  $CD$  braids is that fermion number  $r = n_a/n_b$  for coverings is associated with single  $CP_2$  page so that the  $n_b$  pages would carry fermion number  $n_a$ . If  $CP_2$  corresponds to factor space and  $CD$  to covering, single pages would carry fermion number  $n_a$  but only  $1/n_B$   $CP_2$  pages would be present so that again the unit of fermion number would be  $n_a$ .

## 12.4 Jones inclusions and generalization of the imbedding space

The original motivation for the generalization of the imbedding space was the idea that the pages of the Big Book would provide correlates for Jones inclusions. In the following an attempt to formulate this vision more precisely is carried out.

### 12.4.1 Basic facts about Jones inclusions

Here only basic facts about Jones inclusions are discussed. Appendix contains a more detailed discussion of inclusions of HFFs.

#### Jones inclusions defined by subgroups of $SL(2, C) \times SU(2)$

Jones inclusions with  $\mathcal{M} : \mathcal{N} < 4$  have representation as  $R_0^G \subset R^G$  with  $G$  a discrete subgroup of  $SU(2)$ .  $SO(3)$  or  $SU(2)$  can be interpreted as acting in  $CP_2$  as rotations. On quantum spinors the action corresponds to double cover of  $G$ .

A more general choice for  $G$  would be as a discrete subgroup  $G_a \times G_b \subset SL(2, C) \times SU(2) \times SU(2)$ . Poincare invariance suggests that the subgroup of  $SL(2, C)$  reduces either to a discrete subgroup of  $SU(2)$  and in the case that the rotation are genuinely 3-dimensional ( $E^6, E^8$ ), the only possible interpretation would be as isotropy group of a particle at rest. When the group acts on plane as in case of  $A_n$  and  $D_{2n}$ , it could be also assigned to a massless particle.

If the group involves boosts it contains an infinite number of elements and it is not clear whether this kind of situation is physically sensible. In this case Jones inclusion could be interpreted as an inclusion for the tensor product of  $G$  invariant algebras associated with  $CD$  and  $CP_2$  degrees of freedom and one would have  $\mathcal{M} : \mathcal{N} = \mathcal{M} : \mathcal{N}(G_a) \times \mathcal{M} : \mathcal{N}(G_b)$ . Since the index increases as the

order of  $G$  increases one has reasons to expect that in the case of  $G_a = SL(2, C)$   $N_a = \infty$  implies larger  $\mathcal{M} : \mathcal{N}(G_a) > 4$ .

A possible interpretation is that the values  $\mathcal{M} : \mathcal{N} \leq 4$  are analogous to bound state energies so that a discrete rotation group acting in the relative rotational degrees of freedom can act as a symmetry group whereas the values  $\mathcal{M} : \mathcal{N} > 4$  are analogous to ionized states for which particles are almost freely moving with respect to each other with a constant velocity.

When one restricts the coefficients to  $G$ -invariant elements of Clifford algebra the Clifford field is  $G$ -invariant under the natural action of  $G$ . This allows two interpretations. Either the Clifford field is  $G$  invariant or that the Clifford field is defined in orbifold  $CD/G_a \times CP_2/G_b$ .  $CD/G_a$  is obtained by replacing hyperboloid  $H_a$  ( $t^2 - x^2 - y^2 - z^2 = a^2$ ) with  $H_a/G_a$ . These spaces have been considered as cosmological models having 3-space with finite volume [65] (also a lattice like structure could be in question).

### The quantum phases associated with sub-groups of $SU(2)$

It is natural to identify quantum phase as that defined by the maximal cyclic subgroup for finite subgroups of  $SU(2)$  and infinite subgroups of  $SL(2, C)$ . Before continuing a brief summary about quantum phases associated with finite subgroups of  $SU(2)$  is in order.  $E_6$  corresponds to  $N = 24$  and  $n = 3$  and  $E_8$  to icosahedron with  $N = 120$ ,  $n = 5$  and Golden mean and the minimal value of  $n$  making possible universal topological quantum computer [81] .

$D_n$  and  $A_n$  have orders  $2n$  and  $n + 1$  and act as symmetry groups of  $n$ -polygon and have  $n$ -element cyclic group as a maximal cyclic subgroup. For double covers the orders are twice this. Thus  $A_n$  resp.  $D_{2n}$  correspond to  $q = \exp(i\pi/n)$  resp.  $q = \exp(i\pi/2n)$ . Note that the restriction  $n \geq 3$  means geometrically that only non-trivial polygons are allowed.

### 12.4.2 Jones inclusions and the hierarchy of Planck constants

The anyonic arguments for the quantization of Planck constant suggest that one can assign separate scalings of Planck constant to  $CD$  and  $CP_2$  degrees of freedom and that these scalings in turn reflect as scalings of  $M^4 \pm$  and  $CP_2$  metrics. This is definitely not in accordance with the original TGD vision based on uniqueness of imbedding space but makes sense if space-time and imbedding space are emergent concepts as the hierarchy of number theoretical von Neumann algebra inclusions indeed suggests. Indeed, the scaling factors of  $CD$  and  $CP_2$  metric remain non-fixed by the general uniqueness arguments since Cartesian product is in question.

#### Hierarchy of Planck constants and choice of quantization axis

Jones inclusions seem to relate in a natural manner to the selection of quantization axis.

1. In the case of  $CD$  the orbifold singularity is for all groups  $G_a$  except  $E_6$  and  $E_8$  the time-like plane  $M^2$  corresponding to a radial ray through origin defining the quantization axis of angular momentum and intersecting light-cone boundary along a preferred light-like ray. For  $E_6$  and  $E_8$  (tetrahedral and icosahedral symmetries) the singularity consists of planes  $M^2$  related by symmetries of  $G$  sharing time-like line  $M^1$  and in this case there are several alternative identifications of the quantization axes as axis around which the maximal cyclic subgroup acts as rotations.
2. From this it should be obvious that Jones inclusions represented in this manner would relate very closely to the selection of quantization axes and provide a geometric representation for this selection at the level of space-time and configuration space. The existence of the preferred direction of quantization at a given level of dark matter level should have observable consequences. For instance, in cosmology this could mean a breaking of perfect rotational symmetry at dark matter space-time sheets. The interpretation would be as a quantum effect in cosmological length scales. An interesting question is whether the observed asymmetry of cosmic microwave background could have interpretation as a quantum effect in cosmological length and time scales.

### Do factor spaces and coverings correspond to the two kinds of Jones inclusions?

What could be the interpretation of the singular coverings and factor spaces? If both geodesic spheres of  $CP_2$  are allowed  $\mathcal{M} : \mathcal{N} = 4$  could correspond to the allowance of cosmic strings and other analogous objects. This option is however asymmetric with respect to  $CD$  and  $CP_2$  and the more plausible option is that the two kinds of Jones inclusions correspond to singular factor spaces and coverings.

1. Jones inclusions appear in two varieties corresponding to  $\mathcal{M} : \mathcal{N} < 4$  and  $\mathcal{M} : \mathcal{N} = 4$  and one can assign a hierarchy of subgroups of  $SU(2)$  with both of them. In particular, their maximal Abelian subgroups  $Z_n$  label these inclusions. The interpretation of  $Z_n$  as invariance group is natural for  $\mathcal{M} : \mathcal{N} < 4$  and it naturally corresponds to the coset spaces. For  $\mathcal{M} : \mathcal{N} = 4$  the interpretation of  $Z_n$  has remained open. Obviously the interpretation of  $Z_n$  as the homology group defining covering would be natural.
2. For covering spaces one would however obtain the degrees of freedom associated with the discrete fiber and the degrees of freedom in question would not disappear completely and would be characterized by the discrete subgroup of  $SU(2)$ . For anyons the non-trivial homotopy of plane brings in non-trivial connection with a flat curvature and the non-trivial dynamics of topological QFTs. Also now one might expect similar non-trivial contribution to appear in the spinor connection of  $\hat{CD} \hat{\times} G_a$  and  $\hat{CP}_2 \hat{\times} G_b$ . In conformal field theory models non-trivial monodromy would correspond to the presence of punctures in plane. This picture is also consistent with the  $G$  singlets of the quantum states despite the fact that fermionic oscillator operators belong to non-trivial irreps of  $G$ .

### Coverings and factors spaces form an algebra like structure

It is easy to see that coverings and factor spaces defining the pages of the Big Book form an algebra like structure.

1. For factor spaces the unit for quantum numbers like orbital angular momentum is multiplied by  $n_a$  resp.  $n_b$  and for coverings it is divided by this number. These two kind of spaces are in a well defined sense obtained by multiplying and dividing the factors of  $\hat{H}$  by  $G_a$  resp.  $G_b$  and multiplication and division are expected to relate to Jones inclusions with  $\mathcal{M} : \mathcal{N} < 4$  and  $\mathcal{M} : \mathcal{N} = 4$ , which both are labeled by a subset of discrete subgroups of  $SU(2)$ .
2. The discrete subgroups of  $SU(2)$  with fixed quantization axis possess a well defined multiplication with product defined as the group generated by forming all possible products of group elements as elements of  $SU(2)$ . This product is commutative and all elements are idempotent and thus analogous to projectors. Trivial group  $G_1$ , two-element group  $G_2$  consisting of reflection and identity, the cyclic groups  $Z_p$ ,  $p$  prime, and tetrahedral, octahedral, and icosahedral groups are the generators of this algebra.

By commutativity one can regard this algebra as an 11-dimensional module having natural numbers as coefficients ("rig"). The trivial group  $G_1$ , two-element group  $G_2$  generated by reflection, and tetrahedral, octahedral, and icosahedral groups define 5 generating elements for this algebra. The products of groups other than trivial group define 10 units for this algebra so that there are 11 units altogether. The groups  $Z_p$  generate a structure analogous to natural numbers acting as analog of coefficients of this structure. Clearly, one has effectively 11-dimensional commutative algebra in 1-1 correspondence with the 11-dimensional "half-lattice"  $N^{11}$  ( $N$  denotes natural numbers). Leaving away reflections, one obtains  $N^7$ . The projector representation suggests a connection with Jones inclusions. An interesting question concerns the possible Jones inclusions assignable to the subgroups containing infinitely manner elements. Reader has of course already asked whether dimensions 11, 7 and their difference 4 might relate somehow to the mathematical structures of M-theory with 7 compactified dimensions. One could introduce generalized configuration space spinor fields in the configuration space labeled by sectors of  $H$  with given quantization axes. By introducing Fourier transform in  $N^{11}$  one would formally obtain an infinite-component field in 11-D space.

### Connection between Jones inclusions, hierarchy of Planck constants, and finite number of spinor modes

The original generalization of the imbedding space to accommodate the hierarchy of Planck constants was based on the idea that the singular coverings and factor spaces associated with the causal diamond  $CD$  and  $CP_2$ , which appears as factors of  $CD \times CP_2$  correspond somehow to Jones inclusions, and that the integers  $n_a$  and  $n_b$  characterizing the orders of maximal cyclic groups of groups  $G_a$  and  $G_b$  associated with the two Cartesian factors correspond to quantum phases  $q = \exp(i2\pi/n_i)$  in such a manner that singular factor spaces correspond to Jones inclusions with index  $\mathcal{M} : \mathcal{N} < 4$  and coverings to those with index  $\mathcal{M} : \mathcal{N} = 4$ .

Since Jones inclusions are interpreted in terms of finite measurement resolution, the mathematical realization of this heuristic picture should rely on the same concept realized also by the fact that the number of non-zero modes for induced spinor fields is finite. This allows to consider two possible interpretations.

1. The finite number of modes defines an approximation to the hyper-finite factor of type  $II_1$  defined by configuration space Clifford algebra.
2. The Clifford algebra spanned by fermionic oscillator operators is quantum Clifford algebra and corresponds to the somewhat nebulous object  $\mathcal{N}/\mathcal{M}$  associated with the inclusion  $\mathcal{M} \subset \mathcal{N}$  and coding the finite measurement resolution to a finite quantum dimension of the Clifford algebra. The fact that quantum dimension is smaller than the actual dimension would reflect correlations between spinor components so that they are not completely independent.

If the latter interpretation is correct then second quantized induced spinor fields should obey quantum variant of anticommutation relations reducing to ordinary anticommutation relations only for  $n_a = n_b = 0$  (no singular coverings nor factor spaces). This would give the desired connection between inclusions and hierarchy of Planck constants. It is possible to have infinite number of quantum group like structure for  $\hbar = \hbar_0$ .

There are two quantum phases  $q$  and one should understand what is the phase that appears in the quantum variant of anti-commutation relations. A possible resolution of the problem relies on the observation that there are two kinds of number theoretic braids. The first kind of number theoretic braid is defined as the intersection of  $M_+$  (or light-like curve of  $\delta M_+^4$  in more general case) and of  $\delta M_+^4$  projection of  $X^2$ . Second of braid is defined as the intersection of  $CP_2$  projection of  $X^2$  of homologically non-trivial sphere  $S_{II}^2$  of  $CP_2$ . The intuitive expectation is that these dual descriptions apply for light-like 3-surfaces associated *resp.* co-associative regions of space-time surface and that both descriptions apply at wormhole throats. The duality of these descriptions is guaranteed also at wormhole throats if physical Planck constant is given by  $\hbar = r\hbar_0$ ,  $r = \hbar(M^4)/\hbar(CP_2)$ , so that only the ratio of the two Planck constants matters in commutation relations. This would suggest that it is  $q = \exp(i2\pi/r)$ , which appears in quantum variant of anti-commutation relations of the induced spinor fields.

### The action of $G_a \times G_b$ on configuration space spinors and spinor fields

The first question is what kind of measurement resolution is in question. In zero energy ontology the included states would typically correspond to insertion of zero energy states to the positive or negative part of the physical state in time scale below the time resolution defined by the time scale assignable to the smallest  $CD$  present in the zero energy state. Does the description in terms of  $G$  invariance apply in this case or does it relate only to time and length scale resolution whereas hierarchy of Planck constants would relate to angle resolution? Assume that this is the case.

The second question is how the idea about  $\mathcal{M}$  as an included algebra defining finite measurement resolution and  $G$  invariance as a symmetry defining  $\mathcal{M}$  as the included algebra relate to each other.

1. One cannot say that  $G$  creates states, which cannot be distinguished from each other. Rather  $G$ -invariant elements of  $\mathcal{M}$  create states whose presence in the state cannot be detected.
2. For covering space option  $\mathcal{M}$  represents states which are invariant under discrete subgroup of  $SU(2)$  acting in the covering. States with integer spin would be below measurement resolution and only fractional spins of form  $j/n$  would be observable. For factor space option  $\mathcal{M}$  would

represents states which are invariant under discrete subgroup of  $SU(2)$  acting in  $H$ -say states with spin. States with spin which is multiple of  $n$  would be below measurement resolution. The situation would be very similar to each other. Number theoretic considerations and the fact that the number of fermionic oscillator operators is finite suggest that that for coverings the condition  $L_z < 1$  and for factor spaces the condition  $L_z < n$  is satisfied by the generators of Clifford algebra regarded as irreducible representation of  $G$ . For factor spaces the interpretation could be in terms of finite angular resolution  $\Delta\phi \leq 2\pi/n$  excluding angular momenta  $L_z \geq n$ . For coverings the resolution would be related to rotations (or rather, braidings) as multiples of  $2\pi$ : multiples  $m2\pi$   $m \geq n$  cannot be distinguished from  $m \bmod n$  multiples.

3. The minimal assumption is that integer orbital angular momenta are excluded for coverings and  $n$ -multiples are excluded for factors spaces. The stronger assumption would be that there is angular momentum cutoff. This point is however very delicate. The states with  $j > n$  can be obtained as tensor products of representations with  $j = m$ . If entanglement is present one cannot anymore express the state as a product of  $\mathcal{M}$  element and  $\mathcal{N}$  element so that the states  $j > n$  created in this manner would not be equivalent with those with  $j \bmod n$ . The replacement of the ordinary tensor product with Connes tensor product would indeed generate automatically entangled states and one could interpret Connes tensor product as a manner to create only the allowed states.
4. For quantum groups allow only finite number of representations up to some maximum spin determined by the integer  $n$  characterizing quantum phase  $q$ . This would mean angular momentum cutoff leaving only a finite number of representations of quantum group [7]. This fits nicely with what one obtains in the case of factor spaces. For coverings the new element is that the unit of spin becomes  $1/n$ : otherwise the situation seems to be similar. Quantum group like structure is obtained if the fermionic oscillator operators satisfy the quantum version of anti-commutation relations. The algebra would be very similar except that the orbital angular momentum labeling oscillator operators has different unit. Oscillator operators are naturally in irreducible representations of  $G$  and only the non-trivial representations of  $G$  are allowed.
5. Besides Jones inclusions corresponding to  $\mathcal{M} : \mathcal{N} < 4$  there are inclusions with  $\mathcal{M} : \mathcal{N} = 4$  to which one can also assign quantum phases. It would be natural to assign covering spaces and factor spaces to these two kinds of inclusions. For the minimal option excluding only the orbital angular momentum which are integers or multiples of  $n$  the fraction of excluded states is very small for coverings so that  $\mathcal{M} : \mathcal{N} = 4$  is natural for this option.  $\mathcal{M} : \mathcal{N} < 4$  would in turn correspond naturally to factor spaces.
6. Since the two kinds of number theoretic braids correspond to points which belong to  $M^2$  or  $S^2$ , one might argue that several quantum anticommutation relations must be satisfied simultaneously. This is not the case since the eigen modes of  $D_{C-S}$  and hence also oscillator operators code information about partonic surface  $X^2$  itself and also about  $X^4(X_i^3)$  rather than being purely local objects. In the case of covering space the oscillator operators can be arranged to irreducible representations of  $G$  and in the case of factor space the oscillator operators are  $G$ -invariant.

One must distinguish between  $G$  invariance for configuration space spinors and spinor fields.

1. In the case of factor spaces 3-surface are  $G$  invariant so that there is no difference between spinors and spinor fields as far as  $G$  is considered. Irreducible representations of  $G$  would correspond to the superpositions of  $G$ -transforms of oscillator operators for a fixed  $G$ -invariant  $X_i^3$ .
2. For covering space option  $G$ -invariance would mean that 3-surface is a mere  $G$ -fold copy of single 3-surface. There is no obvious reason to assume this. Hence one cannot separate spinorial degrees of freedom from configuration space degrees of freedom since  $G$  affects both the spin degrees of freedom and the 3-surface. Irreducible representations of  $G$  would correspond to genuine configuration space spinor fields involving a superposition of  $G$ -transforms of also  $X_i^3$ . The presence of both orbital and spin degrees of freedom could provide alternative explanation for why  $\mathcal{M} : \mathcal{N} = 4$  holds true for covering space option.

If the fermionic oscillator algebra is interpreted as a representation for  $\mathcal{N}/\mathcal{M}$ , allowed fermionic oscillator operators belong to non-trivial irreps of  $G$ . One can however ask whether the many-fermion states created by these operators are  $G$ -invariant for some physical reason so that one would have kind of  $G$ -confinement forcing the states to be many-fermion states with standard unit of quantum numbers for coverings and integer multiples of  $n$  for factor spaces. This would conform with the ideas that anyonicity is a microscopic property not visible at the level of entire state and that many-fermion systems in the anyonic state resulting in strong coupling limit for ordinary value of  $\hbar$  are in question. The processes changing the value of Planck constant would be phase transitions involving all fermions of the  $G$ -invariant state and would be slow for this reason. This would also contribute to the invisibility of dark matter.

### 12.4.3 Questions

#### What is the role of dimensions?

Could the dimensions of  $CD$  and  $CP_2$  and the dimensions of spaces defined by the choice of the quantization axes play a fundamental role in the construction from the constraint that the fundamental group is non-trivial?

1. Suppose that the sub-manifold in question is geodesic sub-manifold containing the orbits of its points under Cartan subgroup defining quantization axes. A stronger assumption would be that the orbit of maximal compact subgroup is in question.
2. For  $M^{2n}$  Cartan group contains translations in time direction with orbit  $M^1$  and Cartan subgroup of  $SO(2n-1)$  and would be  $M^n$  so that  $\hat{M}^{2n}$  would have a trivial fundamental group for  $n > 2$ . Same result applies in massless case for which one has  $SO(1,1) \times SO(2n-2)$  acts as Cartan subgroup. The orbit under maximal compact subgroup would not be in question.
3. For  $CP_2$  homologically non-trivial geodesic sphere  $CP_1$  contains orbits of the Cartan subgroup. For  $CP_n = SU(n+1)/SU(n) \times U(1)$  having real dimension  $2n$  the sub-manifold  $CP_{n-1}$  contains orbits of the Cartan subgroup and defines a sub-manifold with codimension 2 so that the dimensional restriction does not appear.
4. For spheres  $S^{n-1} = SO(n)/SO(n-1)$  the dimension is  $n-1$  and orbit of  $SO(n-1)$  of point left fixed by Cartan subgroup  $SO(2) \times ..$  would for  $n=2$  consist of two points and  $S_{n-2}$  in more general case. Again co-dimension 2 condition would be satisfied.

#### What about holes of the configuration space?

One can raise analogous questions at the level of configuration space geometry. Vacuum extremals correspond to Lagrangian sub-manifolds  $Y^2 \subset CP_2$  with vanishing induced Kähler form. They correspond to singularities of the configuration space ("world of classical worlds") and configuration space spinor fields should vanish for the vacuum extremals. Effectively this would mean a hole in configuration space, and the question is whether this hole could also naturally lead to the introduction of covering spaces and factor spaces of the configuration spaces. How much information about the general structure of the theory just this kind of decomposition might allow to deduce? This kind of singularities are infinite-dimensional variants of those discussed in catastrophe theory and this suggests that their understanding might be crucial.

#### Are more general inclusions of HFFs possible?

The proposed scenario could be criticized because discrete subgroups of  $SU(2)$  are in a preferred position. The Jones inclusions considered correspond to quantum spinor representations of various quantum groups  $SU(2)_q$ ,  $q = \exp(i2\pi/n)$ . This explains the result  $\mathcal{M} : \mathcal{N} \leq 4$ . These representations are certainly in preferred role as far as configuration space spinor fields are considered but it is possible to assign a hierarchy of inclusions of HFFs labeled by quantum phase  $q$  with arbitrary representation of an arbitrary compact Lie group. These inclusions would be analogous to discrete states in the continuum  $\mathcal{M} : \mathcal{N} > 4$ .

Since the inclusions are characterized by single quantum phase  $q = \exp(i2\pi/n)$  in the case of compact Lie groups (Appendix), one can ask whether more general discrete groups than subgroups of  $SU(2)$  should be allowed. The inclusions of HFFs associated with higher dimensional Lie groups have  $\mathcal{M} : \mathcal{N} > 4$  and are analogous to bound states in continuum (Appendix). In the case of  $CP_2$  this would allow to consider much more general sub-groups.

The question is therefore whether some principle selects subgroups of  $SU(2)$ . There are indeed good arguments supporting the hypothesis that only discrete Abelian subgroups of  $SU(2)$  are possible.

1. The notion of number theoretic braid allows only the only subgroups of rotation group leaving  $M^2$  invariant and sub-groups of  $SU(3)$  leaving geodesic sphere  $S^2_i$  invariant. This would drop groups having genuinely 3-D action. In the case of  $SU(3)$  discrete subgroups of  $SO(3)$  or  $U(2)$  remain under consideration. The geodesic sphere of type II is however analogous to North/South pole of  $S^2$  and second phase factor associated with the coordinates  $(\xi^1, \xi^2)$  becomes redundant since  $(|\xi^1|^2 + |\xi^2|^2)^{1/2}$  becomes infinite at  $S^2_{II}$  so that  $\xi^1/\xi^2$  becomes appropriate coordinate. Hence action of  $U(2)$  reduces to that of  $SU(2)$  since  $\xi^1$  and  $\xi^2$  correspond to same value of color hyper charge associated with  $U(1)$ .
2. A physically attractive possibility is that  $G_a \times G_b$  leaves the choice of quantization axes invariant. This condition makes sense also for coverings. This would leave only Abelian groups into consideration and drop  $D_{2n}$ ,  $E_6$ , and  $E_8$ . It is quite possible that only these groups define sectors of the generalized imbedding space. This means that  $G_b = Z_{n_1} \times Z_{n_2} \subset U(1)_I \times U(1)_Y \subset SU(2) \times U(1)_Y$  and even more general subgroups of  $SU(3)$  (if non-commutativity is allowed) are a priori possible. Again the first argument reduces the list to cyclic subgroups of  $SU(2)$ .
3. The products of groups  $Z_n$  are also number theoretically in a very special position since they relate naturally to the finite cyclic extensions and also to the maximal Abelian extension of rationals. With this restriction on  $G_a \times G_b$  one can consider the hypothesis that elementary particles correspond are maximally quantum critical systems left invariant by all groups  $G_a \times G_b$  respecting a given choice of quantization axis and implying that darkness is associated only to field bodies and Planck constant becomes characterizer of interactions rather than elementary particles themselves.

### 12.4.4 How does the hierarchy of Planck constants affect the modified Dirac equation?

It is not quite obvious how  $\hbar/\hbar_0 = \hbar(M^4)/\hbar(CP_2)$  and  $\hbar(M^4)$  and  $\hbar(CP_2)$  make themselves visible in the dynamics of the theory. To see what is involved some simple dimensional considerations are needed.

#### General view about the role of $\hbar$

The usual convention of putting  $\hbar = 1$  simplifies things tremendously but when  $\hbar$  is assumed to have a spectrum, one is forced to check how  $\hbar$  appears in the theory.

1.  $\hbar$  appears in the anticommutators of the induced fermion fields restricted to the points of the number theoretic braids. Standard canonical anticommutation rule states that the anticommutator  $\{\bar{\Psi}\hat{\Gamma}^0(x_m), \Psi(x_n)\}$  equals to  $\hbar\delta_{m,n}$ . This is due to the dimension  $\sqrt{\hbar}/L^{3/2}$  of the induced spinor field forcing the modified Dirac action to be proportional to  $1/\hbar$ . The overall scaling of the action does not matter at all since it implies only an overall scaling of the eigenvalue spectrum giving an additive constant to Kähler action. The scaling of  $M^4$  and  $CP_2$  metrics by the same factor induces the scaling of the modified gamma matrices  $\hat{\Gamma}^\alpha$  by same factor which does not affect the value Kähler function apart from additive constant. This conforms with the Weyl invariance of Kähler action. One can therefore identify  $\hbar$  as a scaling factor of  $M^4$  metric when  $CP_2$  metric is scaled down to its standard form. By introducing a scaled up  $M^4$  coordinate, the standard form of metric is obtained but the size of causal diamond  $CD$  is scaled up so that various values of  $\hbar$  label different sizes of  $CD$ . Therefore radiative corrections reflect breaking of the scaling invariance with respect to  $M^4$  scalings for the preferred extremals.

2. General Coordinate Invariance forces to conclude that Kähler gauge potential is dimensionless so that Kähler action must be proportional to  $\hbar_0/g_K^2$  or  $\hbar/g_K^2$ . The latter option would lead to non-sensible results since the action of  $CP_2$  type vacuum extremals would be scaled up and gravitational constant would be extremely small for dark matter with large Planck constant. The first option is also consistent with the fact that the scaling of  $1/\hbar$ -factor in the modified Dirac action affects Kähler function only by an addition of a constant term.
3. It is important to notice the difference between Kähler gauge potential, which is classical field, and gauge potential of QFTs which is quantum field. By General Coordinate Invariance Kähler gauge potential is dimensionless whereas quantal gauge potential has different dimension  $[\hbar/g]/L = [\sqrt{\hbar}]/L$ . The instanton term in Kähler action is also dimensionless and the invariance under the overall scaling of  $\hbar$  requires that the scaling factor equals to  $k/4\pi$ . Instanton term therefore brings in no dependence on  $\hbar$  at the classical level and the character of CP breaking depends on  $\hbar$  only via the breaking of scale invariance.

The book like structure of  $M^4$  and  $CP_2$  means that if the  $M^4$  resp.  $CP_2$  projection partonic surface corresponds to a light-like ray of  $M^2$  or preferred geodesic sphere  $S_i^2$  of  $CP_2$ , problems might be encountered since the value of  $\hbar$  is non-unique.  $S_I^2$  produces no problems since it corresponds to vanishing induced Kähler field so that vertices vanish. Partonic 2-surfaces with  $S_{II}^2$  projection need not correspond to preferred extremals. Problems are avoided if these kind of 2-surfaces are not allowed as vertices. Since M-matrix characterizes zero energy state, this kind of condition can be posed at least formally.

An interesting question is what happens in exact quantum criticality (with respect to the change of Planck constant). Could one have a topological field theory in  $S_i^2$  or factorizing QFT in  $M^2$  as one might expect on basis of the observation that at criticality the theory reduces to a pure topological QFT or something analogous to it? For factorizing QFT in  $M^2$  particle scattering is elastic [31] : particles just pass by and at most permute their momenta. The S-matrix reduces to a braiding S-matrix at the limits  $v \rightarrow 0$  and  $v \rightarrow c$  for particle velocities. The S-matrix of factorizing QFTs does not depend on  $\hbar$  as is clear from the fact that it depends only on the rapidity differences of the incoming and outgoing particles: this can be seen also from exact some exact solutions to the defining relations of Zamolodchikov algebra [49] . Also the N-point functions of topological QFTs are independent of  $\hbar$  since there is no coupling constant strength with dimensions of  $\hbar$  (such as  $g^2$  in gauge theory) and no fundamental mass parameter so that  $\hbar\omega/m$  for some characteristic frequency could introduce  $\hbar$  dependence.

Fusion rules suggest that also the N-point functions of conformal field theories can be made independent of Planck constant by a suitable scaling of conformal fields. This is suggested also by the fact that the commutation relations of conformal algebras (energy momentum tensor and Kac-Moody currents) allow indeed elimination of  $\hbar$  completely by an appropriate scaling of generators. All this conforms with the notion that radiative corrections correspond to the breaking of scale invariance in  $M^4$  degrees of freedom.

### Do anyonic phases make $\hbar(M^4)$ and $\hbar(CP_2)$ separately visible?

There are good reasons to expect that something in the modified Dirac equation differentiates between different pages of book like structure associated with  $CD$  (causal diamond of  $M^4$ ) and  $CP_2$  realizing the hierarchy of phases with different Planck constants. The ratio  $\hbar(CD)/\hbar(CP_2)$  is visible via radiative corrections and reflects the breaking of scale invariance associated with scalings of  $CD$  making itself manifest at the level of preferred extremals. One could however ask whether also information about  $\hbar(CD)$  and  $\hbar(CP_2)$  rather than only their ratio could be coded to the modified Dirac action.

The intuitive view is that non-standard values of Planck constant correspond to anyonic or at least potentially anyonic phases of matter with fractionization of quantum numbers. This suggests that the Kähler gauge potential of  $CP_2$  extends to that in  $CD \times CP_2$  and possess what gauge theorist would call a pure gauge part. This part could be present also in  $CD$ . Since Kähler gauge potential does not relate to a genuine gauge field ( $U(1)$  gauge transformations correspond to symplectic transformations of  $CP_2$  and are symmetries only for vacuum extremals), even the addition of a pure gauge might change physics. A more conservative assumption is that the pure gauge part cannot be eliminated by a non-singular global gauge transformation as it typically is in topological gauge theories defined by Chern-Simons action.

**The modification of Kähler gauge potential in  $CD$**

The singular pure gauge part is visible in the modified Dirac equation in the covariant derivative  $D_\alpha$ , which receives  $\Delta A_\alpha$  term:  $D_\alpha \rightarrow D_\alpha + \Delta A_\alpha$ .

Let us consider first what happens in the case of  $CD$ .

1. Let  $M^2 \times E^2$  denote the decomposition of  $M^4$  implied by the hierarchy of Planck constants and introduce cylindrical coordinates  $(t, z, \rho, \phi)$ .
2. The presence of  $M^2$  singularity means that there z-axis represents an infinitely thin cylindrical hole in  $E^3$  and homology group is thus non-trivial. Therefore one can one introduce a modification of Kähler gauge potential not allowed in  $E^3$ . The modification is  $\Delta A_\phi = \Delta = k/n$ . As a consequence, the phases  $exp(im\phi)$  associated with the eigenstates of orbital angular momentum are transformed to  $exp(i(m - k/n)\phi)$  and become many-valued unless one replaces  $CD$  with its  $n$ -fold covering, which is just what has been done.
3. That spin fractionization takes place becomes clear by studying the expression of the angular momentum current  $J_z$  for modified Dirac operator. If the first variation of  $D_K$  vanishes in absence of  $\Delta A$ , there is no contribution to conserved charges from  $D_\alpha$  term and only the change of  $\Psi$  under the symmetry transformation contributes.  $\Delta A_\phi$  however brings to the current associated with  $J_z$  an additional term which reduces to fermion current multiplied by  $\Delta A$  when  $\Delta A_\phi$  constant. Genuine charge fractionization results but only if one cannot eliminate  $\Delta A_\phi$  by a gauge transformation, which is well defined for the entire partonic 2-surface. This is the case if  $X^2$  encloses the tip of  $CD$  so that homological triviality of  $X^2$  in  $CD \setminus M^2$  can be seen as a necessary condition for anyonization.
4.  $\Delta A$  modifies conserved currents associated with all those symmetries which affect the value of  $\phi$ , in particular translations in the plane  $E^2$ . If one accepts the angular momentum fractionization in this manner, then only the projection of four-momentum to the plane  $M^2$  is good quantum number. Angular momentum and square of transversal momentum would be additional good quantum numbers. That this is the case is suggested also by p-adic mass calculations and parton model of hadrons.

**The modification of Kähler gauge potential in  $CP_2$**

In  $CP_2$  degrees of freedom the homologically trivial geodesic sphere  $S^2_I$  and its homologically non-trivial counterpart  $S^2_{II}$  define candidates for the two backs of the  $CP_2$  book.

1. First a summary of some basic facts about  $CP_2$  is in order.
  - (a) The Eguchi-Hanson coordinates  $(\xi^1, \xi^2)$  of  $CP_2$  to which  $U(2)$  by definition acts linearly are related to the "spherical coordinates" via the equations

$$\begin{aligned} \xi^1 &= r \exp(i \frac{(\Psi + \Phi)}{2}) \cos(\frac{\Theta}{2}) , \\ \xi^2 &= r \exp(i \frac{(\Psi - \Phi)}{2}) \sin(\frac{\Theta}{2}) . \end{aligned} \tag{12.4.1}$$

The ranges of the variables  $r, \Theta, \Phi, \Psi$  are  $[0, \infty], [0, \pi], [0, 4\pi], [0, 2\pi]$  respectively. The different choices of quantization of  $I_3$  and  $Y_A$  are related by  $SU(3)$  rotations of these coordinates.

- (b) In these coordinates Kähler gauge potential is given by

$$B_K = \frac{r(d\Psi + \cos\Theta d\Phi)}{2F} , \quad F = 1 + r^2 . \tag{12.4.2}$$

Kähler gauge potentials for different choices of quantization axes are related by  $U(1)$  gauge transformation induced by the  $SU(3)$  rotation in question.

(c) The standard representatives for the geodesic spheres of  $CP_2$  are given by the equations

$$S_I^2 : \xi^1 = \bar{\xi}^2 \text{ or equivalently } (\Theta = \pi/2, \Psi = 0) ,$$

$$S_{II}^2 : \xi^1 = \xi^2 \text{ or equivalently } (\Theta = \pi/2, \Phi = 0) .$$

2. The natural identification of the quantization axes corresponds to directions which remain invariant under  $SO(2) \subset SO(3) \subset SU(3)$  for  $S_I^2$ . For  $S_{II}^2$  the action of  $U(2)$  reduces to that of  $SU(2)$  since and  $U(1)$  inducing same phase rotation of both complex coordinates  $(\xi^1, \xi^2)$  is the natural identification defined the invariant manifolds which induce slicing of  $S^2$  to circles parallel to equator. The circles to which  $\Delta A$  can be assigned are circles "going around"  $S_I^2$ .
3. In the case of  $S_I^2$  different values of angle  $\Phi$  correspond to the same point of  $S_I^2$  and rotations "around"  $S_I^2$  correspond to rotations  $\Psi \rightarrow \Psi + \delta\Psi$  so that  $\Delta A_\Psi$  would be naturally non-vanishing in this case. For  $S_{II}^2$  the roles of  $\Phi$  and  $\Psi$  are changed.
4.  $\Delta A$  would be thus of form  $\Delta A_\Phi + \Delta A_\Psi$  if one accepts  $CP_2$  book with two backs.

### $\Delta A$ is necessary for charge fractionization

The introduction of  $\Delta A$  explicitly into the modified Dirac equation means an explicit breaking of Lorentz invariance and color symmetry. The interpretation is as an imbedding space correlate for the choice of quantization axes. Lorentz symmetry is something sacred and this motivates the question whether the instanton term in modified Dirac action could be enough. It however seems impossible to understand charge fractionization without this term. A further justification for  $\Delta A$  comes from the requirement that it makes both  $\hbar(CD)$  and  $\hbar(CP_2)$  visible in the fundamental physics rather than only their ratio  $\hbar/\hbar_0 = \hbar(CD)/\hbar(CP_2)$ .  $\Delta A$  indeed implies charge fractionization as the following argument shows in more detail.

1. The values of  $\Delta A$  relate to the values of integers  $n_a$  and  $n_b$  appearing in the integers  $n_a$  and  $n_b$  appearing in the expression of Planck constants  $\hbar(CD)$  and  $\hbar(CP_2)$  and characterizing the orders of maximal cyclic subgroups associated with the covering. For singular coverings  $\Delta A(CD) = 1/n_a$  ( $\Delta A(CP_2) = 1/n_b$ ) would hold true naturally. For singular factor spaces one would have  $\Delta A(CD) = n_a$  ( $\Delta A(CP_2) = n_b$ ).
2. The full Kähler gauge potential would be of form  $A + \Delta A(M^4) + \Delta A(CP_2)$ . As consequence, the Chern-Simons term appearing at  $X_I^3$  is of form  $A \wedge J + \Delta A(M^4) \wedge J + \Delta A(CP_2) \wedge J$  and contains anomalous parts.  $\Delta A(M^4)$  implies that  $C - S$  action is non-vanishing also for 2-dimensional  $CP_2$  projection at least when  $X^2$  has homologically non-trivial  $CP_2$  projection.
  - (a) As already explained,  $\Delta A$  gives an anomalous contribution to spin and color hypercharge and isopin. The contribution is of form  $\bar{\Psi} \hat{\Gamma}^\alpha \Delta A_\phi \Psi$  and boils down to a shift  $\Delta S_z = \Delta A_\phi$  for single fermion state. Shift is in question whereas non-standard values of  $\hbar$  imply scaling of the basic charge unit.
  - (b) What happens in the case of electro-weak charges is not quite obvious. Electro-weak gauge charges can be identified as fermionic Noether charges associated with  $D_K$ . Noether currents are of form  $\bar{\Psi} \{ \hat{\Gamma}^\alpha, Q \} \Psi$ . The charge matrices associated with the couplings of photon and  $Z^0$  are covariantly constant being combinations of matrices  $P_\pm = (1 \pm \Gamma_9)/2$  (coupling to Kähler gauge potential), matrix  $P_\pm J$ ,  $J = J^{kl} \Sigma_{kl}$  (coupling to the vectorial part of spinor curvature),  $P_\pm (1 - \gamma_5) J^{kl} \Sigma_{kl}$  (left handed coupling of  $Z^0$ ).  $\{ \hat{\Gamma}^\alpha, Q \}$  does not contribute to the divergence of Noether current so that these Noether currents are conserved.  $W$  boson charge matrices are not covariantly constant. The non-conservation of corresponding Noether currents obviously reflects electro-weak symmetry breaking. There is no anomalous contribution to electro-weak gauge charges.
  - (c) An old idea of TGD - motivated by the fact that  $U(2) \subset SU(3)$  can be identified with the holonomy group of spinor connection identifiable as  $U(2)_{ew}$  - is that electro-weak gauge charges can be identified as color gauge charges assignable to color Noether currents whereas

quark and gluon color resides in  $CP_2$  partial waves for center of mass degrees of freedom of  $X^3$  and thus in configuration space degrees of freedom. In fact, the vanishing of the first variation of  $D_K$  implies that these charges are vanishing so that the idea as such does not work and by previous observation need not to do so. The anomalous contribution is however non-vanishing since its first variation does not vanish and gives to the electro weak currents an anomalous contribution of form  $\bar{\Psi}\hat{\Gamma}^\alpha(a\Delta A_\Phi + b\Delta A_\Psi)\Psi$ , where  $a$  and  $b$  depend on the detailed correspondence between electro-weak and color hyper-charge and isospin. Anomalous contributions to isospins are identifiable as such and anomalous Kähler contribution must be proportional to the anomalous color hyper-charge. Leptons (quarks) couple to  $n = -3$  ( $n = 1$ ) multiple of Kähler gauge potential so that the contribution to anomalous Kähler charge is of form  $nk\Delta A_\Psi$ , where  $k = 1$  is the simplest guess. This predicts the shifts  $\Delta I_{3,ew} = \Delta A_\Phi$  and  $\Delta Q_K = n\Delta A_\Psi$  allowing to deduce the shifts of em and  $Z^0$  charges.

3.  $\Delta A$  affects the transversal part  $D_K(X^2)$  of the modified Dirac operator via covariant derivative, which means that the preferred extremal is modified since the moduli of the eigenvalues are modified. Charge fractionization should also make itself visible as a selection of the preferred extremal of Kähler action through stationary phase approximation. The phase factor  $\exp(i \int Tr(QA_\mu)dx^\mu)$ , where  $Q$  is the charge matrix characterizing particle assigned to the strands of number theoretic braid generates a correlation between the properties of preferred extremal and quantum numbers associated with  $X_I^3$ . If  $Q$  is replaced with the fractionized charge the desired correlation results but not otherwise if one believes following argument. Stationary phase approximation gives field equations in which charges at partonic strands play the role of sources:  $\Delta A$  is not visible in the source nor in the motion of sources nor in the equations of the extremals of  $C - S$  action. Thus it seems that extremum is not affected by the modification of Chern-Simons action unless very delicate effects are involved.

## 12.5 Vision about dark matter as phases with non-standard value of Planck constant

### 12.5.1 Dark rules

It is useful to summarize the basic phenomenological view about dark matter.

#### The notion of relative darkness

The essential difference between TGD and more conventional models of dark matter is that darkness is only relative concept.

1. Generalized imbedding space forms a book like structure and particles at different pages of the book are dark relative to each other since they cannot appear in the same vertex identified as the partonic 2-surface along which light-like 3-surfaces representing the lines of generalized Feynman diagram meet.
2. Particles at different space-time sheets act via classical gauge field and gravitational field and can also exchange gauge bosons and gravitons (as also fermions) provided these particles can leak from page to another. This means that dark matter can be even photographed [6]. This interpretation is crucial for the model of living matter based on the assumption that dark matter at magnetic body controls matter visible to us. Dark matter can also suffer a phase transition to visible matter by leaking between the pages of the Big Book.
3. The notion of standard value  $\hbar_0$  of  $\hbar$  is not a relative concept in the sense that it corresponds to rational  $r = 1$ . In particular, the situation in which both  $CD$  and  $CP_2$  correspond to trivial coverings and factor spaces would naturally correspond to standard physics.

### Is dark matter anyonic?

In [57] a detailed model for the Kähler structure of the generalized imbedding space is constructed. What makes this model non-trivial is the possibility that  $CP_2$  Kähler form can have gauge parts which would be excluded in full imbedding space but are allowed because of singular covering/factor-space property. The model leads to the conclusion that dark matter is anyonic if the partonic 2-surface, which can have macroscopic or even astrophysical size, encloses the tip of  $CD$  within it. Therefore the partonic 2-surface is homologically non-trivial when the tip is regarded as a puncture. Fractional charges for anyonic elementary particles imply confinement to the partonic 2-surface and the particles can escape the two surface only via reactions transforming them to ordinary particles. This would mean that the leakage between different pages of the big book is a rare phenomenon. This could partially explain why dark matter is so difficult to observe.

### Field body as carrier of dark matter

The notion of "field body" implied by topological field quantization is essential. There would be em,  $Z^0$ ,  $W$ , gluonic, and gravitonic field bodies, each characterized by its one prime. The motivation for considering the possibility of separate field bodies seriously is that the notion of induced gauge field means that all induced gauge fields are expressible in terms of four  $CP_2$  coordinates so that only single component of a gauge potential allows a representation as an independent field quantity. Perhaps also separate magnetic and electric field bodies for each interaction and identifiable as flux quanta must be considered. This kind of separation requires that the fermionic content of the flux quantum (say fermion and anti-fermion at the ends of color flux tube) is such that it conforms with the quantum numbers of the corresponding boson.

What is interesting that the conceptual separation of interactions to various types would have a direct correlate at the level of space-time topology. From a different perspective inspired by the general vision that many-sheeted space-time provides symbolic representations of quantum physics, the very fact that we make this conceptual separation of fundamental interactions could reflect the topological separation at space-time level.

p-Adic mass calculations for quarks encourage to think that the p-adic length scale characterizing the mass of particle is associated with its electromagnetic body and in the case of neutrinos with its  $Z^0$  body.  $Z^0$  body can contribute also to the mass of charged particles but the contribution would be small. It is also possible that these field bodies are purely magnetic for color and weak interactions. Color flux tubes would have exotic fermion and anti-fermion at their ends and define colored variants of pions. This would apply not only in the case of nuclear strings but also to molecules and larger structures so that scaled variants of elementary particles and standard model would appear in all length scales as indeed implied by the fact that classical electro-weak and color fields are unavoidable in TGD framework.

One can also go further and distinguish between magnetic field body of free particle for which flux quanta start and return to the particle and "relative field" bodies associated with pairs of particles. Very complex structures emerge and should be essential for the understanding the space-time correlates of various interactions. In a well-defined sense they would define space-time correlate for the conceptual analysis of the interactions into separate parts. In order to minimize confusion it should be emphasized that the notion of field body used in this chapter relates to those space-time correlates of interactions, which are more or less *static* and related to the formation of *bound states*.

### 12.5.2 Phase transitions changing Planck constant

The general picture is that p-adic length scale hierarchy corresponds to p-adic coupling constant evolution and hierarchy of Planck constants to the coupling constant evolution related to phase resolution. Both evolutions imply a book like structure of the generalized imbedding space.

#### Transition to large $\hbar$ phase and failure of perturbation theory

One of the first ideas was that the transition to large  $\hbar$  phase occurs when perturbation theory based on the expansion in terms of gauge coupling constant ceases to converge: Mother Nature would take care of the problems of theoretician. The transition to large  $\hbar$  phase obviously reduces the value of gauge coupling strength  $\alpha \propto 1/\hbar$  so that higher orders in perturbation theory are reduced whereas

the lowest order "classical" predictions remain unchanged. A possible quantitative formulation of the criterion is that maximal 2-particle gauge interaction strength parameterized as  $Q_1 Q_2 \alpha$  satisfies the condition  $Q_1 Q_2 \alpha \simeq 1$ .

A justification for this picture would be that in non-perturbative phase large quantum fluctuations are present (as functional integral formalism suggests). At space-time level this could mean that space-time sheet is near to a non-deterministic vacuum extremal -at least if homologically trivial geodesic sphere defines the number theoretic braids. At certain critical value of coupling constant strength one expects that the transition amplitude for phase transition becomes very large. The resulting phase would be of course different from the original since typically charge fractionization would occur.

One should understand why the failure of the perturbation theory (expected to occur for  $\alpha Q_1 Q_2 > 1$ ) induces the reduction of Clifford algebra, scaling down of  $CP_2$  metric, and whether the  $G$ -symmetry is exact or only approximate. A partial understanding already exists. The discrete  $G$  symmetry and the reduction of the dimension of Clifford algebra would have interpretation in terms of a loss of degrees of freedom as a strongly bound state is formed. The multiple covering of  $M_{\pm}^4$  accompanying strong binding can be understood as an automatic consequence of  $G$ -invariance. A concrete realization for the binding could be charge fractionization which would not allow the particles bound on large light-like 3-surface to escape without transformation to ordinary particles.

Two examples perhaps provide more concrete view about this idea.

1. The proposed scenario can reproduce the huge value of the gravitational Planck constant. One should however develop a convincing argument why non-perturbative phase for the gravitating dark matter leads to a formation of  $G_a \times$  covering of  $CD \setminus M^2 \times CP_2 \setminus S_I^2$  with the huge value of  $\hbar_{eff} = n_a/n_b \simeq GM_1 M_2/v_0$ . The basic argument is that the dimensionless parameter  $\alpha_{gr} = GM_1 M_2/4\pi\hbar$  should be so small that perturbation theory works. This gives  $\hbar_{gr} \geq GM_1 M_2/4\pi$  so that order of magnitude is predicted correctly.
2. Color confinement represents the simplest example of a transition to a non-perturbative phase. In this case  $A_2$  and  $n = 3$  would be the natural option. The value of Planck constant would be 3 times higher than its value in perturbative QCD. Hadronic space-time sheets would be 3-fold coverings of  $M_{\pm}^4$  and baryonic quarks of different color would reside on 3 separate sheets of the covering. This would resolve the color statistics paradox suggested by the fact that induced spinor fields do not possess color as spin like quantum number and by the facts that for orbifolds different quarks cannot move in independent  $CP_2$  partial waves assignable to  $CP_2$  cm degrees of freedom as in perturbative phase.

### The mechanism of phase transition and selection rules

The mechanism of phase transition is at classical level similar to that for ordinary phase transitions. The partonic 2-surface decomposes to regions corresponding to difference values of  $\hbar$  at quantum criticality in such a manner that regions in which induced Kähler form is non-vanishing are contained within single page of imbedding space. It might be necessary to assume that only a region corresponding to single value of  $\hbar$  is possible for partonic 2-surfaces and  $\delta CD \times CP_2$  so that quantum criticality would be associated with the intermediate state described by the light-like 3-surface. One could also see the phase transition as a leakage of  $X^2$  from given page to another: this is like going through a closed door through a narrow slit between door and floor. By quantum criticality the points of number theoretic braid are already in the slit.

As in the case of ordinary phase transitions the allowed phase transitions must be consistent with the symmetries involved. This means that if the state is invariant under the maximal cyclic subgroups  $G_a$  and  $G_b$  then also the final state must satisfy this condition. This gives constraints to the orders of maximal cyclic subgroups  $Z_a$  and  $Z_b$  for initial and final state:  $n(Z_{a_i})$  resp.  $n(Z_{b_i})$  must divide  $n(Z_{a_f})$  resp.  $n(Z_{b_f})$  or vice versa in the case that factors of  $Z_i$  do not leave invariant the states. If this is the case similar condition must hold true for appropriate subgroups. In particular, powers of prime  $Z_{p^n}$ ,  $n = 1, 2, \dots$  define hierarchies of allowed phase transitions.

### 12.5.3 Coupling constant evolution and hierarchy of Planck constants

If the overall vision is correct, quantum TGD would be characterized by two kinds of couplings constant evolutions. p-Adic coupling constant evolution would correspond to length scale resolution

and the evolution with respect to Planck constant to phase resolution. Both evolution would have number theoretic interpretation.

### Evolution with respect to phase resolution

The coupling constant evolution in phase resolution in p-adic degrees of freedom corresponds to emergence of algebraic extensions allowing increasing variety of phases  $\exp(i2\pi/n)$  expressible p-adically. This evolution can be assigned to the emergence of increasingly complex quantum phases and the increase of Planck constant.

One expects that quantum phases  $q = \exp(i\pi/n)$  which are expressible using only iterated square root operation are number theoretically very special since they correspond to algebraic extensions of p-adic numbers obtained by an iterated square root operation, which should emerge first. Therefore systems involving these values of  $q$  should be especially abundant in Nature. That arbitrarily high square roots are involved as becomes clear by studying the case  $n = 2^k$ :  $\cos(\pi/2^k) = \sqrt{[1 + \cos(\pi/2^{k-1})]}/2$ .

These polygons are obtained by ruler and compass construction and Gauss showed that these polygons, which could be called Fermat polygons, have  $n_F = 2^k \prod_s F_{n_s}$  sides/vertices: all Fermat primes  $F_{n_s}$  in this expression must be different. The analog of the p-adic length scale hypothesis emerges since larger Fermat primes are near a power of 2. The known Fermat primes  $F_n = 2^{2^n} + 1$  correspond to  $n = 0, 1, 2, 3, 4$  with  $F_0 = 3$ ,  $F_1 = 5$ ,  $F_2 = 17$ ,  $F_3 = 257$ ,  $F_4 = 65537$ . It is not known whether there are higher Fermat primes.  $n = 3, 5, 15$ -multiples of p-adic length scales clearly distinguishable from them are also predicted and this prediction is testable in living matter. I have already earlier considered the possibility that Fermat polygons could be of special importance for cognition and for biological information processing [52] .

This condition could be interpreted as a kind of resonance condition guaranteeing that scaled up sizes for space-time sheets have sizes given by p-adic length scales. The numbers  $n_F$  could take the same role in the evolution of Planck constant assignable with the phase resolution as Mersenne primes have in the evolution assignable to the p-adic length scale resolution.

The Dynkin diagrams of exceptional Lie groups  $E_6$  and  $E_8$  are exceptional as subgroups of rotation group in the sense that they cannot be reduced to symmetry transformations of plane. They correspond to the symmetry group  $S_4 \times Z_2$  of tetrahedron and  $A_5 \times Z_2$  of dodecahedron or its dual polytope icosahedron ( $A_5$  is 60-element subgroup of  $S_5$  consisting of even permutations). Maximal cyclic subgroups are  $Z_4$  and  $Z_5$  and thus their orders correspond to Fermat polygons. Interestingly,  $n = 5$  corresponds to minimum value of  $n$  making possible topological quantum computation using braids and also to Golden Mean.

### Is there a correlation between the values of p-adic prime and Planck constant?

The obvious question is whether there is a correlation between p-adic length scale and the value of Planck constant. One-to-one correspondence is certainly excluded but loose correlation seems to exist.

1. In [3] the information about the number theoretic anatomy of Kähler coupling strength is combined with input from p-adic mass calculations predicting  $\alpha_K$  to be the value of fine structure constant at the p-adic length scale associated with electron. One can also develop an explicit expression for gravitational constant assuming its renormalization group invariance on basis of dimensional considerations and this model leads to a model for the fraction of volume of the wormhole contact (piece of  $CP_2$  type extremal) from the volume of  $CP_2$  characterizing gauge boson and for similar volume fraction for the piece of the  $CP_2$  type vacuum extremal associated with fermion.
2. The requirement that gravitational constant is renormalization group invariant implies that the volume fraction depends logarithmically on p-adic length scale and Planck constant (characterizing quantum scale). The requirement that this fraction in the range  $(0, 1)$  poses a correlation between the rational characterizing Planck constant and p-adic length scale. In particular, for space-time sheets mediating gravitational interaction Planck constant must be larger than  $\hbar_0$  above length scale which is about .1 Angstrom. Also an upper bound for  $\hbar$  for given p-adic length scale results but is very large. This means that quantum gravitational effects should become important above atomic length scale [3] .

## 12.6 Some applications

Below some applications of the hierarchy of Planck constants as a model of dark matter are briefly discussed. The range of applications varying from elementary particle physics to cosmology and I hope that this will convince the reader that the idea has strong physical motivations.

### 12.6.1 A simple model of fractional quantum Hall effect

The generalization of the imbedding space suggests that it could be possible to understand fractional quantum Hall effect [2] at the level of basic quantum TGD. This section represents the first rough model of QHE constructed for a couple of years ago is discussed. Needless to emphasize, the model represents only the basic idea and involves ad hoc assumption about charge fractionization.

Recall that the formula for the quantized Hall conductance is given by

$$\begin{aligned}\sigma &= \nu \times \frac{e^2}{h} , \\ \nu &= \frac{n}{m} .\end{aligned}\tag{12.6.1}$$

Series of fractions in  $\nu = 1/3, 2/5, 3/7, 4/9, 5/11, 6/13, 7/15, \dots, 2/3, 3/5, 4/7, 5/9, 6/11, 7/13, \dots, 5/3, 8/5, 11/7, 14/9, \dots, 4/3, 7/5, 10/7, 13/9, \dots, 1/5, 2/9, 3/13, \dots, 2/7, 3/11, \dots, 1/7, \dots$  with odd denominator have been observed as are also  $\nu = 1/2$  and  $\nu = 5/2$  states with even denominator [2] .

The model of Laughlin [13] cannot explain all aspects of FQHE. The best existing model proposed originally by Jain is based on composite fermions resulting as bound states of electron and even number of magnetic flux quanta [11] . Electrons remain integer charged but due to the effective magnetic field electrons appear to have fractional charges. Composite fermion picture predicts all the observed fractions and also their relative intensities and the order in which they appear as the quality of sample improves.

The generalization of the notion of imbedding space suggests the possibility to interpret these states in terms of fractionized charge, spin, and electron number. There are  $2 \times 2 = 4$  combinations of covering and factor spaces of  $CP_2$  and three of them can lead to the increase of Planck constant. Besides this one can consider two options for the formula of Planck constant so that which the very meager theoretical background one can make only guesses. In the following a model based on option II for which the number of states is conserved in the phase transition changing  $\hbar$ .

1. The easiest manner to understand the observed fractions is by assuming that both  $CD$  and  $CP_2$  correspond to covering spaces so that both spin and electric charge and fermion number are fractionized. This means that  $e$  in electronic charge density is replaced with fractional charge. Quantized magnetic flux is proportional to  $e$  and the question is whether also here fractional charge appears. Assume that this does not occur.
2. With this assumption the expression for the Planck constant becomes for Option II as  $r = \hbar/\hbar_0 = n_a/n_b$  and charge and spin units are equal to  $1/n_b$  and  $1/n_a$  respectively. This gives  $\nu = nm_a/n_b$ . The values  $m = 2, 3, 5, 7, \dots$  are observed. Planck constant can have arbitrarily large values. There are general arguments stating that also spin is fractionized in FQHE.
3. Both  $\nu = 1/2$  and  $\nu = 5/2$  state has been observed [2, 8] . The fractionized charge is  $e/4$  in the latter case [8, 16] . Since  $n_i > 3$  holds true if coverings and factor spaces are correlated for Jones inclusions, this requires  $n_a = 4$  and  $n_b = 8$  for  $\nu = 1/2$  and  $n_b = 4$  and  $n_a = 10$  for  $\nu = 5/2$ . Correct fractionization of charge is predicted. For  $n_b = 2$  also  $Z_2$  would appear as the fundamental group of the covering space. Filling fraction  $1/2$  corresponds in the composite fermion model and also experimentally to the limit of zero magnetic field [11] .  $n_b = 2$  is inconsistent with the observed fractionization of electric charge for  $\nu = 5/2$  and with the vision inspired by Jones inclusions.
4. A possible problematic aspect of the TGD based model is the experimental absence of even values of  $n_b$  except  $n_b = 2$  (Laughlin's model predicts only odd values of  $n$ ). A possible explanation is that by some symmetry condition possibly related to fermionic statistics (as in Laughlin model)

$n_a/n_b$  must reduce to a rational with an odd denominator for  $n_b > 2$ . In other words, one has  $n_a \propto 2^r$ , where  $2^r$  the largest power of 2 divisor of  $n_b$ .

5. Large values of  $n_a$  emerge as  $B$  increases. This can be understood from flux quantization. One has  $e \int BdS = n\hbar(M^4) = nn_a\hbar_0$ . By using actual fractional charge  $e_F = e/n_b$  in the flux factor would give  $e_F \int BdS = n(n_a/n_b)\hbar_0 = n\hbar$ . The interpretation is that each of the  $n_a$  sheets contributes one unit to the flux for  $e$ . Note that the value of magnetic field in given sheet is not affected so that the build-up of multiple covering seems to keep magnetic field strength below critical value.
6. The understanding of the thermal stability is not trivial. The original FQHE was observed in 80 mK temperature corresponding roughly to a thermal energy of  $T \sim 10^{-5}$  eV. For graphene the effect is observed at room temperature. Cyclotron energy for electron is (from  $f_e = 6 \times 10^5$  Hz at  $B = .2$  Gauss) of order thermal energy at room temperature in a magnetic field varying in the range 1-10 Tesla. This raises the question why the original FQHE requires so low temperature. The magnetic energy of a flux tube of length  $L$  is by flux quantization roughly  $e^2 B^2 S \sim E_c(e)m_e L$  ( $\hbar_0 = c = 1$ ) and exceeds cyclotron roughly by a factor  $L/L_e$ ,  $L_e$  electron Compton length so that thermal stability of magnetic flux quanta is not the explanation. A possible explanation is that since FQHE involves several values of Planck constant, it is quantum critical phenomenon and is characterized by a critical temperature. The differences of the energies associated with the phase with ordinary Planck constant and phases with different Planck constant would characterize the transition temperature.

As already noticed, it is possible to imagine several other options and the assumption about charge fractionization -although consistent with fractionization for  $\nu = 5/2$ , is rather adhoc. Therefore the model can be taken as a warm-up exercise only. In [57], where the delicacies of Kähler structure of generalized imbedding space are discussed, also a more detailed of QHE is discussed.

### 12.6.2 Gravitational Bohr orbitology

The basic question concerns justification for gravitational Bohr orbitology [64]. The basic vision is that visible matter identified as matter with  $\hbar = \hbar_0$  ( $n_a = n_b = 1$ ) concentrates around dark matter at Bohr orbits for dark matter particles. The question is what these Bohr orbits really mean. Should one in improved approximation relate Bohr orbits to 3-D wave functions for dark matter as ordinary Bohr rules would suggest or do the Bohr orbits have some deeper meaning different from that in wave mechanics. Anyonic variants of partonic 2-surfaces with astrophysical size are a natural guess for the generalization of Bohr orbits.

#### Dark matter as large $\hbar$ phase

D. Da Rocha and Laurent Nottale have proposed that Schrödinger equation with Planck constant  $\hbar$  replaced with what might be called gravitational Planck constant  $\hbar_{gr} = \frac{GmM}{v_0}$  ( $\hbar = c = 1$ ).  $v_0$  is a velocity parameter having the value  $v_0 = 144.7 \pm .7$  km/s giving  $v_0/c = 4.6 \times 10^{-4}$ . This is rather near to the peak orbital velocity of stars in galactic halos. Also subharmonics and harmonics of  $v_0$  seem to appear. The support for the hypothesis coming from empirical data is impressive [64].

Nottale and Da Rocha believe that their Schrödinger equation results from a fractal hydrodynamics. Many-sheeted space-time however suggests astrophysical systems are not only quantum systems at larger space-time sheets but correspond to a gigantic value of gravitational Planck constant. The gravitational (ordinary) Schrödinger equation -or at least Bohr rules with appropriate interpretation - would provide a solution of the black hole collapse (IR catastrophe) problem encountered at the classical level. The resolution of the problem inspired by TGD inspired theory of living matter is that it is the dark matter at larger space-time sheets which is quantum coherent in the required time scale.

#### Prediction for the parameter $v_0$

One of the key questions relate to the value of the parameter  $v_0$ . Before the introduction of the hierarchy of Planck constants I proposed that the value of the parameter  $v_0$  assuming that cosmic strings and their decay remnants are responsible for the dark matter. The harmonics of  $v_0$  can be

understood as corresponding to perturbations replacing cosmic strings with their  $n$ -branched coverings so that tension becomes  $n$ -fold much like the replacement of a closed orbit with an orbit closing only after  $n$  turns.  $1/n$ -sub-harmonic would result when a magnetic flux tube split into  $n$  disjoint magnetic flux tubes. The planetary mass ratios can be produced with an accuracy better than 10 per cent assuming ruler and compass phases.

### Further predictions

The study of inclinations (tilt angles with respect to the Earth's orbital plane) leads to a concrete model for the quantum evolution of the planetary system. Only a stepwise breaking of the rotational symmetry and angular momentum Bohr rules plus Newton's equation (or geodesic equation) are needed, and gravitational Schrödinger equation holds true only inside flux quanta for the dark matter.

1. During pre-planetary period dark matter formed a quantum coherent state on the ( $Z^0$ ) magnetic flux quanta (spherical cells or flux tubes). This made the flux quantum effectively a single rigid body with rotational degrees of freedom corresponding to a sphere or circle (full  $SO(3)$  or  $SO(2)$  symmetry).
2. In the case of spherical shells associated with inner planets the  $SO(3) \rightarrow SO(2)$  symmetry breaking led to the generation of a flux tube with the inclination determined by  $m$  and  $j$  and a further symmetry breaking, kind of an astral traffic jam inside the flux tube, generated a planet moving inside flux tube. The semiclassical interpretation of the angular momentum algebra predicts the inclinations of the inner planets. The predicted (real) inclinations are 6 (7) resp. 2.6 (3.4) degrees for Mercury resp. Venus). The predicted (real) inclination of the Earth's spin axis is 24 (23.5) degrees.
3. The  $v_0 \rightarrow v_0/5$  transition allowing to understand the radii of the outer planets in the model of Da Rocha and Nottale can be understood as resulting from the splitting of ( $Z^0$ ) magnetic flux tube to five flux tubes representing Earth and outer planets except Pluto, whose orbital parameters indeed differ dramatically from those of other planets. The flux tube has a shape of a disk with a hole glued to the Earth's spherical flux shell.

It is important to notice that effectively a multiplication  $n \rightarrow 5n$  of the principal quantum number is in question. This allows to consider also alternative explanations. Perhaps external gravitational perturbations have kicked dark matter from the orbit or Earth to  $n = 5k$ ,  $k = 2, 3, \dots, 7$  orbits: the fact that the tilt angles for Earth and all outer planets except Pluto are nearly the same, supports this explanation. Or perhaps there exist at least small amounts of dark matter at all orbits but visible matter is concentrated only around orbits containing some critical amount of dark matter and these orbits satisfy  $n \bmod 5 = 0$  for some reason.

4. A remnant of the dark matter is still in a macroscopic quantum state at the flux quanta. It couples to photons as a quantum coherent state but the coupling is extremely small due to the gigantic value of  $\hbar_{gr}$  scaling alpha by  $\hbar/\hbar_{gr}$ : hence the darkness.

The rather amazing coincidences between basic bio-rhythms and the periods associated with the states of orbits in solar system suggest that the frequencies defined by the energy levels of the gravitational Schrödinger equation might entrain with various biological frequencies such as the cyclotron frequencies associated with the magnetic flux tubes. For instance, the period associated with  $n = 1$  orbit in the case of Sun is 24 hours within experimental accuracy for  $v_0$ .

### Comparison with Bohr quantization of planetary orbits

The predictions of the generalization of the p-adic length scale hypothesis are consistent with the TGD based model for the Bohr quantization of planetary orbits and some new non-trivial predictions follow.

1. The model can explain the enormous values of gravitational Planck constant  $\hbar_{gr}/\hbar_0 = \simeq GMm/v_0 = n_a/n_b$ . The favored values of this parameter should correspond to  $n_{F_a}/n_{F_b}$  so that the mass ratios  $m_1/m_2 = n_{F_{a,1}}n_{F_{b,2}}/n_{F_{b,1}}n_{F_{a,2}}$  for planetary masses should be preferred. The general prediction  $GMm/v_0 = n_a/n_b$  is of course not testable.

2. Nottale [10] has suggested that also the harmonics and sub-harmonics of  $\hbar_{gr}$  are possible and in fact required by the model for planetary Bohr orbits (in TGD framework this is not absolutely necessary [64]). The prediction is that favored values of  $n$  should be of form  $n_F = 2^k \prod F_i$  such that  $F_i$  appears at most once. In Nottale's model for planetary orbits as Bohr orbits in solar system [64]  $n = 5$  harmonics appear and are consistent with either  $n_{F,a} \rightarrow F_1 n_{F_a}$  or with  $n_{F,b} \rightarrow n_{F_b}/F_1$  if possible.

The prediction for the ratios of planetary masses can be tested. In the table below are the experimental mass ratios  $r_{exp} = m(pl)/m(E)$ , the best choice of  $r_R = [n_{F,a}/n_{F,b}] * X$ ,  $X$  common factor for all planets, and the ratios  $r_{pred}/r_{exp} = n_{F,a}(planet)n_{F,b}(Earth)/n_{F,a}(Earth)n_{F,b}(planet)$ . The deviations are at most 2 per cent.

<i>planet</i>	<i>Me</i>	<i>V</i>	<i>E</i>	<i>M</i>	<i>J</i>
<i>y</i>	$\frac{2^{13} \times 5}{17}$	$2^{11} \times 17$	$2^9 \times 5 \times 17$	$2^8 \times 17$	$\frac{2^{23} \times 5}{7}$
<i>y/x</i>	1.01	.98	1.00	.98	1.01
<i>planet</i>	<i>S</i>	<i>U</i>	<i>N</i>	<i>P</i>	
<i>y</i>	$2^{14} \times 3 \times 5 \times 17$	$\frac{2^{21} \times 5}{17}$	$\frac{2^{17} \times 17}{3}$	$\frac{2^4 \times 17}{3}$	
<i>y/x</i>	1.01	.98	.99	.99	

Table 1. The table compares the ratios  $x = m(pl)/(m(E))$  of planetary mass to the mass of Earth to prediction for these ratios in terms of integers  $n_F$  associated with Fermat polygons.  $y$  gives the best fit for the allowed factors of the known part  $y$  of the rational  $n_{F,a}/n_{F,b} = yX$  characterizing planet, and the ratios  $y/x$ . Errors are at most 2 per cent.

A stronger prediction comes from the requirement that  $GMm/v_0$  equals to  $n = n_{F_a}/n_{F_b}$   $n_F = 2^k \prod_k F_{n_k}$ , where  $F_i = 2^{2^i} + 1$ ,  $i = 0, 1, 2, 3, 4$  is Fibonacci prime. The fit using solar mass and Earth mass gives  $n_F = 2^{254} \times 5 \times 17$  for  $1/v_0 = 2044$ , which within the experimental accuracy equals to the value  $2^{11} = 2048$  whose powers appear as scaling factors of Planck constant in the model for living matter [24]. For  $v_0 = 4.6 \times 10^{-4}$  reported by Nottale the prediction is by a factor 16/17.01 too small (6 per cent discrepancy).

A possible solution of the discrepancy is that the empirical estimate for the factor  $GMm/v_0$  is too large since  $m$  contains also the the visible mass not actually contributing to the gravitational force between dark matter objects whereas  $M$  is known correctly. The assumption that the dark mass is a fraction  $1/(1 + \epsilon)$  of the total mass for Earth gives

$$1 + \epsilon = \frac{17}{16} \tag{12.6.2}$$

in an excellent approximation. This gives for the fraction of the visible matter the estimate  $\epsilon = 1/16 \simeq 6$  per cent. The estimate for the fraction of visible matter in cosmos is about 4 per cent so that estimate is reasonable and would mean that most of planetary and solar mass would be also dark (as a matter dark energy would be in question).

That  $v_0(eff) = v_0/(1 - \epsilon) \simeq 4.6 \times 10^{-4}$  equals with  $v_0(eff) = 1/(2^7 \times F_2) = 4.5956 \times 10^{-4}$  within the experimental accuracy suggests a number theoretical explanation for the visible-to-dark fraction.

The original unconsciously performed identification of the gravitational and inertial Planck constants leads to some confusing conclusions but it seems that the new view about the quantization of Planck constants resolves these problems and allows to see  $\hbar_{gr}$  as a special case of  $\hbar_I$ .

1.  $\hbar_{gr}$  is proportional to the product of masses of interacting systems and not a universal constant like  $\hbar$ . One can however express the gravitational Bohr conditions as a quantization of circulation  $\oint v \cdot dl = n(GM/v_0)\hbar_0$  so that the dependence on the planet mass disappears as required by Equivalence Principle. This would suggest that gravitational Bohr rules relate to velocity rather than inertial momentum as is indeed natural. The quantization of circulation is consistent with the basic prediction that space-time surfaces are analogous to Bohr orbits.

2.  $\hbar_{gr}$  seems to characterize a relationship between planet and central mass and quite generally between two systems with the property that smaller system is topologically condensed at the space-time sheet of the larger system. Thus it would seem that  $\hbar_{gr}$  is not a universal constant and cannot correspond to a special value of ordinary Planck constant. Certainly this would be the case if  $\hbar_I$  is quantized as  $\lambda^k$ -multiplet of ordinary Planck constant with  $\lambda \simeq 2^{11}$ .

The recent view about the quantization of Planck constant in terms of coverings of  $CD$  seems to resolve these problems.

1. The integer quantization of Planck constants is consistent with the huge values of gravitational Planck constant within experimental resolution and the killer test for  $\hbar = \hbar_{gr}$  emerges if one takes seriously the stronger prediction  $\hbar_{gr} = n_{F,a}/n_{F,b}$ .
2. One can also regard  $\hbar_{gr}$  as ordinary Planck constant  $\hbar_{eff}$  associated with the space-time sheet along which the masses interact provided each pair  $(M, m_i)$  of masses is characterized by its own sheets. These sheets could correspond to flux tube like structures carrying the gravitational flux of dark matter. If these sheets corresponds to  $n_{F_a}$ -fold covering of  $CD$ , one can understand  $\hbar_{gr}$  as a particular instance of the  $\hbar_{eff}$ .

### Quantum Hall effect and dark anyonic systems in astrophysical scales

Bohr orbitology could be understood if dark matter concentrates on 2-dimensional partonic surfaces usually assigned with elementary particles and having size of order  $CP_2$  radius. The interpretation is in terms of wormhole throats assignable to topologically condensed  $CP_2$  type extremals (fermions) and pairs of them assignable to wormhole contacts (gauge bosons). Wormhole throat defines the light-like 3-surface at which the signature of metric of space-time surface changes from Minkowskian to Euclidian.

Large value of Planck constant would allow partons with astrophysical size. Since anyonic systems are 2-dimensional, the natural idea is that dark matter corresponds to systems carrying large fermion number residing at partonic 2-surfaces of astrophysical size and that visible matter condenses around these. Not only black holes but also ordinary stars, planetary systems, and planets could correspond at the level of dark matter to atom like structures consisting of anyonic 2-surfaces which can have complex topology (flux tubes associated with planetary orbits connected by radial flux tubes to the central spherical anyonic surface). Charge and spin fractionization are key features of anyonic systems and Jones inclusions inspiring the generalization of imbedding space indeed involve quantum groups central in the modeling of anyonic systems. Hence one has could hopes that a coherent theoretical picture could emerge along these lines.

This seems to be the case. Anyons and charge and spin fractionization are discussed in detail [57] and leads to a precise identification of the delicacies involved with the Kähler gauge potential of  $CP_2$  Kähler form in the sectors of the generalized imbedding space corresponding to various pages of boook like structures assignable to  $CD$  and  $CP_2$ . The basic outcome is that anyons correspond geometrically to partonic 2-surfaces at the light-like boundaries of  $CD$  containing the tip of  $CD$  inside them. This is what gives rise to charge fractionization and also to confinement like effects since elementary particles in anyonic states cannot as such leak to the other pages of the generalized imbedding space.  $G_a$  and  $G_b$  invariance of the states imply that fractionization occurs only at single particle level and total charge is integer valued.

This picture is much more flexible that that based on  $G_a$  symmetries of  $CD$  orbifold since partonic 2-surfaces do not possess any orbifold symmetries in  $CD$  sector anymore. In this framework various astrophysical structures such as spokes and circles would be parts of anyonic 2-surfaces with complex topology representing quantum geometrically quantum coherence in the scale of say solar system. Planets would have formed by the condensation of ordinary matter in the vicinity of the anyonic matter. This would predict stars, planetary system, and even planets to have onion-like structure consisting of shells at the level of dark matter. Similar conclusion is suggested also by purely classical model for the final state of star predicting that matter is strongly concentrated at the surface of the star [77].

### Anyonic view about blackholes

A new element to the model of black hole comes from the vision that black hole horizon as a light-like 3-surface corresponds to a light-like orbit of light-like partonic 2-surface. This allows two kinds of black holes. Fermion like black hole would correspond to a deformed  $CP_2$  type extremal which Euclidian signature of metric and topologically condensed at a space-time sheet with a Minkowskian signature. Boson like black hole would correspond to a wormhole contact connecting two space-time sheets with Minkowskian signature. Wormhole contact would be a piece deformed  $CP_2$  type extremal possessing two light-like throats defining two black hole horizons very near to each other. It does not seem absolutely necessary to assume that the interior metric of the black-hole is realized in another space-time sheet with Minkowskian signature.

Second new element relates to the value of Planck constant. For  $\hbar_{gr} = 4GM^2$  the Planck length  $L_P(\hbar) = \sqrt{\hbar G}$  equals to Schwarzschild radius and Planck mass equals to  $M_P(\hbar) = \sqrt{\hbar/G} = 2M$ . If the mass of the system is below the ordinary Planck mass:  $M \leq m_P(\hbar_0)/2 = \sqrt{\hbar_0/4G}$ , gravitational Planck constant is smaller than the ordinary Planck constant.

Black hole surface contains ultra dense matter so that perturbation theory is not expected to converge for the standard value of Planck constant but do so for gravitational Planck constant. If the phase transition increasing Planck constant is a friendly gesture of Nature making perturbation theory convergent, one expects that only the black holes for which Planck constant is such that  $GM^2/4\pi\hbar < 1$  holds true are formed. Black hole entropy -being proportional to  $1/\hbar$ - is of order unity so that TGD black holes are not very entropic.

If the partonic 2-surface surrounds the tip of causal diamond  $CD$ , the matter at its surface is in anyonic state with fractional charges. Anyonic black hole can be seen as single gigantic elementary particle stabilized by fractional quantum numbers of the constituents preventing them from escaping from the system and transforming to ordinary visible matter. A huge number of different black holes are possible for given value of  $\hbar$  since there is infinite variety of pairs  $(n_a, n_b)$  of integers giving rise to same value of  $\hbar$ .

One can imagine that the partonic surface is not exact sphere except for ideal black holes but contains large number of magnetic flux tubes giving rise to handles. Also a pair of spheres with different radii can be considered with surfaces of spheres connected by braided flux tubes. The braiding of these handles can represent information and one can even consider the possibility that black hole can act as a topological quantum computer. There would be no sharp difference between the dark parts of black holes and those of ordinary stars. Only the volume containing the complex flux tube structures associated with the orbits of planets and various objects around star would become very small for black hole so that the black hole might code for the topological information of the matter collapsed into it.

### 12.6.3 Accelerating periods of cosmic expansion as phase transitions increasing the value of Planck constant

There are several pieces of evidence for accelerated expansion, which need not mean cosmological constant, although this is the interpretation adopted in [4, 2]. Quantum cosmology predicts that astrophysical objects do not follow cosmic expansion except in jerk-wise quantum leaps increasing the value of the gravitational Planck constant. This assumption provides explanation for the apparent cosmological constant. Also planets are predicted to expand in this manner. This provides a new version of Expanding Earth theory originally postulated to explain the intriguing findings suggesting that continents have once formed a connected continent covering the entire surface of Earth but with radius which was one half of the recent one.

#### The four pieces of evidence for accelerated expansion

##### 1. Supernovas of type Ia

Supernovas of type Ia define standard candles since their luminosity varies in an oscillatory manner and the period is proportional to the luminosity. The period gives luminosity and from this the distance can be deduced by using Hubble's law:  $d = cz/H_0$ ,  $H_0$  Hubble's constant. The observation was that the farther the supernova was the more dimmer it was as it should have been. In other words, Hubble's

constant increased with distance and the cosmic expansion was accelerating rather than decelerating as predicted by the standard matter dominated and radiation dominated cosmologies.

### 2. Mass density is critical and 3-space is flat

It is known that the contribution of ordinary and dark matter explaining the constant velocity of distance stars rotating around galaxy is about 25 per cent from the critical density. Could it be that total mass density is critical?

From the anisotropy of cosmic microwave background one can deduce that this is the case. What criticality means geometrically is that 3-space defined as surface with constant value of cosmic time is flat. This reflects in the spectrum of microwave radiation. The spots representing small anisotropies in the microwave background temperature is 1 degree and this correspond to flat 3-space. If one had dark matter instead of dark energy the size of spot would be .5 degrees!

Thus in a cosmology based on general relativity cosmological constant remains the only viable option. The situation is different in TGD based quantum cosmology based on sub-manifold gravity and hierarchy of gravitational Planck constants.

### 3. The energy density of vacuum is constant in the size scale of big voids

It was observed that the density of dark energy would be constant in the scale of  $10^8$  light years. This length scale corresponds to the size of big voids containing galaxies at their boundaries.

### 4. Integrated Sachs-Wolf effect

Also so called integrated Sachs-Wolf effect supports accelerated expansion. Very slow variations of mass density are considered. These correspond to gravitational potentials. Cosmic expansion tends to flatten them but mass accretion to form structures compensates this effect so that gravitational potentials are unaffected and there is no effect of CMB. Situation changes if dark matter is replaced with dark energy the accelerated expansion flattening the gravitational potentials wins the tendency of mass accretion to make them deeper. Hence if photon passes by an over-dense region, it receives a little energy. Similarly, photon loses energy when passing by an under-dense region. This effect has been observed.

## Accelerated expansion in classical TGD

The minimum TGD based explanation for accelerated expansion involves only the fact that the imbeddings of critical cosmologies correspond to accelerated expansion. A more detailed model allows to understand why the critical cosmology appears during some periods.

The first observation is that critical cosmologies (flat 3-space) imbeddable to 8-D imbedding space  $H$  correspond to negative pressure cosmologies and thus to accelerating expansion. The negativity of the counterpart of pressure in Einstein tensor is due to the fact that space-time sheet is forced to be a 4-D surface in 8-D imbedding space. This condition is analogous to a force forcing a particle at the surface of 2-sphere and gives rise to what could be called constraint force. Gravitation in TGD is sub-manifold gravitation whereas in GRT it is manifold gravitation. This would be minimum interpretation involving no assumptions about what mechanism gives rise to the critical periods.

## Accelerated expansion and hierarchy of Planck constants

One can go one step further and introduce the hierarchy of Planck constants. The basic difference between TGD and GRT based cosmologies is that TGD cosmology is quantum cosmology. Smooth cosmic expansion is replaced by an expansion occurring in discrete jerks corresponding to the increase of gravitational Planck constant. At space-time level this means the replacement of 8-D imbedding space  $H$  with a book like structure containing almost-copies of  $H$  with various values of Planck constant as pages glued together along critical manifold through which space-time sheet can leak between sectors with different values of  $\hbar$ . This process is the geometric correlate for the the phase transition changing the value of Planck constant.

During these phase transition periods critical cosmology applies and predicts automatically accelerated expansion. Neither genuine negative pressure due to "quintessence" nor cosmological constant is needed. Note that quantum criticality replaces inflationary cosmology and predicts a unique cosmology apart from single parameter. Criticality also explains the fluctuations in microwave temperature

as long range fluctuations characterizing criticality.

### Accelerated expansion and flatness of 3-cosmology

Observations 1) and 2) about super-novae and critical cosmology (flat 3-space) are consistent with this cosmology. In TGD dark energy must be replaced with dark matter because the mass density is critical during the phase transition. This does not lead to wrong sized spots since it is the increase of Planck constant which induces the accelerated expansion understandable also as a constraint force due to imbedding to  $H$ .

### The size of large voids is the characteristic scale

The TGD based model in its simplest form model assigns the critical periods of expansion to large voids of size  $10^8$  ly. Also larger and smaller regions can express similar periods and dark space-time sheets are expected to obey same universal "cosmology" apart from a parameter characterizing the duration of the phase transition. Observation 3) that just this length scale defines the scale below which dark energy density is constant is consistent with TGD based model.

The basic prediction is jerkwise cosmic expansion with jerks analogous to quantum transitions between states of atom increasing the size of atom. The discovery of large voids with size of order  $10^8$  ly but age much longer than the age of galactic large voids conforms with this prediction. On the other hand, it is known that the size of galactic clusters has not remained constant in very long time scale so that jerkwise expansion indeed seems to occur.

### Do cosmic strings with negative gravitational mass cause the phase transition inducing accelerated expansion

Quantum classical correspondence is the basic principle of quantum TGD and suggest that the effective antigravity manifested by accelerated expansion might have some kind of concrete space-time correlate. A possible correlate is super heavy cosmic string like objects at the center of large voids which have negative gravitational mass under very general assumptions. The repulsive gravitational force created by these objects would drive galaxies to the boundaries of large voids. At some state the pressure of galaxies would become too strong and induce a quantum phase transition forcing the increase of gravitational Planck constant and expansion of the void taking place much faster than the outward drift of the galaxies. This process would repeat itself. In the average sense the cosmic expansion would not be accelerating.

### 12.6.4 Phase transition changing Planck constant and expanding Earth theory

TGD predicts that cosmic expansion at the level of individual astrophysical systems does not take place continuously as in classical gravitation but through discrete quantum phase transitions increasing gravitational Planck constant and thus various quantum length and time scales. The reason would be that stationary quantum states for dark matter in astrophysical length scales cannot expand. One would have the analog of atomic physics in cosmic scales. Increases of  $\hbar$  by a power of two are favored in these transitions but also other scalings are possible.

This has quite far reaching implications.

1. These periods have a highly unique description in terms of a critical cosmology for the expanding space-time sheet. The expansion is accelerating. The accelerating cosmic expansion can be assigned to this kind of phase transition in some length scale (TGD Universe is fractal). There is no need to introduce cosmological constant and dark energy would be actually dark matter.
2. The recently observed void which has same size of about  $10^8$  light years as large voids having galaxies near their boundaries but having an age which is much higher than that of the large voids, would represent one example of jerk-wise expansion.
3. This picture applies also to solar system and planets might be perhaps seen as having once been parts of a more or less connected system, the primordial Sun. The Bohr orbits for inner and outer planets correspond to gravitational Planck constant which is 5 times larger for outer

planets. This suggests that the space-time sheet of outer planets has suffered a phase transition increasing the size scale by a factor of 5. Earth can be regarded either as  $n=1$  orbit for Planck constant associated with outer planets or  $n=5$  orbit for inner planetary system. This might have something to do with the very special position of Earth in planetary system. One could even consider the possibility that both orbits are present as dark matter structures. The phase transition would also explain why  $n=1$  and  $n=2$  Bohr orbits are absent and one only  $n=3,4$ , and 5 are present.

4. Also planets should have experienced this kind of phase transitions increasing the radius: the increase by a factor two would be the simplest situation.

The obvious question - that I did not ask - is whether this kind of phase transition might have occurred for Earth and led from a completely granite covered Earth - Pangeia without seas - to the recent Earth. Neither it did not occur to me to check whether there is any support for a rapid expansion of Earth during some period of its history.

Situation changed when my son visited me last Saturday and told me about a Youtube video [7] by Neal Adams, an American comic book and commercial artist who has also produced animations for geologists. We looked the amazing video a couple of times and I looked it again yesterday. The video is very impressive artwork but in the lack of references skeptic probably cannot avoid the feeling that Neal Adams might use his highly developed animation skills to cheat you. I found also a polemic article [1] of Adams but again the references were lacking. Perhaps the reason of polemic tone was that the concrete animation models make the expanding Earth hypothesis very convincing but geologists refuse to consider seriously arguments by a layman without a formal academic background.

### The claims of Adams

The basic claims of Adams were following.

1. The radius of Earth has increased during last 185 million years (dinosaurs [1] appeared for about 230 million years ago) by about factor 2. If this is assumed all continents have formed at that time a single super-continent, Pangeia, filling the entire Earth surface rather than only 1/4 of it since the total area would have grown by a factor of 4. The basic argument was that it is very difficult to imagine Earth with 1/4 of surface containing granite and 3/4 covered by basalt. If the initial situation was covering by mere granite -as would look natural- it is very difficult for a believer in thermodynamics to imagine how the granite would have gathered to a single connected continent.
2. Adams claims that Earth has grown by keeping its density constant, rather than expanded, so that the mass of Earth has grown linearly with radius. Gravitational acceleration would have thus doubled and could provide a partial explanation for the disappearance of dinosaurs: it is difficult to cope in evolving environment when you get slower all the time.
3. Most of the sea floor is very young and the areas covered by the youngest basalt are the largest ones. This Adams interprets this by saying that the expansion of Earth is accelerating. The alternative interpretation is that the flow rate of the magma slows down as it recedes from the ridge where it erupts. The upper bound of 185 million years for the age of sea floor requires that the expansion period - if it is already over - lasted about 185 million years after which the flow increasing the area of the sea floor transformed to a convective flow with subduction so that the area is not increasing anymore.
4. The fact that the continents fit together - not only at the Atlantic side - but also at the Pacific side gives strong support for the idea that the entire planet was once covered by the super-continent. After the emergence of subduction theory this evidence as been dismissed.
5. I am not sure whether Adams mentions the following objections [2] . Subduction only occurs on the other side of the subduction zone so that the other side should show evidence of being much older in the case that oceanic subduction zones are in question. This is definitely not the case. This is explained in plate tectonics as a change of the subduction direction. My explanation would be that by the symmetry of the situation both oceanic plates bend down so that this would represent new type of boundary not assumed in the tectonic plate theory.

6. As a master visualizer Adams notices that Africa and South-America do not actually fit together in absence of expansion unless one assumes that these continents have suffered a deformation. Continents are not easily deformable stuff. The assumption of expansion implies a perfect fit of *all* continents without deformation.

Knowing that the devil is in the details, I must admit that these arguments look rather convincing to me and what I learned from Wikipedia articles supports this picture.

### The critic of Adams of the subduction mechanism

The prevailing tectonic plate theory [5] has been compared to the Copernican revolution in geology. The theory explains the young age of the seafloor in terms of the decomposition of the lithosphere to tectonic plates and the convective flow of magma to which oceanic tectonic plates participate. The magma emerges from the crests of the mid ocean ridges representing a boundary of two plates and leads to the expansion of sea floor. The variations of the polarity of Earth's magnetic field coded in sea floor provide a strong support for the hypothesis that magma emerges from the crests.

The flow back to would take place at so called oceanic trenches [3] near continents which represent the deepest parts of ocean. This process is known as subduction. In subduction oceanic tectonic plate bends and penetrates below the continental tectonic plate, the material in the oceanic plate gets denser and sinks into the magma. In this manner the oceanic tectonic plate suffers a metamorphosis returning back to the magma: everything which comes from Earth's interior returns back. Subduction mechanism explains elegantly formation of mountains [4] (orogeny), earth quake zones, and associated zones of volcanic activity [6].

Adams is very polemic about the notion of subduction, in particular about the assumption that it generates steady convective cycle. The basic objections of Adams against subduction are following.

1. There are not enough subduction zones to allow a steady situation. According to Adams, the situation resembles that for a flow in a tube which becomes narrower. In a steady situation the flow should accelerate as it approaches subduction zones rather than slow down. Subduction zones should be surrounded by large areas of sea floor with constant age. Just the opposite is suggested by the fact that the youngest portion of sea-floor near the ridges is largest. The presence of zones at which both ocean plates bend down could improve the situation. Also jamming of the flow could occur so that the thickness of oceanic plate increases with the distance from the eruption ridge. Jamming could increase also the density of the oceanic plate and thus the effectiveness of subduction.
2. There is no clear evidence that subduction has occurred at other planets. The usual defense is that the presence of sea is essential for the subduction mechanism.
3. One can also wonder what is the mechanism that led to the formation of single super continent Pangeia covering 1/4 of Earth's surface. How probable the gathering of all separate continents to form single cluster is? The later events would suggest that just the opposite should have occurred from the beginning.

### Expanding Earth theories are not new

After I had decided to check the claims of Adams, the first thing that I learned is that Expanding Earth theory [2], whose existence Adams actually mentions, is by no means new. There are actually many of them.

The general reason why these theories were rejected by the main stream community was the absence of a convincing physical mechanism of expansion or of growth in which the density of Earth remains constant.

1. 1888 Yarkovski postulated some sort of aether absorbed by Earth and transforming to chemical elements (TGD version of aether could be dark matter). 1909 Mantovani postulated thermal expansion but no growth of the Earth's mass.
2. Paul Dirac's idea about changing Planck constant led Pascual Jordan in 1964 to a modification of general relativity predicting slow expansion of planets. The recent measurement of the gravitational constant imply that the upper bound for the relative change of gravitational constant

is 10 times too small to produce large enough rate of expansion. Also many other theories have been proposed but they are in general conflict with modern physics.

3. The most modern version of Expanding Earth theory is by Australian geologist Samuel W. Carey. He calculated that in Cambrian period (about 500 million years ago) all continents were stuck together and covered the entire Earth. Deep seas began to evolve then.

### Summary of TGD based theory of Expanding Earth

TGD based model differs from the tectonic plate model but allows subduction which cannot imply considerable back-flow of magma. Let us sum up the basic assumptions and implications.

1. The expansion is or was due to a quantum phase transition increasing the value of gravitational Planck constant and forced by the cosmic expansion in the average sense.
2. Tectonic plates do not participate to the expansion and therefore new plate must be formed and the flow of magma from the crests of mid ocean ridges is needed. The decomposition of a single plate covering the entire planet to plates to create the mid ocean ridges is necessary for the generation of new tectonic plate. The decomposition into tectonic plates is thus prediction rather than assumption.
3. The expansion forced the decomposition of Pangeia super-continent covering entire Earth for about 530 million years ago to split into tectonic plates which began to recede as new non-expanding tectonic plate was generated at the ridges creating expanding sea floor. The initiation of the phase transition generated formation of deep seas.
4. The eruption of plasma from the crests of ocean ridges generated oceanic tectonic plates which did not participate to the expansion by density reduction but by growing in size. This led to a reduction of density in the interior of the Earth roughly by a factor  $1/8$ . From the upper bound for the age of the seafloor one can conclude that the period lasted for about 185 million years after which it transformed to convective flow in which the material returned back to the Earth interior. Subduction at continent-ocean floor boundaries and downwards double bending of tectonic plates at the boundaries between two ocean floors were the mechanisms. Thus tectonic plate theory would be more or less the correct description for the recent situation.
5. One can consider the possibility that the subducted tectonic plate does not transform to magma but is fused to the tectonic layer below continent so that it grows to an iceberg like structure. This need not lead to a loss of the successful predictions of plate tectonics explaining the generation of mountains, earthquake zones, zones of volcanic activity, etc...
6. From the video of Adams it becomes clear that the tectonic flow is East-West asymmetric in the sense that the western side is more irregular at large distances from the ocean ridge at the western side. If the magma rotates with slightly lower velocity than the surface of Earth (like liquid in a rotating vessel), the erupting magma would rotate slightly slower than the tectonic plate and asymmetry would be generated.
7. If the planet has not experienced a phase transition increasing the value of Planck constant, there is no need for the decomposition to tectonic plates and one can understand why there is no clear evidence for tectonic plates and subduction in other planets. The conductive flow of magma could occur below this plate and remain invisible.

The biological implications might provide a possibility to test the hypothesis.

1. Great steps of progress in biological evolution are associated with catastrophic geological events generating new evolutionary pressures forcing new solutions to cope in the new situation. Cambrian explosion indeed occurred about 530 years ago (the book "Wonderful Life" of Stephen Gould [3] explains this revolution in detail) and led to the emergence of multicellular creatures, and generated huge number of new life forms living in seas. Later most of them suffered extinction: large number of phylae and groups emerged which are not present nowadays.

Thus Cambrian explosion is completely exceptional as compared to all other dramatic events in the evolution in the sense that it created something totally new rather than only making more complex something which already existed. Gould also emphasizes the failure to identify any great change in the environment as a fundamental puzzle of Cambrian explosion. Cambrian explosion is also regarded in many quantum theories of consciousness (including TGD) as a revolution in the evolution of consciousness: for instance, micro-tubuli emerged at this time. The periods of expansion might be necessary for the emergence of multicellular life forms on planets and the fact that they unavoidably occur sooner or later suggests that also life develops unavoidably.

2. TGD predicts a decrease of the surface gravity by a factor  $1/4$  during this period. The reduction of the surface gravity would have naturally led to the emergence of dinosaurs 230 million years ago as a response coming 45 million years after the accelerated expansion ceased. Other reasons led then to the decline and eventual catastrophic disappearance of the dinosaurs. The reduction of gravity might have had some gradually increasing effects on the shape of organisms also at microscopic level and manifest itself in the evolution of genome during expansion period.
3. A possibly testable prediction following from angular momentum conservation ( $\omega R^2 = \text{constant}$ ) is that the duration of day has increased gradually and was four times shorter during the Cambrian era. For instance, genetically coded bio-clocks of simple organisms during the expansion period could have followed the increase of the length of day with certain lag or failed to follow it completely. The simplest known circadian clock is that of the prokaryotic cyanobacteria. Recent research has demonstrated that the circadian clock of *Synechococcus elongatus* can be reconstituted in vitro with just the three proteins of their central oscillator. This clock has been shown to sustain a 22 hour rhythm over several days upon the addition of ATP: the rhythm is indeed faster than the circadian rhythm. For humans the average innate circadian rhythm is however 24 hours 11 minutes and thus conforms with the fact that human genome has evolved much later than the expansion ceased.
4. Scientists have found a fossil of a sea scorpion with size of 2.5 meters [7], which has lived for about 10 million years for 400 million years ago in Germany. The gigantic size would conform nicely with the much smaller value of surface gravity at that time. The finding would conform nicely with the much smaller value of surface gravity at that time. Also the emergence of trees could be understood in terms of a gradual growth of the maximum plant size as the surface gravity was reduced. The fact that the oldest known tree fossil is 385 million years old [5] conforms with this picture.

### Did intra-terrestrial life burst to the surface of Earth during Cambrian expansion?

The possibility of intra-terrestrial life [30] is one of the craziest TGD inspired ideas about the evolution of life and it is quite possible that in its strongest form the hypothesis is unrealistic. One can however try to find what one obtains from the combination of the IT hypothesis with the idea of pre-Cambrian granite Earth. Could the harsh pre-Cambrian conditions have allowed only intra-terrestrial multicellular life? Could the Cambrian explosion correspond to the moment of birth for this life in the very concrete sense that the magma flow brought it into the day-light?

1. Gould emphasizes the mysterious fact that very many life forms of Cambrian explosion looked like final products of a long evolutionary process. Could the eruption of magma from the Earth interior have induced a burst of intra-terrestrial life forms to the Earth's surface? This might make sense: the life forms living at the bottom of sea do not need direct solar light so that they could have had intra-terrestrial origin. It is quite possible that Earth's mantle contained low temperature water pockets, where the complex life forms might have evolved in an environment shielded from meteoric bombardment and UV radiation.
2. Sea water is salty. It is often claimed that the average salt concentration inside cell is that of the primordial sea: I do not know whether this claim can be really justified. If the claim is true, the cellular salt concentration should reflect the salt concentration of the water inside the pockets. The water inside water pockets could have been salty due to the diffusion of the salt from ground but need not have been same as that for the ocean water (higher than for cell interior and for

obvious reasons). Indeed, the water in the underground reservoirs in arid regions such as Sahara is salty, which is the reason for why agriculture is absent in these regions. Note also that the cells of marine invertebrates are osmoconformers able to cope with the changing salinity of the environment so that the Cambrian revolutionaries could have survived the change in the salt concentration of environment.

3. What applies to Earth should apply also to other similar planets and Mars [3] is very similar to Earth. The radius is .533 times that for Earth so that after quantum leap doubling the radius and thus Schumann frequency scale (7.8 Hz would be the lowest Schumann frequency) would be essentially same as for Earth now. Mass is .131 times that for Earth so that surface gravity would be .532 of that for Earth now and would be reduced to .131 meaning quite big dinosaurs! have learned that Mars probably contains large water reservoirs in it's interior and that there is an un-identified source of methane gas usually assigned with the presence of life. Could it be that Mother Mars is pregnant and just waiting for the great quantum leap when it starts to expand and gives rise to a birth of multicellular life forms. Or expressing freely how Bible describes the moment of birth: in the beginning there was only darkness and water and then God said Let the light come!

To sum up, TGD would provide only the long sought mechanism of expansion and a possible connection with the biological evolution. It would be indeed fascinating if Planck constant changing quantum phase transitions in planetary scale would have profoundly affected the biosphere.

### 12.6.5 Allais effect as evidence for large values of gravitational Planck constant?

Allais effect [1, 5] is a fascinating gravitational anomaly associated with solar eclipses. It was discovered originally by M. Allais, a Nobelist in the field of economy, and has been reproduced in several experiments but not as a rule. The experimental arrangement uses so called paraconical pendulum, which differs from the Foucault pendulum in that the oscillation plane of the pendulum can rotate in certain limits so that the motion occurs effectively at the surface of sphere.

#### Experimental findings

Consider first a brief summary of the findings of Allais and others [5] .

a) In the ideal situation (that is in the absence of any other forces than gravitation of Earth) paraconical pendulum should behave like a Foucault pendulum. The oscillation plane of the paraconical pendulum however begins to rotate.

b) Allais concludes from his experimental studies that the orbital plane approach always asymptotically to a limiting plane and the effect is only particularly spectacular during the eclipse. During solar eclipse the limiting plane contains the line connecting Earth, Moon, and Sun. Allais explains this in terms of what he calls the anisotropy of space.

c) Some experiments carried out during eclipse have reproduced the findings of Allais, some experiments not. In the experiment carried out by Jeverdan and collaborators in Romania it was found that the period of oscillation of the pendulum decreases by  $\Delta f/f \simeq 5 \times 10^{-4}$  [1, 7] which happens to correspond to the constant  $v_0 = 2^{-11}$  appearing in the formula of the gravitational Planck constant. It must be however emphasized that the overall magnitude of  $\Delta f/f$  varies by five orders of magnitude. Even the sign of  $\Delta f/f$  varies from experiment to experiment.

d) There is also quite recent finding by Popescu and Olenici, which they interpret as a quantization of the plane of oscillation of paraconical oscillator during solar eclipse [11] .

#### TGD based models for Allais effect

I have already earlier proposed an explanation of the effect in terms of classical  $Z^0$  force [6] . If the  $Z^0$  charge to mass ratio of pendulum varies and if Earth and Moon are  $Z^0$  conductors, the resulting model is quite flexible and one might hope it could explain the high variation of the experimental results.

The rapid variation of the effect during the eclipse is however a problem for this approach and suggests that gravitational screening or some more general interference effect might be present. Gravitational screening alone cannot however explain Allais effect.

A model based on the idea that gravitational interaction is mediated by topological light rays (MEs) and that gravitons correspond to a gigantic value of the gravitational Planck constant however explains the Allais effect as an interference effect made possible by macroscopic quantum coherence in astrophysical length scales. Equivalence Principle fixes the model to a high degree and one ends up with an explicit formula for the anomalous gravitational acceleration and the general order of magnitude and the large variation of the frequency change as being due to the variation of the distance ratio  $r_{S,P}/r_{M,P}$  ( $S, M,$  and  $P$  refer to Sun, Moon, and pendulum respectively). One can say that the pendulum acts as an interferometer.

### 12.6.6 Applications to elementary particle physics, nuclear physics, and condensed matter physics

The hierarchy of Planck constants could have profound implications for even elementary particle physics since the strong constraints on the existence of new light particles coming from the decay widths of intermediate gauge bosons can be circumvented because direct decays to dark matter are not possible. On the other hand, if light scaled versions of elementary particles exist they must be dark since otherwise their existence would be visible in these decay widths. The constraints on the existence of dark nuclei and dark condensed matter are much milder. Cold fusion and some other anomalies of nuclear and condensed matter physics - in particular the anomalies of water- might have elegant explanation in terms of dark nuclei.

#### Leptohadron hypothesis

TGD suggests strongly the existence of lepto-hadron [76]. Lepto-hadrons are bound states of color excited leptons and the anomalous production of  $e^+e^-$  pairs in heavy ion collisions finds a nice explanation as resulting from the decays of lepto-hadrons with basic condensate level  $k = 127$  and having typical mass scale of one  $MeV$ . The recent indications on the existence of a new fermion with quantum numbers of muon neutrino and the anomaly observed in the decay of ortho-positronium give further support for the lepto-hadron hypothesis. There is also evidence for anomalous production of low energy photons and  $e^+e^-$  pairs in hadronic collisions.

The identification of lepto-hadrons as a particular instance in the predicted hierarchy of dark matters interacting directly only via graviton exchange allows to circumvent the lethal counter arguments against the lepto-hadron hypothesis ( $Z^0$  decay width and production of colored lepton jets in  $e^+e^-$  annihilation) even without assumption about the loss of asymptotic freedom.

PCAC hypothesis and its sigma model realization lead to a model containing only the coupling of the lepto-pion to the axial vector current as a free parameter. The prediction for  $e^+e^-$  production cross section is of correct order of magnitude only provided one assumes that lepto-pions (or electro-pions) decay to lepto-nucleon pair  $e_{ex}^+ e_{ex}^-$  first and that lepto-nucleons, having quantum numbers of electron and having mass only slightly larger than electron mass, decay to lepton and photon. The peculiar production characteristics are correctly predicted. There is some evidence that the resonances decay to a final state containing  $n > 2$  particle and the experimental demonstration that lepto-nucleon pairs are indeed in question, would be a breakthrough for TGD.

During 18 years after the first published version of the model also evidence for colored  $\mu$  has emerged [22]. Towards the end of 2008 CDF anomaly [6] gave a strong support for the colored excitation of  $\tau$ . The lifetime of the light long lived state identified as a charged  $\tau$ -pion comes out correctly and the identification of the reported 3 new particles as p-adically scaled up variants of neutral  $\tau$ -pion predicts their masses correctly. The observed muon jets can be understood in terms of the special reaction kinematics for the decays of neutral  $\tau$ -pion to 3  $\tau$ -pions with mass scale smaller by a factor 1/2 and therefore almost at rest. A spectrum of new particles is predicted. The discussion of CDF anomaly [76] led to a modification and generalization of the original model for lepto-pion production and the predicted production cross section is consistent with the experimental estimate.

### Cold fusion, plasma electrolysis, and burning salt water

The article of Kanarev and Mizuno [12] reports findings supporting the occurrence of cold fusion in NaOH and KOH hydrolysis. The situation is different from standard cold fusion where heavy water  $D_2O$  is used instead of  $H_2O$ .

In nuclear string model nucleon are connected by color bonds representing the color magnetic body of nucleus and having length considerably longer than nuclear size. One can consider also dark nuclei for which the scale of nucleus is of atomic size [47] , [47] . In this framework can understand the cold fusion reactions reported by Mizuno as nuclear reactions in which part of what I call dark proton string having negatively charged color bonds (essentially a zoomed up variant of ordinary nucleus with large Planck constant) suffers a phase transition to ordinary matter and experiences ordinary strong interactions with the nuclei at the cathode. In the simplest model the final state would contain only ordinary nuclear matter. The generation of plasma in plasma electrolysis can be seen as a process analogous to the positive feedback loop in ordinary nuclear reactions.

Rather encouragingly, the model allows to understand also deuterium cold fusion and leads to a solution of several other anomalies.

1. The so called lithium problem of cosmology (the observed abundance of lithium is by a factor 2.5 lower than predicted by standard cosmology [6] ) can be resolved if lithium nuclei transform partially to dark lithium nuclei.
2. The so called  $H_{1.5}O$  anomaly of water [4, 3, 6, 19] can be understood if 1/4 of protons of water forms dark lithium nuclei or heavier dark nuclei formed as sequences of these just as ordinary nuclei are constructed as sequences of  ${}^4He$  and lighter nuclei in nuclear string model. The results force to consider the possibility that nuclear isotopes unstable as ordinary matter can be stable dark matter.
3. The mysterious behavior burning salt water [1] can be also understood in the same framework.
4. The model explains the nuclear transmutations observed in Kanarev's plasma electrolysis. This kind of transmutations have been reported also in living matter long time ago [12, 21] . Intriguingly, several biologically important ions belong to the reaction products in the case of NaOH electrolysis. This raises the question whether cold nuclear reactions occur in living matter and are responsible for generation of biologically most important ions.

### 12.6.7 Applications to biology and neuroscience

The notion of field or magnetic body regarded as carrier of dark matter with large Planck constant and quantum controller of ordinary matter is the basic idea in the TGD inspired model of living matter.

#### Do molecular symmetries in living matter relate to non-standard values of Planck constant?

Water is exceptional element and the possibility that  $G_a$  as symmetry of singular factor space of  $CD$  in water and living matter is intriguing.

1. There is evidence for an icosahedral clustering in [10] [5] . Synaptic contacts contain clathrin molecules which are truncated icosahedrons and form lattice structures and are speculated to be involved with quantum computation like activities possibly performed by microtubules. Many viruses have the shape of icosahedron. One can ask whether these structures could be formed around templates formed by dark matter corresponding to 120-fold covering of  $CP_2$  points by  $CD$  points and having  $\hbar(CP_2) = 5\hbar_0$  perhaps corresponding color confined light dark quarks. Of course, a similar covering of  $CD$  points by  $CP_2$  could be involved.
2. It should be noticed that single nucleotide in DNA double strands corresponds to a twist of  $2\pi/10$  per single DNA triplet so that 10 DNA strands corresponding to length  $L(151) = 10$  nm (cell membrane thickness) correspond to  $3 \times 2\pi$  twist. This could be perhaps interpreted as evidence for group  $C_{10}$  perhaps making possible quantum computation at the level of DNA.

3. What makes realization of  $G_a$  as a symmetry of singular factor space of  $CD$  is that the biomolecules most relevant for the functioning of brain (DNA nucleotides, aminoacids acting as neurotransmitters, molecules having hallucinogenic effects) contain aromatic 5- and 6-cycles.

These observations led to an identification of the formula for Planck constant (two alternatives were allowed by the condition that Planck constant is algebraic homomorphism) which was not consistent with the model for dark gravitons. If one accepts the proposed formula of Planck constant, the dark space-time sheets with large Planck constant correspond to factor spaces of both  $\hat{C}D \setminus M^2$  and of  $CP_2 \setminus S^2_I$ . This identification is of course possible and it remains to be seen whether it leads to any problems. For gravitational space-time sheets only coverings of both  $CD$  and  $CP_2$  make sense and the covering group  $G_a$  has very large order and does not correspond to geometric symmetries analogous to those of molecules.

### High $T_c$ super-conductivity in living matter

The model for high  $T_c$  super-conductivity realized as quantum critical phenomenon predicts the basic scales of cell membrane [11] from energy minimization and p-adic length scale hypothesis. This leads to the vision that cell membrane and possibly also its scaled up dark fractal variants define Josephson junctions generating Josephson radiation communicating information about the nearby environment to the magnetic body.

Any model of high  $T_c$  superconductivity should explain various strange features of high  $T_c$  superconductors. One should understand the high value of  $T_c$ , the ambivalent character of high  $T_c$  superconductors suggesting both BCS type Cooper pairs and exotic Cooper pairs with non-vanishing spin, the existence of pseudogap temperature  $T_{c1} > T_c$  and scaling law for resistance for  $T_c \leq T < T_{c1}$ , the role of fluctuating charged stripes which are anti-ferromagnetic defects of a Mott insulator, the existence of a critical doping, etc... [21, 20].

There are reasons to believe that high  $T_c$  super-conductors correspond to quantum criticality in which at least two (cusp catastrophe as in van der Waals model), or possibly three or even more phases, are competing. A possible analogy is provided by the triple critical point for water vapor, liquid phase and ice coexist. Instead of long range thermal fluctuations long range quantum fluctuations manifesting themselves as fluctuating stripes are present [21].

The TGD based model for high  $T_c$  super-conductivity [11] relies on the notions of quantum criticality, general ideas of catastrophe theory, dynamical Planck constant, and many-sheeted space-time. The 4-dimensional spin glass character of space-time dynamics deriving from the vacuum degeneracy of the Kähler action defining the basic variational principle would realize space-time correlates for quantum fluctuations.

1. Two kinds of super-conductivities and ordinary non-super-conducting phase would be competing at quantum criticality at  $T_c$  and above it only one super-conducting phase and ordinary conducting phase located at stripes representing ferromagnetic defects making possible formation of  $S = 1$  Cooper pairs.
2. The first super-conductivity would be based on exotic Cooper pairs of large  $\hbar$  dark electrons with  $\hbar = 2^{11}\hbar_0$  and able to have spin  $S = 1$ , angular momentum  $L = 2$ , and total angular momentum  $J = 2$ . Second type of super-conductivity would be based on BCS type Cooper pairs having vanishing spin and bound by phonon interaction. Also they have large  $\hbar$  so that gap energy and critical temperature are scaled up in the same proportion. The exotic Cooper pairs are possible below the pseudo gap temperature  $T_{c1} > T_c$  but are unstable against decay to BCS type Cooper pairs which above  $T_c$  are unstable against a further decay to conduction electrons flowing along stripes. This would reduce the exotic super-conductivity to finite conductivity obeying the observed scaling law for resistance.
3. The mere assumption that electrons of exotic Cooper pairs feed their electric flux to larger space-time sheet via *two* elementary particle sized wormhole contacts rather than only *one* wormhole contacts implies that the throats of wormhole contacts defining analogs of Higgs field must carry quantum numbers of quark and anti-quark. This inspires the idea that cylindrical space-time sheets, the radius of which turns out to be about about 5 nm, representing zoomed up dark electrons of Cooper pair with Planck constant  $\hbar = 2^{11}\hbar_0$  are colored and bound by a scaled

up variant of color force to form a color confined state. Formation of Cooper pairs would have nothing to do with direct interactions between electrons. Thus high  $T_c$  super-conductivity could be seen as a first indication for the presence of scaled up variant of QCD in mesoscopic length scales.

This picture leads to a concrete model for high  $T_c$  superconductors as quantum critical superconductors [11] . p-Adic length scale hypothesis stating that preferred p-adic primes  $p \simeq 2^k$ ,  $k$  integer, with primes (in particular Mersenne primes) preferred, makes the model quantitative.

1. An unexpected prediction is that coherence length  $\xi$  is actually  $\hbar_{eff}/\hbar_0 = 2^{11}$  times longer than the coherence length 5-10 Angstroms deduced theoretically from gap energy using conventional theory and varies in the range  $1 - 5 \mu\text{m}$ , the cell nucleus length scale. Hence type I super-conductor would be in question with stripes as defects of anti-ferromagnetic Mott insulator serving as duals for the magnetic defects of type I super-conductor in nearly critical magnetic field.
2. At quantitative level the model reproduces correctly the four poorly understood photon absorption lines and allows to understand the critical doping ratio from basic principles.
3. The current carrying structures have structure locally similar to that of axon including the double layered structure of cell membrane and also the size scales are predicted to be same. One of the characteristic absorption lines has energy of .05 eV which corresponds to the Josephson energy for neuronal membrane for activation potential  $V = 50$  mV. Hence the idea that axons are high  $T_c$  superconductors is highly suggestive. Dark matter hierarchy coming in powers  $\hbar/\hbar_0 = 2^{k11}$  suggests hierarchy of Josephson junctions needed in TGD based model of EEG [24] .

### Magnetic body as a sensory perceiver and intentional agent

The hypothesis that dark magnetic body serves as an intentional agent using biological body as a motor instrument and sensory receptor is consistent with Libet's findings about strange time delays of consciousness. Magnetic body would carry cyclotron Bose-Einstein condensates of various ions. Magnetic body must be able to perform motor control and receive sensory input from biological body.

Cell membrane would be a natural sensor providing information about cell interior and exterior to the magnetic body and dark photons at appropriate frequency range would naturally communicate this information. The strange quantitative co-incidences with the physics of cell membrane and high  $T_c$  super-conductivity support the idea that Josephson radiation generated by Josephson currents of dark electrons through cell membrane is responsible for this communication [24] .

Also fractally scaled up versions of cell membrane at higher levels of dark matter hierarchy (in particular those corresponding to powers  $n = 2^{k11}$ ) are possible and the model for EEG indeed relies on this hypothesis. The thickness for the fractal counterpart of cell membrane thickness would be  $2^{44}$  fold and of order of depth of ionosphere! Although this looks weird it is completely consistent with the notion of magnetic body as an intentional agent.

Motor control would be most naturally performed via genome: this is achieved if flux sheets traverse through DNA strands. Flux quantization for large values of Planck constant requires rather large widths for the flux sheets. If flux sheet contains sequences of genomes like the page of book contains lines of text, a coherent gene expression becomes possible at level of organs and even populations and one can speak about super- and hyper-genomes. Introns might relate to the collective gene expression possibly realized electromagnetically rather than only chemically [11, 12] .

Dark cyclotron radiation with photon energy above thermal energy could be used for coordination purposes at least. The predicted hierarchy of copies of standard model physics leads to ask whether also dark copies of electro-weak gauge bosons and gluons could be important in living matter. As already mentioned, dark  $W$  bosons could make possible charge entanglement and non-local quantum bio-control by inducing voltage differences and thus ionic currents in living matter.

The identification of plasmoids as rotating magnetic flux structures carrying dark ions and electrons as primitive life forms is natural in this framework. There exists experimental support for this identification [4] but the main objection is the high temperature involved: this objection could be circumvented if large  $\hbar$  phase is involved. A model for the pre-biotic evolution relying also on this idea is discussed in [30] .

At the level of biology there are now several concrete applications leading to a rich spectrum of predictions. Magnetic flux quanta would carry charged particles with large Planck constant.

1. The shortening of the flux tubes connecting biomolecules in a phase transition reducing Planck constant could be a basic mechanism of bio-catalysis and explain the mysterious ability of biomolecules to find each other. Similar process in time direction could explain basic aspects of symbolic memories as scaled down representations of actual events.
2. The strange behavior of cell membrane suggests that a dominating portion of important biological ions are actually dark ions at magnetic flux tubes so that ionic pumps and channels are needed only for visible ions. This leads to a model of nerve pulse explaining its unexpected thermodynamical properties with basic properties of Josephson currents making it unnecessary to use pumps to bring ions back after the pulse. The model predicts automatically EEG as Josephson radiation and explains the synchrony of both kHz radiation and of EEG.
3. The DC currents of Becker could be accompanied by Josephson currents running along flux tubes making possible dissipation free energy transfer and quantum control over long distances and meridians of chinese medicine could correspond to these flux tubes.
4. The model of DNA as topological quantum computer assumes that nucleotides and lipids are connected by ordinary or "wormhole" magnetic flux tubes acting as strands of braid and carrying dark matter with large Planck constant. The model leads to a new vision about TGD in which the assignment of nucleotides to quarks allows to understand basic regularities of DNA not understood from biochemistry.
5. Each physical system corresponds to an onionlike hierarchy of field bodies characterized by  $p$ -adic primes and value of Planck constant. The highest value of Planck constant in this hierarchy provides kind of intelligence quotient characterizing the evolutionary level of the system since the time scale of planned action and memory correspond to the temporal distance between tips of corresponding causal diamond ( $CD$ ). Also the spatial size of the system correlates with the Planck constant. This suggests that great evolutionary leaps correspond to the increase of Planck constant for the highest level of hierarchy of personal magnetic bodies. For instance, neurons would have much more evolved magnetic bodies than ordinary cells.
6. At the level of DNA this vision leads to an idea about hierarchy of genomes. Magnetic flux sheets traversing DNA strands provide a natural mechanism for magnetic body to control the behavior of biological body by controlling gene expression. The quantization of magnetic flux states that magnetic flux is proportional to  $\hbar$  and thus means that the larger the value of  $\hbar$  is the larger the width of the flux sheet is. For larger values of  $\hbar$  single genome is not enough to satisfy this condition. This leads to the idea that the genomes of organs, organism, and even population, can organize like lines of text at the magnetic flux sheets and form in this manner a hierarchy of genomes responsible for a coherent gene expression at level of cell, organ, organism and population and perhaps even entire biosphere. This would also provide a mechanism by which collective consciousness would use its biological body - biosphere.

### DNA as topological quantum computer

I ended up with the recent model of tqc in bottom-up manner and this representation is followed also in the text. The model which looks the most plausible one relies on two specific ideas.

1. Sharing of labor means conjugate DNA would do tqc and DNA would "print" the outcome of tqc in terms of mRNA yielding amino-acids in the case of exons. RNA could result also in the case of introns but not always. The experience about computers and the general vision provided by TGD suggests that introns could express the outcome of tqc also electromagnetically in terms of standardized field patterns as Gariaev's findings suggest [2]. Also speech would be a form of gene expression. The quantum states braid (in zero energy ontology) would entangle with characteristic gene expressions. This argument turned out to be based on a slightly wrong belief about DNA: later I learned that both strand and its conjugate are transcribed but in different directions. The symmetry breaking in the case of transcription is only local which is also visible

in DNA replication as symmetry breaking between leading and lagging strand. Thus the idea about *entire* leading strand devoted to printing and second strand to tqc must be weakened appropriately.

2. The manipulation of braid strands transversal to DNA must take place at 2-D surface. Here dancing metaphor for topological quantum computation [17] generalizes. The ends of the space-like braid are like dancers whose feet are connected by thin threads to a wall so that the dancing pattern entangles the threads. Dancing pattern defines both the time-like braid, the running of classical tqc program and its representation as a dynamical pattern. The space-like braid defined by the entangled threads represents memory storage so that tqc program is automatically written to memory as the braiding of the threads during the tqc. The inner membrane of the nuclear envelope and cell membrane with entire endoplasmic reticulum included are good candidates for dancing halls. The 2-surfaces containing the ends of the hydrophobic ends of lipids could be the parquets and lipids the dancers. This picture seems to make sense.

One ends up to the model also in top-down manner.

1. Darwinian selection for which standard theory of self-organization [13] provides a model, should apply also to tqc programs. Tqc programs should correspond to asymptotic self-organization patterns selected by dissipation in the presence of metabolic energy feed. The spatial and temporal pattern of the metabolic energy feed characterizes the tqc program - or equivalently - sub-program call.
2. Since braiding characterizes the tqc program, the self-organization pattern should correspond to a hydrodynamical flow or a pattern of magnetic field inducing the braiding. Braid strands must correspond to magnetic flux tubes of the magnetic body of DNA. If each nucleotide is transversal magnetic dipole it gives rise to transversal flux tubes, which can also connect to the genome of another cell.
3. The output of tqc sub-program is probability distribution for the outcomes of state function reduction so that the sub-program must be repeated very many times. It is represented as four-dimensional patterns for various rates (chemical rates, nerve pulse patterns, EEG power distributions,...) having also identification as temporal densities of zero energy states in various scales. By the fractality of TGD Universe there is a hierarchy of tqc's corresponding to p-adic and dark matter hierarchies. Programs (space-time sheets defining coherence regions) call programs in shorter scale. If the self-organizing system has a periodic behavior each tqc module defines a large number of almost copies of itself asymptotically. Generalized EEG could naturally define this periodic pattern and each period of EEG would correspond to an initiation and halting of tqc. This brings in mind the periodically occurring sol-gel phase transition inside cell near the cell membrane.
4. Fluid flow must induce the braiding which requires that the ends of braid strands must be anchored to the fluid flow. Recalling that lipid mono-layers of the cell membrane are liquid crystals and lipids of interior mono-layer have hydrophilic ends pointing towards cell interior, it is easy to guess that DNA nucleotides are connected to lipids by magnetic flux tubes and hydrophilic lipid ends are stuck to the flow.
5. The topology of the braid traversing cell membrane cannot be affected by the hydrodynamical flow. Hence braid strands must be split during tqc. This also induces the desired magnetic isolation from the environment. Halting of tqc reconnects them and make possible the communication of the outcome of tqc.
6. There are several problems related to the details of the realization. How nucleotides A,T,C,G are coded to strand color and what this color corresponds to? The prediction that wormhole contacts carrying quark and anti-quark at their ends appear in all length scales in TGD Universe resolves the problem. How to split the braid strands in a controlled manner? High  $T_c$  super conductivity provides a partial understanding of the situation: braid strand can be split only if the supra current flowing through it vanishes. From the proportionality of Josephson current to the quantity  $\sin(\int 2eV dt)$  it follows that a suitable voltage pulse  $V$  induces DC supra-current

and its negative cancels it. The conformation of the lipid controls whether it can follow the flow or not. How magnetic flux tubes can be cut without breaking the conservation of the magnetic flux? The notion of wormhole magnetic field saves the situation now: after the splitting the flux returns back along the second space-time sheet of wormhole magnetic field.

To sum up, it seems that essentially all new physics involved with TGD based view about quantum biology enter to the model in crucial manner.

### Quantum model of nerve pulse and EEG

In this article a unified model of nerve pulse and EEG is discussed.

1. In TGD Universe the function of EEG and its variants is to make possible communications from the cell membrane to the magnetic body and the control of the biological body by the magnetic body via magnetic flux sheets traversing DNA by inducing gene expression. This leads to the notions of super- and hyper-genome predicting coherent gene expression at level of organs and population.
2. The assignment the predicted ranged classical weak and color gauge fields to dark matter hierarchy was a crucial step in the evolution of the model, and led among other things to a model of high  $T_c$  superconductivity predicting the basic scales of cell, and also to a generalization of EXG to a hierarchy of ZXGs, WXGs, and GXGs corresponding to  $Z^0$ ,  $W$  bosons and gluons.
3. Dark matter hierarchy and the associated hierarchy of Planck constants plays a key role in the model. For instance, in the case of EEG Planck constant must be so large that the energies of dark EEG photons are above thermal energy at physiological temperatures. The assumption that a considerable fraction of the ionic currents through the cell membrane are dark currents flowing along the magnetic flux tubes explains the strange findings about ionic currents through cell membrane. Concerning the model of nerve pulse generation, the newest input comes from the model of DNA as a topological quantum computer and experimental findings challenging Hodgkin-Huxley model as even approximate description of the situation.
4. The identification of the cell interior as gel phase containing most of water as structured water around cytoskeleton - rather than water containing bio-molecules as solutes as assumed in Hodgkin-Huxley model - allows to understand many of the anomalous behaviors associated with the cell membrane and also the different densities of ions in the interior and exterior of cell at qualitative level. The proposal of Pollack that basic biological functions involve phase transitions of gel phase generalizes in TGD framework to a proposal that these phase transitions are induced by quantum phase transitions changing the value of Planck constant. In particular, gel-sol phase transition for the peripheral cytoskeleton induced by the primary wave would accompany nerve pulse propagation. This view about nerve pulse is not consistent with Hodgkin-Huxley model.

The model leads to the following picture about nerve pulse and EEG.

1. The system would consist of two superconductors- microtubule space-time sheet and the space-time sheet in cell exterior- connected by Josephson junctions represented by magnetic flux tubes defining also braiding in the model of tqc. The phase difference between two super-conductors would obey Sine-Gordon equation allowing both standing and propagating solitonic solutions. A sequence of rotating gravitational penduli coupled to each other would be the mechanical analog for the system. Soliton sequences having as a mechanical analog penduli rotating with constant velocity but with a constant phase difference between them would generate moving kHz synchronous oscillation. Periodic boundary conditions at the ends of the axon rather than chemistry determine the propagation velocities of kHz waves and kHz synchrony is an automatic consequence since the times taken by the pulses to travel along the axon are multiples of same time unit. Also moving oscillations in EEG range can be considered and would require larger value of Planck constant in accordance with vision about evolution as gradual increase of Planck constant.

2. During nerve pulse one pendulum would be kicked so that it would start to oscillate instead of rotating and this oscillation pattern would move with the velocity of kHz soliton sequence. The velocity of kHz wave and nerve pulse is fixed by periodic boundary conditions at the ends of the axon implying that the time spent by the nerve pulse in traveling along axon is always a multiple of the same unit: this implies kHz synchrony. The model predicts the value of Planck constant for the magnetic flux tubes associated with Josephson junctions and the predicted force caused by the ionic Josephson currents is of correct order of magnitude for reasonable values of the densities of ions. The model predicts kHz em radiation as Josephson radiation generated by moving soliton sequences. EEG would also correspond to Josephson radiation: it could be generated either by moving or standing soliton sequences (latter are naturally assignable to neuronal cell bodies for which  $\hbar$  should be correspondingly larger): synchrony is predicted also now.

## 12.7 Some mathematical speculations

### 12.7.1 The content of McKay correspondence in TGD framework

The possibility to assign Dynkin diagrams with the inclusions of  $II_1$  algebras is highly suggestive concerning possible physical interpretations. The basic findings are following.

1. For  $\beta = \mathcal{M} : \mathcal{N} < 4$  Dynkin diagrams code for the inclusions and correspond to simply laced Lie algebras.  $SU(2)$ ,  $D_{2n+1}$ , and  $E_7$  are excluded.
2. Extended ADE Dynkin diagrams coding for simply laced ADE Kac Moody algebras appear at  $\beta = 4$ . Also  $SU(2)$  Kac Moody algebra appears.

#### Does TGD give rise to ADE hierarchy of gauge theories

The first question is whether any finite subgroup  $G \subset SU(2)$  acting in  $CP_2$  degrees of freedom could somehow give rise to multiplets of the corresponding gauge group having interactions described by a gauge theory. Orbifold picture suggests that might be the case.

1. The "sheets" for the space-time sheet forming an  $N(G)$ -fold cover of  $CD$  are in one-one correspondence with group  $G$ . This degeneracy gives rise to additional states and these states correspond to the group algebra having basis given by group characters  $\chi(g)$ . One obtains irreducible representations of  $G$  with degeneracies given by their dimensions. Altogether one obtains  $N(G)$  states in this manner. In the case of  $A(n)$  the number of these states is  $n + 1$ , the number of the states of the fundamental representation of  $SU(n + 1)$ . In the same manner, for  $D_{2n}$  the number of these states equals to the number of states in the fundamental representation of  $D_{2n}$ . It seems that the rule is quite general. Thus these representations would in the case of fermions give the states of the fundamental representation of the corresponding gauge group.
2. From fermion and antifermion states one can construct in a similar manner pairs giving  $N(G)^2$  states defining in the case of  $A(n)$   $n^2 - 1$ -dimensional gauge boson multiplet plus singlet. Also other groups must give boson multiplet plus possible other multiplets. For instance, for  $D(4)$  the number of states is 64 and boson multiplet is 8-dimensional so that many other spin 1 states result.
3. These findings give hopes that the orbifold multiplets could be modelled by a gauge theory based on corresponding gauge group. What is nice that this huge hierarchy of gauge theories is associated with dark matter so that the predictivity and falsifiability are not lost unlike in M-theory.

#### Does one obtain also a hierarchy of conformal theories with ADE Kac Moody symmetry?

Consider next the question Kac Moody interactions correspond to extended ADE diagrams are possible.

1. In this case the notion of orbifold seems to break down since the symmetry related points form a continuum  $SU(2)$  and space-time surface would become 6-dimensional if the  $CD$  projection is 4-dimensional. If one takes space-time as something which emerges, one could take this possibility half seriously. A more natural natural possibility is that  $CD$  projection is 2-dimensional geodesic sphere in which case one would have string like objects so that conformal field theory with Kac-Moody algebra would emerge naturally.
2. The new degrees of freedom would define 2-dimensional continuum and it would not be completely surprising if conformal field theory based on ADE Kac Moody algebra could describe the situation. One possibility is that these continua for different inclusions correspond to  $SU(2)$  decompose to an  $N(G)$ -fold covers of  $S^2/G$  orbifold so that also now groups  $G$  would be involved with the Jones inclusions, which might provide a hint about how to construct them.  $S^2/G$  would play the role of stringy world sheet for the conformal field theory in question. This effective re-arrangement of the topology  $S^2$  might be due to the fact that conformal fields possess  $G$  symmetry which effectively groups points of  $S^2$  to  $n(G)$ -multiplets. The localized representations of the Lie group corresponding to  $G$  would correspond to the multiplets obtained from the representations of group algebra of  $G$  as in previous case.
3. The formula for the scaling factor of  $CD$  metric would give infinite scaling factor if one identifies the scaling factor as maximal order of cyclic subgroup of  $SU(2)$ . As a matter fact there is no finite cyclic subgroup of this kind. The solution to the problem would be identification of the scaling factor as the order of the maximal cyclic subgroup of  $G$  so that the scaling factors would be same for the two situations related by McKay correspondence.

### Generalization to $CD$ degrees of freedom

One can ask whether the proposed picture generalizes formally also the case of  $CD$ .

1. In this case quantum groups would correspond to discrete subgroups  $G \subset SL(2, C)$ . Kac Moody group would correspond to  $G$ -Kac Moody algebra made local with respect to  $SL(2, C)$  orbit in  $CD$  divided by  $G$ . These orbits are 3-dimensional hyperboloids  $H_a$  with a constant value of light cone proper time  $a$  so that the division by  $G$  gives fundamental domain  $H_a/G$  with a finite 3-volume.
2. The 4-dimensionality of space-time would require 1-dimensional  $CP_2$  projection. Vacuum extremals of Kähler action would be in question. Robertson-Walker metric have 1-dimensional  $CP_2$  projection and carry non-vanishing density of gravitational mass so that in this sense the theory would be non-trivial.  $G$  would label different lattice like cosmologies defined by tessellations with fundamental domain  $H_a/G$ .
3. The multiplets of  $G$  would correspond to collections of points, one from each cells of the lattice like structure. Macroscopic quantum coherence would be realized in cosmological scales. If one takes seriously the vision about the role of short distance p-adic physics as a generator of long range correlations of the real physics reflected as p-adic fractality, this idea does not look so weird anymore.

Complexified modular group  $SL(2, Z + iZ)$  and its subgroups are interesting as far as p-adicization is considered. The principal congruence subgroups  $\Gamma(N)$  of  $SL(2, Z + iZ)$  which are unit matrices modulo  $N$  define normal subgroups of the complex modular group and are especially interesting candidates for groups  $G \subset SL(2, C)$ . The group  $\Gamma(N = p^k)$  labeling fundamental domains of the tessellation  $H_a/\Gamma(N = p^k)$  defines a mathematically attractive candidate for a point set associated with the intersections of p-adic space-time sheets with real space-time sheets. Also analogous groups for algebraic extensions of  $Z$  are interesting.

The simplest discrete subgroup of  $SL(2, C)$  with infinite number of elements would corresponds to powers of boost to single direction and correspond at the non-relativistic limit to multiples of basic velocity. This could also give rise to quantization of cosmic recession velocities. There is evidence for the quantization of cosmic recession velocities (for a model in which single object produces quantized redshifts see [21] ) and it is interesting to see whether they could be interpreted in terms of the lattice like periodicity in cosmological length scales implied by the

effective reduction of physics to  $M_+^4/G_n$ . In [9] the values  $z = 2.63, 3.45, 4.47$  of cosmic red shift are listed. These correspond to recession velocities  $v = (z^2 - 1)/(z^2 + 1)$  are (0.75,0.85,0.90). The corresponding hyperbolic angles are given by  $\eta = \text{acosh}(1/(1 - v^2))$  and the values of  $\eta$  are (1.46, 1.92, 2.39). The differences  $\eta(2) - \eta(1) = .466$  and  $\eta(3) - \eta(2) = .467$  are same within experimental uncertainties. One has however  $\eta(n)/(\eta(2) - \eta(1)) = (3.13, 4.13, 5.13)$  instead of (3, 4, 5). A possible interpretation is in terms of the velocity of the observer with respect to the frame in which quantization of  $\eta$  happens.

**Quantitative support for the interpretation**

A more detailed analysis of the situation gives support for the proposed vision.

1. A given value of quantum group deformation parameter  $q = \exp(i\pi/n)$  makes sense for any Lie algebra but now a preferred Lie-algebra is assigned to a given value of quantum deformation parameter. At the limit  $\beta = 4$  when quantum deformation parameter becomes trivial, the gauge symmetry is replaced by Kac Moody symmetry.
2. The prediction is that Kac-Moody central extension parameter should vanish for  $\beta < 4$ . There is an intriguing relationship to formula for the quantum phase  $q_{KM}$  associated with (possibly trivial) Kac-Moody central extension and the phase defined by ADE diagram

$$\begin{aligned} q_{KM} &= \exp(i\phi) \quad , \quad \phi_1 = \frac{\pi}{k+h^v} \quad , \\ q_{Jones} &= \exp(i\phi) \quad , \quad \phi = \frac{\pi}{h} \end{aligned}$$

In the first formula sum of Kac-Moody central extension parameter  $k$  and dual Coxeter number  $h^v$  appears whereas Coxeter number  $h$  appears in the second formula. Internal consistency requires

$$k + h^v = h \quad . \tag{12.7.1}$$

It is easy see that the dual Coxeter number  $h^v$  and Coxeter number  $h$  given by  $h = (\text{dim}(g) - r)/r$ , where  $r$  is the dimension of Cartan algebra of  $g$ , are identical for ADE algebras so that the Kac-Moody central extension parameter  $k$  must indeed vanish. For  $SO(2n + 1)$ ,  $Sp(n)$ ,  $G_2$ , and  $F_4$  the condition  $h = h^v$  does not hold true but one has  $h(n) = 2n = h^v + 1$  for  $SO(2n + 1)$ ,  $h(n) = 2n = 2(h^v - 1)$  for  $Sp(n)$ ,  $h = 6 = h^v + 2$  for  $G_2$ , and  $h = 12 = h^v + 3$  for  $F_4$ .

What is intriguing that  $G_2$ , which seems to play a fundamental role in the dual formulation of quantum TGD based on the identification of space-times as surfaces in hyper-octonionic space  $M^8$  [72] is not allowed. As a matter fact,  $G_2 \rightarrow SU(3)$  reduction occurs also in the dual formulation based on  $G_2/SU(3)$  coset model and is required by the separate conservation of quark and lepton numbers predicted by TGD. ADE groups would be associated with the interaction between space-time sheets rather than entire dynamics and need not have anything to do with the Kac-Moody algebra associated with color and electro-weak interactions appearing in the construction of physical states [41] .

3. There seems to be a concrete connection with conformal field theories. This connection would allow to understand the emergence of quantum groups appearing naturally in these theories. Quite generally, the conformal central extension parameter for unitary Virasoro representations resulting by Sugawara construction from Kac Moody representations satisfies either of the conditions

$$\begin{aligned} c &\geq \frac{k \text{dim}(g)}{k + h^v} + 1 \quad , \\ c &= \frac{k \text{dim}(g)}{k + h^v} + 1 - \frac{6}{(h - 1)h} \quad . \end{aligned} \tag{12.7.2}$$

For  $k = 0$ , which should be interesting for  $\beta < 4$ , the second formula reduces to

$$c = 1 - \frac{6}{(h-1)h} . \quad (12.7.3)$$

The formula gives the values of  $c$  for minimal conformal field theories with finite number of conformal fields and real conformal weights. Indeed,  $h$  in this formula seems to correspond to the same  $h$  as appearing in the expression  $\beta \equiv \mathcal{M} : \mathcal{N} = 4\cos^2(\pi/h)$  .

$\beta = 3, h = 6$  corresponds to three-state Potts model with  $c = 4/5$  which should thus have a gauge group for which Coxeter number is 6: the group should be either  $SU(6)$  or  $SO(8)$ . Two-state Potts model, that is Ising model with  $\beta = 2, h = 4$  would correspond to  $c = 1/2$  and to a gauge group  $SU(4)$  or  $SO(4)$ . For  $h = 3$  ("one-state Potts model") with group  $SU(3)$  one would have  $c = 0$  and vanishing conformal anomaly so that conformal degrees of freedom would become pure gauge degrees of freedom.

These observations give support for the following picture.

1. Quite generally, the number of states of the generalized  $\beta$ -state Potts model has an interpretation as the dimension  $\beta = \mathcal{M} : \mathcal{N}$  of  $\mathcal{M}$  as  $\mathcal{N}$ -module. Besides the models with integer number of states there is an infinite number of models for which the number of states is not an integer. The conditions  $c \leq 1$  guaranteeing real conformal weights and  $\beta \leq 4$  correspond to each other for these models.
2.  $\beta > 4$  Potts models would be formally obtained by allowing  $h$  to be imaginary in the defining formula for  $\mathcal{M} : \mathcal{N}$ . In this case  $c$  would be however complex so that the theory would not be unitary.
3. For minimal models with ( $\beta < 4, c < 1$ ) Kac-Moody central extension parameter is vanishing so that Kac Moody algebra indeed acts like gauge symmetries and gauge symmetries would be in question. ( $\beta = 4, c = 1$ ) would define a "four-state Potts model" with infinite-dimensional unitary group acting as a gauge group. On the other hand, the appearance of extended ADE Dynkin diagrams suggests strongly that this limit is not realized but that  $\beta = \mathcal{M} : \mathcal{N} = 4$  corresponds to  $k = 1$  conformal field theory allowing Kac Moody symmetries for any ADE group, which as simply-laced groups allows vertex operator construction. The appearance of  $k\dim(g)/(k+g)$  in the more general formula would thus code the Kac Moody group whereas for  $\beta < 4$  ADE diagram codes for the preferred gauge group characterizing the minimal CFT.
4. The possibility that any ADE gauge group or Kac-Moody group can characterize the interaction between space-time sheets conforms with the idea about Universe as a Topological Quantum Computer able to simulate any conceivable quantum dynamics. Of course, one cannot exclude the possibility that only electro-weak and color symmetries are realized in this manner.

### $G_a$ as a symmetry group of magnetic body and McKay correspondence

The group  $G_a \subset SU(2) \subset SL(2, C)$  means exact rotational symmetry realized in terms of  $CD$  coverings of  $CP_2$ . The 5 and 6-cycles in biochemistry (sugars, DNA,...) are excellent candidates for these symmetries. For very large values of Planck constant, say for the values  $\hbar(CD)/\hbar(CP_2) = GMm/v_0 = (n_a/n_b)\hbar_0$ ,  $v_0 = 2^{-11}$ , required by the model for planetary orbits as Bohr orbits [64],  $G_a$  is huge and corresponds to either  $Z_{n_a}$  or in the case of even value of  $n_a$  to the group generated by  $Z_n$  and reflection acting on plane and containing  $2n_a$  elements.

The notion of magnetic body seems to provide the only conceivable candidate for a geometric object possessing  $G_a$  as symmetries. In the first approximation the magnetic field associated with a dark matter system is expected to be modellable as a dipole field having rotational symmetry around the dipole axis. Topological quantization means that this field decomposes into flux tube like structures related by the rotations of  $Z_n$  or  $D_{2n}$ . Dark particles would have wave functions delocalized to this set of these flux quanta and span group algebra of  $G_a$ . Magnetic flux quanta are indeed assumed to

mediate gravitational interactions in the TGD based model for the quantization of radii of planetary orbits and this explains the dependence of  $\hbar_{gr}$  on the masses of planet and central object [64].

For the model of dark matter hierarchy appearing in the model of living matter one has  $n_a = 2^{11k}$ ,  $k = 1, 2, 3, \dots, 7$  for cyclotron time scales below life cycle for a magnetic field  $B_d = .2$  Gauss at  $k = 4$  level of hierarchy (the field strength is fixed by the effects of ELF em fields on vertebrate brain at harmonics of cyclotron frequencies of biologically important ions [24]). Note that  $B_d$  scales as  $2^{-11k}$  from the requirement that cyclotron energy is constant.

ADE correspondence between subgroups of  $SU(2)$  and Lie groups in ADE hierarchy encourages to consider the possibility that TGD could mimic ADE hierarchy of gauge theories. In the case of  $G_a$  this would mean that many fermion states constructed from single fermion states, which are in one-one correspondence with the elements of  $G_a$  group algebra, would define multiplets of the gauge group corresponding to the Dynkin diagram characterizing  $G_a$ : for instance,  $SU(n_a)$  in the case of  $Z_{n_a}$ . Fermion multiplet would contain  $n_a$  states and gauge boson multiplet  $n_a^2 - 1$  states. This would provide enormous information processing capacity since for  $n_a = 2^{11k}$  fermion multiplet would code exactly  $11k$  bits of information. Magnetic body could represent binary information using the many-particle states belonging to the representations of say  $SU(n_a)$  at its flux tubes.

### 12.7.2 Jones inclusions, the large $N$ limit of $SU(N)$ gauge theories and AdS/CFT correspondence

The framework based on Jones inclusions has an obvious resemblance with larger  $N$  limit of  $SU(N)$  gauge theories and also with the celebrated AdS/CFT correspondence [45] so that a more detailed comparison is in order.

#### Large $N$ limit of gauge theories and series of Jones inclusions

The large  $N$  limit of  $SU(N)$  gauge field theories has as definite resemblance with the series of Jones inclusions with the integer  $n \geq 3$  characterizing the quantum phase  $q = \exp(i\pi/n)$  and the order of the maximal cyclic subgroup of the subgroup of  $SU(2)$  defining the inclusion. Recall that all ADE groups except  $D_{2n+1}$  and  $E_7$  are allowed ( $SU(2)$  is excluded since it would correspond to  $n = 2$ ).

The limiting procedure keeps the value of  $g^2 N$  fixed. Rather remarkably, this is equivalent with keeping  $\alpha N$  constant but assuming  $\hbar$  to scale as  $n = N$ . Thus the quantization of Planck constants would provide a physical laboratory for the testing of large  $N$  limit.

The observation suggesting a description of YM theories in terms of closed strings is that Feynman diagrams can be interpreted as being imbedded at closed 2-surfaces of minimal genus guaranteeing that the internal lines meet except in vertices. The contribution of genus  $g$  diagrams is proportional to  $N^{g-1}$  at the large  $N$  limit. The interpretation in terms of closed partonic 2-surfaces is highly suggestive and the  $N^{g-1}$  should come from the multiple covering property of  $CP_2$  by  $N$   $CD$ -points (or vice versa) with the finite subgroup of  $G \subset SU(2)$  defining the Jones inclusion and acting as symmetries of the surface.

#### Analogy between stacks of branes and multiple coverings of $CD$ and $CP_2$

An important aspect of AdS/CFT dualities is a prediction of an infinite hierarchy of gauge groups, which as such is as interesting as the claimed dualities. The prediction relies on the notion  $Dp$ -branes.  $Dp$ -branes are  $p + 1$ -dimensional surfaces of the target space at which the ends of open strings can end. In the simplest situation one considers  $N$  parallel  $p$ -branes at the limit when the distances between branes characterized by an expectation value of Higgs fields approach zero to obtain what is called  $N$ -stack of branes. There are  $N^2$  different strings connecting the branes and the heuristic idea is that they correspond to gauge bosons of  $U(N)$  gauge theory. Note that the requirement that AdS/CFT dualities exist forces the introduction of branes and the optimistic interpretation is that a non-perturbative effect of still unknown M-theory is in question. In the limit of an ideal stack one assumes that  $U(N)$  gauge theory at the brane representing the stack is obtained. The branes must also carry a  $p$ -form defining gauge potential for a closed  $p + 1$ -form. This Ramond charge is quantized and its value equals to  $N$ .

Consider now the group  $G_a \times G_b \subset SL(2, C) \times SU(2) \subset SU(3)$  defining double Jones inclusion and implying the scalings  $\hbar(M^4) \rightarrow n(G_b)\hbar(M^4)$  and  $\hbar(CP_2) \rightarrow n(G_a)\hbar(CP_2)$ . These space-time surfaces

define  $n(G_a)$ -fold multiple coverings of  $CP_2$  and  $n(G_b)$ -fold multiple coverings of  $CD$ . In  $CP_2$  degrees of freedom the collection of  $G_b$ -related partonic 2-surfaces (/3-surfaces/4-surfaces) is highly analogous to the stack of branes. In  $CD$  degrees of freedom the stack of copies of surface typically correspond to along a circle ( $A_n, D_{2n}$  or at vertices of tetrahedron or isosahedron).

In TGD framework the interpretation strings are not needed to define gauge fields. The group algebra of  $G$  realized as discrete plane waves at  $G$ -orbit gives rise to representations of  $G$ . The hypothesis supported by few examples is that these additional degrees of freedom allow to construct multiplets of the gauge group assignable to the ADE diagram characterizing the inclusion.

### AdS/CFT duality

AdS/CFT duality is a further aspect of the brane construction. The dual description of the situation is in terms of a string theory in a background in which  $N$ -brane acts as a macroscopic object giving rise to a black-hole like object in (say) 10-dimensional target space. This background has the form  $AdS_5 \times X_5$ , where  $AdS_5$  is 5-dimensional hyperboloid of  $M^6$  and thus allows  $SO(4, 2)$  as isometries.  $X_5$  is compact constant curvature space.  $S_5$  gives rise to  $N = 4$  SUSY in  $M^4$  with  $M^4$  interpreted as a brane. The first support for the dualities comes from the symmetries: for instance, the  $N = 4$  super-symmetrized isometries of  $AdS_5 \times S^5$  are same as the symmetries of 4-dimensional  $N = 4$  SUSY for  $p = 3$  branes.  $N$ -branes can be used as models for black holes in target space and black-hole entropy can be calculated using either target space picture or conformal field theory at brane and the results turn out to be the same.

Does the TGD equivalent of this duality exist in some sense?

1. As far as partonic 2-surfaces identified as 1-branes are considered, conformal field theory description is trivially true. In TGD framework the analog of Ramond charges are the integers  $n_a$  and  $n_b$  characterizing the multiplicities of the maximal Abelian subgroups having clear topological meaning. This conforms with the observation that large  $N$  limit of the gauge field theories can be formulated in terms of closed surfaces at which the Feynman diagrams are imbedded without self crossings. It seems that the integers  $n_a$  and  $n_b$  characterizing the Jones inclusion naturally take the role of Ramond charge: this does not of course exclude the possibility they can be expressed as fluxes at space-time level as will be indeed found.
2. Conformal field theory description can be generalized in the sense that one replaces the  $n(G_a) \times n(G_b)$  partonic surfaces with single one and describes the new states as primary fields arranged into representations of the ADE group in question. This would mean that the standard model gauge group extends by additional factor which is however non-trivially related to it.
3. If one can accept the idea that the conformal field theory description for partons gives rise to  $M^4$  gauge theory as an approximate description, it is not too difficult to imagine that also ADE hierarchy of gauge theories results as a description of the exotic states. One can say that CFT in  $p$ -brane is replaced now with CFT on partonic 2-surface (1-brane) analogous to a closed string.
4. In the minimal interpretation there is no need to add strings connecting the branches of the double covering of the partonic 2-surface whose function is essentially that of making possible gauge bosons as fermion anti-fermion pairs. One could of course imagine gauge fluxes as counterparts of strings but just the fact that  $G$ -invariance dictates the configurations completely forces to question this kind of dynamics.
5. There is no reason to expect the emergence of  $N = 4$  super-symmetric field theory in  $M^4$  as in the case of super-string models. The reasons should be already obvious: super-conformal generators  $G$  anticommute to  $L_0$  proportional to mass squared rather than four-momentum and the spectrum extended by  $G_a \times G_b$  degeneracy contains more states.

One can of course ask whether higher values of  $p$  could make sense in TGD framework.

1. It seems that the light-like orbits of the partonic 2-surfaces defining 2-branes do not bring in anything new since the generalized conformal invariance makes it possible the restriction to a 2-dimensional cross section of the light like causal determinant.

2. The idea of regarding space-time surface  $X^4$  as a 3-brane in  $H$  in which some kind of conformal field theory is defined is in conflict with the basis ideas of TGD. The role of  $X^4$  interior is to provide classical correlates for quantum dynamics to make possible quantum measurement theory and also introduce correlations between partonic 2-surfaces even in the case that partonic conformal dynamics reduces to a topological string theory. It is quantum classical correspondence which corresponds to this duality.

### What is the counterpart of the Ramond charge in TGD?

The condition that there exist a  $p$ -form defining  $p + 1$ -gauge field with  $p$ -charge equal to  $n_a$  or  $n_b$  is a rather stringent additional condition also in TGD framework. For  $n < \infty$  this kind of charge is defined by Jones inclusion and represented topologically so that Ramond charge is not needed in  $n < \infty$  case. By the earlier arguments one must however be able to assign integers  $n_a$  and  $n_b$  also to  $G = SU(2)$  inclusions with Kac-Moody algebra characterized by an extended ADE diagram with the phases  $q_i = \exp(i\pi/n_i)$  relating to the monodromy of the theory. Since Jones inclusion does not define in this case the value of  $n < \infty$  in any obvious manner, the counterpart of the Ramond charge is needed.

1. For partonic 2-surfaces ordinary gauge potential would define this form and the condition would state that magnetic flux equals to  $n$  so that the anyonic partonic two-surfaces would be homologically non-trivial in  $CP_2$  degrees of freedom. String ends would define basic example of this situation. This would be the case also in  $M^4_+$  degrees of freedom: the partonic 2-surface would essentially wind  $n_a$  times around the tip of  $\delta CD$  and the gauge field in question would be monopole magnetic field in  $\delta CD$ . This kind of situation need not correspond to anything cosmological since future and past light-cones appear in the basic definition of the scattering amplitudes.
2. For  $p = 3$  Chern-Simons action for the induced  $CP_2$  Kähler form associated with the partonic 2-surface indeed defines this kind of charge. Ramond charge should be simply  $N$ .  $CP_2$  type extremals or their small deformations satisfy this constraint and are indeed very natural in elementary particle physics context but too restrictive in a more general context.

Note that the light-like orbits of non-deformed  $CP_2$  extremals have light-like random curve as an  $M^4$  projection and the conformal symmetries of  $M^4$  obviously respect light-likeness property. Hence  $SO(4, 2)$  symmetry characterizing  $AdS_5/CFT$  is not excluded but would be broken by  $p$ -adic thermodynamics and by TGD based Higgs mechanism involving the identification of inertial momentum as average value of non-conserved gravitational momentum parallel to the light-like zitterbewegung orbit.

### Can one speak about black hole like structures in TGD framework?

For  $AdS/CFT$  correspondence there is also a dynamical coupling to the target space metric. The coupling to H-metric is present also now since the overall scalings of the  $CD$  resp.  $CP_2$  metrics by  $n_b$  resp. by  $n_a$  are involved. This applies to when multiple covering is used explicitly. In the description in which one replaces the multiple covering by ordinary  $M^4 \times CP_2$ , the metric suffers a genuine change and something analogous to the black-hole type metrics encountered in  $AdS/CFT$  correspondence might be encountered.

Consider as an example an  $n_a$ -fold covering of  $CP_2$  points by  $M^4$  points (ADE diagram  $A_{n_a-1}$ ). The  $n$ -fold covering means only  $n2\pi$  rotation for the phase angle  $\psi$  of  $CP_2$  complex coordinate leads to the original point. The replacement  $\psi \rightarrow \psi/n_a$  gives rise to what would look like ordinary  $M^4 \times CP_2$  but with a modified  $CP_2$  metric. The metric components containing  $\psi$  as index are scaled down by  $1/n_a$  or  $1/n_a^2$ . Notice that  $\Psi$  effectively disappears from the dynamics at the large  $n_a$  limit.

If one uses an effective description in which covering is eliminated the metric is indeed affected at the level of imbedding space black hole like structures at the level of dynamic space might make emerge also in TGD framework at large  $N$  limit since the masses of the objects in question become large and  $CP_2$  metric is scaled by  $N$  so that  $CP_2$  has very large size at this limit. This need not lead to any inconsistencies if these phases are interpreted as dark matter. At the elementary particle level  $p$ -adic thermodynamics predicts that  $p$ -adic entropy is proportional to thermal mass squared which implies elementary particle black-hole analogy.

### Other dualities

Also quantum classical correspondence defines in a loose sense a duality justifying the basic assumptions of quantum measurement theory. The light-like orbits of 2-D partons are characterized by a generalization of ordinary 2-D conformal invariance so that CFT part of the duality would be very natural. The dynamical target space would be replaced with the space-time surface  $X^4$  with a dynamical metric providing classical correlates for the quantum dynamics at partonic 2-surfaces. The duality in this sense cannot be however exact since classical dynamics cannot fully represent quantum dynamics.

Classical description is not expected to be unique. The basic condition on space-time surfaces assignable to a given configuration of partonic 2-surfaces associated with the surface  $X_V^3$  defining S-matrix element are posed by quantum classical correspondence. Both hyper-quaternionic and co-hyper-quaternionic space-time surfaces are acceptable and this would define a fundamental duality.

A concrete example about this HQ-coHQ duality would be the equivalence of space-time descriptions using 4-D  $CP_2$  type extremals and 4-D string like objects connecting them. If one restricts to  $CP_2$  type extremals and string like objects of from  $X^2 \times Y^2$ , the target space reduces effectively to  $M^4$  and the dynamical degrees of freedom correspond in both cases to transversal  $M^4$  degrees of freedom. Note that for  $CP_2$  type extremals the conditions stating that random light-likeness of the  $M^4$  projection of the  $CP_2$  type extremal are equivalent to Virasoro conditions.  $CP_2$  type extremals could be identified as co-HQ surfaces whereas stringlike objects would correspond to HQ aspect of the duality.

HQ-coHQ provides dual classical descriptions of same phenomena. Particle massivation would be a basic example. Higgs mechanism in a gauge theory description based on  $CP_2$  type extremals would rely on zitterbewegung implying that the average value of gravitational mass identified as inertial mass is non-vanishing and is discussed already. Higgs field would be assigned to the wormhole contacts. The dual description for the massivation would be in terms of string tension and mass squared would be proportional to the distance between  $G$ -related points of  $CP_2$ .

These observations would suggest that also a super-conformal algebra containing  $SL(2, R) \times SU(2)_L \times U(1)$  or its compact version exists and corresponds to a trivial inclusion. This is indeed the case [43]. The so called large  $N = 4$  super-conformal algebra contains energy momentum current, 2+2 super generators  $G$ ,  $SU(2) \times SU(2) \times U(1)$  Kac-Moody algebra (both  $SU(2)$  and  $SL(2, R)$ ) could be interpreted as acting on  $M^4$  spin degrees of freedom, and 2 spin 1/2 fermionic currents having interpretation in terms of right handed neutrinos corresponding to two H-chiralities. Interestingly, the scalar generator is now missing.

### 12.7.3 Could McKay correspondence and Jones inclusions relate to each other?

The understanding of Langlands correspondence for general reductive Lie groups in TGD framework seems to require some physical mechanism allowing the emergence of these groups in TGD based physics. The physical idea would be that quantum dynamics of TGD is able to emulate the dynamics of any gauge theory or even stringy dynamics of conformal field theory having Kac-Moody type symmetry and that this emulation relies on quantum deformations induced by finite measurement resolution described in terms of Jones inclusions of sub-factors characterized by group  $G$  leaving elements of sub-factor invariant. Finite measurement resolution would result simply from the fact that only quantum numbers defined by the Cartan algebra of  $G$  are measured.

There are good reasons to expect that infinite Clifford algebra has the capacity needed to realize representations of an arbitrary Lie group. It is indeed known that that any quantum group characterized by quantum parameter which is root of unity or positive real number can be assigned to Jones inclusion [74]. For  $q = 1$  this would give ordinary Lie groups. In fact, all amenable groups define unique sub-factor and compact Lie groups are amenable ones.

It was so called McKay correspondence [90] which originally stimulated the idea about TGD as an analog of Universal Turing machine able to mimic both ADE type gauge theories and theories with ADE type Kac-Moody symmetry algebra. This correspondence and its generalization might also provide understanding about how general reductive groups emerge. In the following I try to cheat the reader to believe that the tensor product of representations of  $SU(2)$  Lie algebras for Connes tensor powers of  $\mathcal{M}$  could induce ADE type Lie algebras as quantum deformations for the direct sum of  $n$

copies of  $SU(2)$  algebras This argument generalizes also to the case of other compact Lie groups.

### About McKay correspondence

McKay correspondence [90] relates discrete finite subgroups of  $SU(2)$  ADE groups. A simple description of the correspondences is as follows [90].

1. Consider the irreps of a discrete subgroup  $G \subset SU(2)$  which correspond to irreps of  $G$  and can be obtained by restricting irreducible representations of  $SU(2)$  to those of  $G$ . The irreducible representations of  $SU(2)$  define the nodes of the graph.
2. Define the lines of graph by forming a tensor product of any of the representations appearing in the diagram with a doublet representation which is always present unless the subgroup is 2-element group. The tensor product regarded as that for  $SU(2)$  representations gives representations  $j - 1/2$ , and  $j + 1/2$  which one can decompose to irreducibles of  $G$  so that a branching of the graph can occur. Only branching to two branches occurs for subgroups yielding extended ADE diagrams. For the linear portions of the diagram the spins of corresponding  $SU(2)$  representations increase linearly as  $\dots, j, j + 1/2, j + 1, \dots$

One obtains extended Dynkin diagrams of ADE series representing also Kac-Moody algebras giving  $A_n, D_n, E_6, E_7, E_8$ . Also  $A_\infty$  and  $A_{-\infty, \infty}$  are obtained in case that subgroups are infinite. The Dynkin diagrams of non-simply laced groups  $B_n$  ( $SO(2n+1)$ ),  $C_n$  (symplectic group  $Sp(2n)$  and quaternionic group  $Sp(n)$ ), and exceptional groups  $G_2$  and  $F_4$  are not obtained.

ADE Dynkin diagrams labeling Lie groups instead of Kac-Moody algebras and having one node less, do not appear in this context but appear in the classification of Jones inclusions for  $\mathcal{M} : \mathcal{N} < 4$ . As a matter fact, ADE type Dynkin diagrams appear in very many contexts as one can learn from John Baez's This Week's Finds [39] .

1. The classification of integral lattices in  $\mathbb{R}^n$  having a basis of vectors whose length squared equals 2
2. The classification of simply laced semisimple Lie groups.
3. The classification of finite sub-groups of the 3-dimensional rotation group.
4. The classification of simple singularities . In TGD framework these singularities could be assigned to origin for orbifold  $CP_2/G$ ,  $G \subset SU(2)$ .
5. The classification of tame quivers.

### Principal graphs for Connes tensor powers $\mathcal{M}$

The thought provoking findings are following.

1. The so called principal graphs characterizing  $\mathcal{M} : \mathcal{N} = 4$  Jones inclusions for  $G = SU(2)$  are extended Dynkin diagrams characterizing ADE type affine (Kac-Moody) algebras.  $D_n$  is possible only for  $n \geq 4$ .
2.  $\mathcal{M} : \mathcal{N} < 4$  Jones inclusions correspond to ordinary ADE type diagrams for a subset of simply laced Lie groups (all roots have same length)  $A_n$  ( $SU(n)$ ),  $D_{2n}$  ( $SO(2n)$ ), and  $E_6$  and  $E_8$ . Thus  $D_{2n+1}$  ( $SO(2n+2)$ ) and  $E_7$  are not allowed. For instance, for  $G = S_3$  the principal graph is not  $D_3$  Dynkin diagram.

The conceptual background behind principal diagram is necessary if one wants to understand the relationship with McKay correspondence.

1. The hierarchy of higher commutations defines an invariant of Jones inclusion  $\mathcal{N} \subset \mathcal{M}$ . Denoting by  $\mathcal{N}'$  the commutant of  $\mathcal{N}$  one has sequences of horizontal inclusions defined as  $C = \mathcal{N}' \cap \mathcal{N} \subset \mathcal{N}' \cap \mathcal{M} \subset \mathcal{N}' \cap \mathcal{M}^1 \subset \dots$  and  $C = \mathcal{M}' \cap \mathcal{M} \subset \mathcal{M}' \cap \mathcal{M}^1 \subset \dots$ . There is also a sequence of vertical inclusions  $\mathcal{M}' \cap \mathcal{M}^k \subset \mathcal{N}' \cap \mathcal{M}^k$ . This hierarchy defines a hierarchy of Temperley-Lieb algebras [122] assignable to a finite hierarchy of braids. The commutants in the hierarchy are

direct sums of finite-dimensional matrix algebras (irreducible representations) and the inclusion hierarchy can be described in terms of decomposition of irreps of  $k^{\text{th}}$  level to irreps of  $(k-1)^{\text{th}}$  level irreps. These decomposition can be described in terms of Bratteli diagrams [53].

2. The information provided by infinite Bratteli diagram can be coded by a much simpler bi-partite diagram having a preferred vertex. For instance, the number of  $2k$ -loops starting from it tells the dimension of  $k^{\text{th}}$  level algebra. This diagram is known as principal graph.

Principal graph emerges also as a concise description of the fusion rules for Connes tensor powers of  $\mathcal{M}$ .

1. It is natural to decompose the Connes tensor powers [90]  $\mathcal{M}_k = \mathcal{M} \otimes_{\mathcal{N}} \dots \otimes_{\mathcal{N}} \mathcal{M}$  to irreducible  $\mathcal{M} - \mathcal{M}$ ,  $\mathcal{N} - \mathcal{M}$ ,  $\mathcal{M} - \mathcal{N}$ , or  $\mathcal{N} - \mathcal{N}$  bi-modules. If  $\mathcal{M} : \mathcal{N}$  is finite this decomposition involves only finite number of terms. The graphical representation of these decompositions gives rise to Bratteli diagram.
2. If  $\mathcal{N}$  has finite depth the information provided by Bratteli diagram can be represented in nutshell using principal graph. The edges of this bipartite graph connect  $\mathcal{M} - \mathcal{N}$  vertices to vertices describing irreducible  $\mathcal{N} - \mathcal{N}$  representations resulting in the decomposition of  $\mathcal{M} - \mathcal{N}$  irreducibles. If this graph is finite,  $\mathcal{N}$  is said to have finite depth.

### A mechanism assigning to tensor powers Jones inclusions ADE type gauge groups and Kac-Moody algebras

The earliest proposals inspired by the hierarchy of Jones inclusions is that in  $\mathcal{M} : \mathcal{N} < 4$  case it might be possible to construct ADE representations of gauge groups or quantum groups and in  $\mathcal{M} : \mathcal{N} = 4$  using the additional degeneracy of states implied by the multiple-sheeted cover  $H \rightarrow H/G_a \times G_b$  associated with space-time correlates of Jones inclusions. Either  $G_a$  or  $G_b$  would correspond to  $G$ . In the following this mechanism is articulated in a more refined manner by utilizing the general properties of generators of Lie-algebras understood now as a minimal set of elements of algebra from which the entire algebra can be obtained by repeated commutation operator (I have often used "Lie algebra generator" as an synonym for "Lie algebra element"). This set is finite also for Kac-Moody algebras.

#### 1. Two observations

The explanation to be discussed relies on two observations.

1. McKay correspondence for subgroups of  $G$  ( $\mathcal{M} : \mathcal{N} = 4$ ) *resp.* its variants ( $\mathcal{M} : \mathcal{N} < 4$ ) and its counterpart for Jones inclusions means that finite-dimensional irreducible representations of allowed  $G \subset SU(2)$  label both the Cartan algebra generators and the Lie (Kac-Moody) algebra generators of  $t_+$  and  $t_-$  in the decomposition  $g = h \oplus t_+ \oplus t_-$ , where  $h$  is the Lie algebra of maximal compact subgroup.
2. Second observation is related to the generators of Lie-algebras and their quantum counterparts (see Appendix for the explicit formulas for the generators of various algebras considered). The observation is that each Cartan algebra generator of Lie- and quantum group algebras, corresponds to a triplet of generators defining an  $SU(2)$  sub-algebra. The Cartan algebra of affine algebra contains besides Lie group Cartan algebra also a derivation  $d$  identifiable as an infinitesimal scaling operator  $L_0$  measuring the conformal weight of the Kac-Moody generators.  $d$  is exceptional in that it does not give rise to a triplet. It corresponds to the preferred node added to the Dynkin diagram to get the extended Dynkin diagram.

#### 2. Is ADE algebra generated as a quantum deformation of tensor powers of $SU(2)$ Lie algebras representations?

The ADE type symmetry groups could result as an effect of finite quantum resolution described by inclusions of HFFs in TGD inspired quantum measurement theory.

1. The description of finite resolution typically leads to quantization since complex rays of state space are replaced as  $\mathcal{N}$  rays. Hence operators, which would commute for an ideal resolution

cease to do so. Therefore the algebra  $SU(2) \otimes \dots \otimes SU(2)$  characterized by  $n$  mutually commuting triplets, where  $n$  is the number of copies of  $SU(2)$  algebra in the original situation and identifiable as quantum algebra appearing in  $\mathcal{M}$  tensor powers with  $\mathcal{M}$  interpreted as  $\mathcal{N}$  module, could suffer quantum deformation to a simple Lie algebra with  $3n$  Cartan algebra generators. Also a deformation to a quantum group could occur as a consequence.

2. This argument makes sense also for discrete groups  $G \subset SU(2)$  since the representations of  $G$  realized in terms of configuration space spinors extend to the representations of  $SU(2)$  naturally.
3. Arbitrarily high tensor powers of  $\mathcal{M}$  are possible and one can wonder why only finite-dimensional Lie algebra results. The fact that  $\mathcal{N}$  has finite depth as a sub-factor means that the tensor products in tensor powers of  $\mathcal{N}$  are representable by a finite Dynkin diagram. Finite depth could thus mean that there is a periodicity involved the  $kn$  tensor powers decomposes to representations of a Lie algebra with  $3n$  Cartan algebra generators. Thus the additional requirement would be that the number of tensor powers of  $\mathcal{M}$  is multiple of  $n$ .

### 3. Space-time correlate for the tensor powers $\mathcal{M} \otimes_{\mathcal{N}} \dots \otimes_{\mathcal{N}} \mathcal{M}$

By quantum classical correspondence there should exist space-time correlate for the formation of tensor powers of  $\mathcal{M}$  regarded as  $\mathcal{N}$  module. A concrete space-time realization for this kind of situation in TGD would be based on  $n$ -fold cyclic covering of  $H$  implied by the  $H \rightarrow H/G_a \times G_b$  bundle structure in the case of say  $G_b$ . The sheets of the cyclic covering would correspond to various factors in the  $n$ -fold tensor power of  $SU(2)$  and one would obtain a Lie algebra, affine algebra or its quantum counterpart with  $n$  Cartan algebra generators in the process naturally. The number  $n$  for space-time sheets would be also a space-time correlate for the finite depth of  $\mathcal{N}$  as a factor.

Configuration space spinors could provide fermionic representations of  $G \subset SU(2)$ . The Dynkin diagram characterizing tensor products of representations of  $G \subset SU(2)$  with doublet representation suggests that tensor products of doublet representations associated with  $n$  sheets of the covering could realize the Dynkin diagram.

Singlet representation in the Dynkin diagram associated with irreps of  $G$  would not give rise to an  $SU(2)$  sub-algebra in ADE Lie algebra and would correspond to the scaling generator. For ordinary Dynkin diagram representing gauge group algebra scaling operator would be absent and therefore also the exceptional node. Thus the difference between  $(\mathcal{M} : \mathcal{N} = 4)$  and  $(\mathcal{M} : \mathcal{N} < 4)$  cases would be that in the Kac-Moody group would reduce to gauge group  $\mathcal{M} : \mathcal{N} < 4$  because Kac-Moody central charge  $k$  and therefore also Virasoro central charge resulting in Sugawara construction would vanish.

### 4. Do finite subgroups of $SU(2)$ play some role also in $\mathcal{M} : \mathcal{N} = 4$ case?

One can ask wonder the possible interpretation for the appearance of extended Dynkin diagrams in  $(\mathcal{M} : \mathcal{N} = 4)$  case. Do finite subgroups  $G \subset SU(2)$  associated with extended Dynkin diagrams appear also in this case. The formal analog for  $H \rightarrow G_a \times G_b$  bundle structure would be  $H \rightarrow H/G_a \times SU(2)$ . This would mean that the geodesic sphere of  $CP_2$  would define the fiber. The notion of number theoretic braid meaning a selection of a discrete subset of algebraic points of the geodesic sphere of  $CP_2$  suggests that  $SU(2)$  actually reduces to its subgroup  $G$  also in this case.

### 5. Why Kac-Moody central charge can be non-vanishing only for $\mathcal{M} : \mathcal{N} = 4$ ?

From the physical point of view the vanishing of Kac-Moody central charge for  $\mathcal{M} : \mathcal{N} < 4$  is easy to understand. If parton corresponds to a homologically non-trivial geodesic sphere, space-time surface typically represents a string like object so that the generation of Kac-Moody central extension would relate directly to the homological non-triviality of partons. For instance, cosmic strings are string like objects of form  $X^2 \times Y^2$ , where  $X^2$  is minimal surface of  $M^2$  and  $Y^2$  is a holomorphic sub-manifold of  $CP_2$  reducing to a homologically non-trivial geodesic sphere in the simplest situation. A conjecture that deserves to be shown wrong is that central charge  $k$  is proportional/equal to the absolute value of the homology (Kähler magnetic) charge  $h$ .

### 6. More general situation

McKay correspondence generalizes also to the case of subgroups of higher-dimensional Lie groups [90]. The argument above makes sense also for discrete subgroups of more general compact Lie groups  $H$  since also they define unique sub-factors. In this case, algebras having Cartan algebra with  $nk$

generators, where  $n$  is the dimension of Cartan algebra of  $H$ , would emerge in the process. Thus there are reasons to believe that TGD could emulate practically any dynamics having gauge group or Kac-Moody type symmetry. An interesting question concerns the interpretation of non-ADE type principal graphs associated with subgroups of  $SU(2)$ .

#### 7. Flavor groups of hadron physics as a support for HFF?

The deformation assigning to an  $n$ -fold tensor power of representations of Lie group  $G$  with  $k$ -dimensional Cartan algebra a representation of a Lie group with  $nk$ -dimensional Cartan algebra could be also seen as a dynamically generated symmetry. If quantum measurement is characterized by the choice of Lie group  $G$  defining measured quantum numbers and defining Jones inclusion characterizing the measurement resolution, the measurement process itself would generate these dynamical symmetries. Interestingly, the flavor symmetry groups of hadron physics cannot be justified from the structure of the standard model having only electro-weak and color group as fundamental symmetries. In TGD framework flavor group  $SU(n)$  could emerge naturally as a fusion of  $n$  quark doublets to form a representation of  $SU(n)$ .

### 12.7.4 Farey sequences, Riemann hypothesis, tangles, and TGD

Farey sequences allow an alternative formulation of Riemann Hypothesis and subsequent pairs in Farey sequence characterize so called rational 2-tangles. In TGD framework Farey sequences relate very closely to dark matter hierarchy, which inspires "*Platonía as the best possible world in the sense that cognitive representations are optimal*" as the basic variational principle of mathematics. This variational principle supports RH.

Possible TGD realizations of tangles, which are considerably more general objects than braids, are considered. One can assign to a given rational tangle a rational number  $a/b$  and the tangles labeled by  $a/b$  and  $c/d$  are equivalent if  $ad - bc = \pm 1$  holds true. This means that the rationals in question are neighboring members of Farey sequence. Very light-hearted guesses about possible generalization of these invariants to the case of general  $N$ -tangles are made.

#### Farey sequences

Some basic facts about Farey sequences [11] demonstrate that they are very interesting also from TGD point of view.

1. Farey sequence  $F_N$  is defined as the set of rationals  $0 \leq q = m/n \leq 1$  satisfying the conditions  $n \leq N$  ordered in an increasing sequence.
2. Two subsequent terms  $a/b$  and  $c/d$  in  $F_N$  satisfy the condition  $ad - bc = 1$  and thus define an element of the modular group  $SL(2, Z)$ .
3. The number  $|F(N)|$  of terms in Farey sequence is given by

$$|F(N)| = |F(N-1)| + \phi(N-1) . \quad (12.7.4)$$

Here  $\phi(n)$  is Euler's totient function giving the number of divisors of  $n$ . For primes one has  $\phi(p) = p-1$  so that in the transition from  $p$  to  $p+1$  the length of Farey sequence increases by one unit by the addition of  $q = 1/(p+1)$  to the sequence.

The members of Farey sequence  $F_N$  are in one-one correspondence with the set of quantum phases  $q_n = \exp(i2\pi/n)$ ,  $0 \leq n \leq N$ . This suggests a close connection with the hierarchy of Jones inclusions, quantum groups, and in TGD context with quantum measurement theory with finite measurement resolution and the hierarchy of Planck constants involving the generalization of the imbedding space. Also the recent TGD inspired ideas about the hierarchy of subgroups of the rational modular group with subgroups labeled by integers  $N$  and in direct correspondence with the hierarchy of quantum critical phases [20] would naturally relate to the Farey sequence.

### Riemann Hypothesis and Farey sequences

Farey sequences are used in two equivalent formulations of the Riemann hypothesis. Suppose the terms of  $F_N$  are  $a_{n,N}$ ,  $0 < n \leq |F_N|$ . Define

$$d_{n,N} = a_{n,N} - \frac{n}{|F_N|} .$$

In other words,  $d_{n,N}$  is the difference between the  $n$ :th term of the  $N$ :th Farey sequence, and the  $n$ :th member of a set of the same number of points, distributed evenly on the unit interval. Franel and Landau proved that both of the following statements

$$\begin{aligned} \sum_{n=1, \dots, |F_N|} |d_{n,N}| &= O(N^r) \text{ for any } r > 1/2 , \\ \sum_{n=1, \dots, |F_N|} d_{n,N}^2 &= O(N^r) \text{ for any } r > 1 . \end{aligned} \quad (12.7.5)$$

are equivalent with Riemann hypothesis.

One could say that RH would guarantee that the numbers of Farey sequence provide the best possible approximate representation for the evenly distributed rational numbers  $n/|F_N|$ .

### Farey sequences and TGD

Farey sequences seem to relate very closely to TGD.

1. The rationals in the Farey sequence can be mapped to the roots of unity by the map  $q \rightarrow \exp(i2\pi q)$ . The numbers  $1/|F_N|$  are in turn mapped to the numbers  $\exp(i2\pi/|F_N|)$ , which are also roots of unity. The statement would be that the algebraic phases defined by Farey sequence give the best possible approximate representation for the phases  $\exp(in2\pi/|F_N|)$  with evenly distributed phase angle.
2. In TGD framework the phase factors defined by  $F_N$  corresponds to the set of quantum phases corresponding to Jones inclusions labeled by  $q = \exp(i2\pi/n)$ ,  $n \leq N$ , and thus to the  $N$  lowest levels of dark matter hierarchy. There are actually two hierarchies corresponding to  $M^4$  and  $CP_2$  degrees of freedom and the Planck constant appearing in Schrödinger equation corresponds to the ratio  $n_a/n_b$  defining quantum phases in these degrees of freedom.  $Z_{n_a \times n_b}$  appears as a conformal symmetry of "dark" partonic 2-surfaces and with very general assumptions this implies that there are only in TGD Universe [20, 18] .
3. The fusion of physics associated with various number fields to single coherent whole requires algebraic universality. In particular, the roots of unity, which are complex algebraic numbers, should define approximations to continuum of phase factors. At least the S-matrix associated with p-adic-to-real transitions and more generally  $p_1 \rightarrow p_2$  transitions between states for which the partonic space-time sheets are  $p_1$ - resp.  $p_2$ -adic can involve only this kind of algebraic phases. One can also say that cognitive representations can involve only algebraic phases and algebraic numbers in general. For real-to-real transitions and real-to-padic transitions U-matrix might be non-algebraic or obtained by analytic continuation of algebraic U-matrix. S-matrix is by definition diagonal with respect to number field and similar continuation principle might apply also in this case.
4. The subgroups of the hierarchy of subgroups of the modular group with rational matrix elements are labeled by integer  $N$  and relate naturally to the hierarchy of Farey sequences. The hierarchy of quantum critical phases is labeled by integers  $N$  with quantum phase transitions occurring only between phases for which the smaller integer divides the larger one [20] .

### Interpretation of RH in TGD framework

Number theoretic universality of physics suggests an interpretation for the Riemann hypothesis in TGD framework. RH would be equivalent to the statement that the Farey numbers provide best possible approximation to the set of rationals  $k/|F_N|$  or to the statement that the roots of unity contained by  $F_N$  define the best possible approximation for the roots of unity defined as  $\exp(ik2\pi/|F_N|)$  with evenly spaced phase angles. The roots of unity allowed by the lowest  $N$  levels of the dark matter hierarchy allows the best possible approximate representation for algebraic phases represented exactly at  $|F_N|$ :th level of hierarchy.

A stronger statement would be that the Platonia, where RH holds true would be the best possible world in the sense that algebraic physics behind the cognitive representations would allow the best possible approximation hierarchy for the continuum physics (both for numbers in unit interval and for phases on unit circle). Platonia with RH would be cognitive paradise.

One could see this also from different view point. "Platonia as the cognitively best possible world" could be taken as the "axiom of all axioms": a kind of fundamental variational principle of mathematics. Among other things it would allow to conclude that RH is true: RH must hold true either as a theorem following from some axiomatics or as an axiom in itself.

### Could rational $N$ -tangles exist in some sense?

The article of Kauffman and Lambropoulou [96] about rational 2-tangles having commutative sum and product allowing to map them to rationals is very interesting from TGD point of view. The illustrations of the article are beautiful and make it easy to get the gist of various ideas. The theorem of the article states that equivalent rational tangles giving trivial tangle in the product correspond to subsequent Farey numbers  $a/b$  and  $c/d$  satisfying  $ad - bc = \pm 1$  so that the pair defines element of the modular group  $SL(2, Z)$ .

#### 1. Rational 2-tangles

1. The basic observation is that 2-tangles are 2-tangles in both "s- and t-channels". Product and sum can be defined for all tangles but only in the case of 2-tangles the sum, which in this case reduces to product in t-channel obtained by putting tangles in series, gives 2-tangle. The so called rational tangles are 2-tangles constructible by using addition of  $\pm[1]$  on left or right of tangle and multiplication by  $\pm[1]$  on top or bottom. Product and sum are commutative for rational 2-tangles but the outcome is not a rational 2-tangle in the general case. One can also assign to rational 2-tangle its negative and inverse. One can map 2-tangle to a number which is rational for rational tangles. The tangles  $[0]$ ,  $[\infty]$ ,  $\pm[1]$ ,  $\pm 1/[1]$ ,  $\pm[2]$ ,  $\pm[1/2]$  define so called elementary rational 2-tangles.
2. In the general case the sum of  $M$ - and  $N$ -tangles is  $M + N$  - 2-tangle and combines various  $N$ -tangles to a monoidal structure. Tensor product like operation giving  $M + N$ -tangle looks to me physically more natural than the sum.
3. The reason why general 2-tangles are non-commutative although 2-braids obviously commute is that 2-tangles can be regarded as sequences of  $N$ -tangles with 2-tangles appearing only as the initial and final state:  $N$  is actually even for intermediate states. Since  $N > 2$ -braid groups are non-commutative, non-commutativity results. It would be interesting to know whether braid group representations have been used to construct representations of  $N$ -tangles.

#### 2. Does generalization to $N \gg 2$ case exist?

One can wonder whether the notion of rational tangle and the basic result of the article about equivalence of tangles might somehow generalize to the  $N > 2$  case.

1. Could the commutativity of tangle product allow to characterize the  $N > 2$  generalizations of rational 2-tangles. The commutativity of product would be a space-time correlate for the commutativity of the S-matrices defining time like entanglement between the initial and final quantum states assignable to the  $N$ -tangle. For 2-tangles commutativity of the sum would have an analogous interpretation. Sum is not a very natural operation for  $N$ -tangles for  $N >$

2. Commutativity means that the representation matrices defined as products of braid group actions associated with the various intermediate states and acting in the same representation space commute. Only in very special cases one can expect commutativity for tangles since commutativity is lost already for braids.
2. The representations of 2-tangles should involve the subgroups of  $N$ -braid groups of intermediate braids identifiable as Galois groups of  $N$ :th order polynomials in the realization as number theoretic tangles. Could non-commutative 2-tangles be characterized by algebraic numbers in the extensions to which the Galois groups are associated? Could the non-commutativity reflect directly the non-commutativity of Galois groups involved? Quite generally one can ask whether the invariants should be expressible using algebraic numbers in the extensions of rationals associated with the intermediate braids.
3. Rational 2-tangles can be characterized by a rational number obtained by a projective identification  $[a, b]^T \rightarrow a/b$  from a rational 2-spinor  $[a, b]^T$  to which  $SL(2(N-1), \mathbb{Z})$  acts. Equivalence means that the columns  $[a, b]^T$  and  $[c, d]^T$  combine to form element of  $SL(2, \mathbb{Z})$  and thus defining a modular transformation. Could more general 2-tangles have a similar representation but in terms of algebraic integers?
4. Could  $N$ -tangles be characterized by  $N - 1$   $2(N - 1)$ -component projective column-spinors  $[a_i^1, a_i^2, \dots, a_i^{2(N-1)}]^T$ ,  $i = 1, \dots, N - 1$  so that only the ratios  $a_i^k/a_i^{2(N-1)} \leq 1$  matter? Could equivalence for them mean that the  $N - 1$  spinors combine to form  $N - 1 + N - 1$  columns of  $SL(2(N - 1), \mathbb{Z})$  matrix. Could  $N$ -tangles quite generally correspond to collections of projective  $N - 1$  spinors having as components algebraic integers and could  $ad - bc = \pm 1$  criterion generalize? Note that the modular group for surfaces of genus  $g$  is  $SL(2g, \mathbb{Z})$  so that  $N - 1$  would be analogous to  $g$  and  $1 \leq N \geq 3$ - braids would correspond to  $g \leq 2$  Riemann surfaces.
5. Dark matter hierarchy leads naturally to a hierarchy of modular sub-groups of  $SL(2, \mathbb{Q})$  labeled by  $N$  (the generator  $\tau \rightarrow \tau + 2$  of modular group is replaced with  $\tau \rightarrow \tau + 2/N$ ). What might be the role of these subgroups and corresponding subgroups of  $SL(2(N - 1), \mathbb{Q})$ . Could they arise in "anyonization" when one considers quantum group representations of 2-tangles with twist operation represented by an  $N$ :th root of unity instead of phase  $U$  satisfying  $U^2 = 1$ ?

### How tangles could be realized in TGD Universe?

The article of Kauffman and Lambropoulou stimulated the question in what senses  $N$ -tangles could be realized in TGD Universe as fundamental structures.

#### 1. Tangles as number theoretic braids?

The strands of number theoretical  $N$ -braids correspond to roots of  $N$ :th order polynomial and if one allows time evolutions of partonic 2-surface leading to the disappearance or appearance of real roots  $N$ -tangles become possible. This however means continuous evolution of roots so that the coefficients of polynomials defining the partonic 2-surface can be rational only in initial and final state but not in all intermediate "virtual" states.

#### 2. Tangles as tangled partonic 2-surfaces?

Tangles could appear in TGD also in second manner.

1. Partonic 2-surfaces are sub-manifolds of a 3-D section of space-time surface. If partonic 2-surfaces have genus  $g > 0$  the handles can become knotted and linked and one obtains besides ordinary knots and links more general knots and links in which circle is replaced by figure eight and its generalizations obtained by adding more circles (eyeglasses for  $N$ -eyed creatures).
2. Since these 2-surfaces are space-like, the resulting structures are indeed tangles rather than only braids. Tangles made of strands with fixed ends would result by allowing spherical partons elongate to long strands with fixed ends. DNA tangles would be the basic example, and are discussed also in the article. DNA sequences to which I have speculatively assigned invisible (dark) braid structures might be seen in this context as space-like "written language representations" of genetic programs represented as number theoretic braids.

### 12.7.5 Only the quantum variants of $M^4$ and $M^8$ emerge from local hyper-finite $II_1$ factors

Super-symmetry suggests that the representations of  $CH$  Clifford algebra  $\mathcal{M}$  as  $\mathcal{N}$  module  $\mathcal{M}/\mathcal{N}$  should have bosonic counterpart in the sense that the coordinate for  $M^8$  representable as a particular  $M^2(Q)$  element should have quantum counterpart. Same would apply to  $M^4$  coordinate representable as  $M^2(C)$  element. Quantum matrix representation of  $\mathcal{M}/\mathcal{N}$  as  $SL_q(2, F)$  matrix,  $F = C, H$  is the natural candidate for this representation. As a matter fact, this guess is not quite correct. It is the interpretation of  $M_2(C)$  as a quaternionic quantum algebra whose generalization to the octonionic quantum algebra works.

Quantum variants of  $M^D$  exist for all dimensions but only spaces  $M^4$  and  $M^8$  and their linear sub-spaces emerge from hyper-finite factors of type  $II_1$ . This is due to the non-associativity of the octonionic representation of the gamma matrices making it impossible to absorb the powers of the octonionic coordinate to the Clifford algebra element so that the local algebra character would disappear. Even more: quantum coordinates for these spaces are commutative operators so that their spectra define ordinary  $M^4$  and  $M^8$  which are thus already quantal concepts.

The commutation relations for  $M_{2,q}(C)$  matrices

$$\begin{pmatrix} a & b \\ c & d \end{pmatrix}, \tag{12.7.6}$$

read as

$$\begin{aligned} ab &= qba, & ac &= qac, & bd &= qdb, & cd &= qdc, \\ [ad, da] &= (q - q^{-1})bc, & bc &= cb. \end{aligned} \tag{12.7.7}$$

These relations can be extended by postulating complex conjugates of these relations for complex conjugates  $a^\dagger, b^\dagger, c^\dagger, d^\dagger$  plus the following non-vanishing commutators of type  $[x, y^\dagger]$ :

$$[a, a^\dagger] = [b, b^\dagger] = [c, c^\dagger] = [d, d^\dagger] = 1. \tag{12.7.8}$$

The matrices representing  $M^4$  point must be expressible as sums of Pauli spin matrices. This can be represented as following conditions on physical states

$$\begin{aligned} O|phys\rangle &= 0, \\ O &\in \{a - a^\dagger, d - d^\dagger, b - c^\dagger, c - b^\dagger\}. \end{aligned} \tag{12.7.9}$$

For instance, the first two conditions follow from the reality of Pauli sigma matrices  $\sigma_x, \sigma_y, \sigma_z$ . These conditions are compatible only if the operators  $O$  commute. This is the case and means also that the operators representing  $M^4$  coordinates commute and it is possible to define quantum states for which  $M^4$  coordinates have well-defined eigenvalues so that ordinary  $M^4$  emerges purely quantally from quaternions whose real coefficients are made non-Hermitian operators to obtain operator complexification of quaternions. Also the quantum states in which  $M^4$  coordinates are emerge naturally.

$M_{2,q}(C)$  matrices define the quantum analog of  $C^4$  and one can wonder whether other linear sub-spaces can be defined consistently or whether  $M_q^4$  and thus Minkowski signature is unique. This seems to be the case. For instance, the replacement  $a - \bar{a} \rightarrow a + \bar{a}$  making also time variable Euclidian is impossible since  $[a + \bar{a}, d - \bar{d}] = 2(q - q^{-1})bc$  does not vanish. The observation that  $M^4$  coordinates can be regarded as eigenvalues of commuting observables proves that quantum  $CD$  and its orbifold description are equivalent.

What about  $M^8$ : does it have analogous description? The representation of  $M^4$  point as  $M_2(C)$  matrix can be interpreted a combination of 4-D gamma matrices defining hyper-quaternionic units. Hyper-octonionic units indeed have anticommutation relations of gamma matrices of  $M^8$  and would give classical representation of  $M^8$ . The counterpart of  $M_{2,q}(C)$  would thus be obtained by replacing the coefficients of hyper-octonionic units with operators satisfying the generalization of  $M_{2,q}(C)$

commutation relations. One should identify the reality conditions and find whether they are mutually consistent.

Introduce the coefficients of  $E^4$  gamma matrices having interpretation as quaterionic units as

$$\begin{aligned} a_0 &= ix(a+d) , & a_3 &= x(a-d) , \\ a_1 &= x(b+c) , & a_2 &= x(ib-c) , \\ x &= \frac{1}{\sqrt{2}} , \end{aligned}$$

and write the commutations relations for them to see how the generalization should be performed.

The selections of commutative and quaternionic sub-algebras of octonion space are fundamental for TGD and quantum octonionic algebra should reflect these selections in its structure. In the case of quaternions the selection of commutative sub-algebra implies the breaking of 4-D Lorentz symmetry. In the case of octonions the selection of quaternion sub-algebra should induce the breaking of 8-D Lorentz symmetry. Quaternionic sub-algebra obeys the commutations of  $M_q(2, C)$  whereas the coefficients in in the complement commute mutually and quantum commute with the complex sub-algebra. This nails down the commutation relations completely:

$$\begin{aligned} [a_0, a_3] &= -i(q - q^{-1})(a_1^2 + a_2^2) , \\ [a_i, a_j] &= 0 , \quad i, j \neq 0, 3 , \\ a_0 a_i &= q a_i a_0 , \quad i \neq 0, 3 , \\ a_3 a_i &= q a_i a_3 , \quad i \neq 0, 3 . \end{aligned} \tag{12.7.10}$$

Checking that  $M^8$  indeed corresponds to commutative subspace defined by the eigenvalues of operators is straightforward.

The argument generalizes easily to other dimensions  $D \geq 4$  but now quaternionic and octonionic units must be replaced by gamma matrices and an explicit matrix representation can be introduced. These gamma matrices can be included as a tensor factor to the infinite-dimensional Clifford algebra so that the local Clifford algebra reduces to a mere Clifford algebra. The units of quantum octonions which are just ordinary octonion units do not however allow matrix representation so that this reduction is not possible and imbedding space and space-time indeed emerge genuinely. The non-associativity of octonions would determine the laws of physics in TGD Universe!

Thus the special role of classical number fields and uniqueness of space-time and imbedding space dimensions becomes really manifest only when a quantal deformation of the quaternionic and octonionic matrix algebras is performed. It is possible to construct the quantal variants of the coset spaces  $M^4 \times E^4 / G_a \times G_b$  by simply posing restrictions on the of eigen states of the commuting coordinate operators. Also the quantum variants of the space-time surface and quite generally, manifolds obtained from linear spaces by geometric constructions become possible.

## 12.8 Appendix

### 12.8.1 About inclusions of hyper-finite factors of type $\text{II}_1$

Many names have been assigned to inclusions: Jones, Wenzl, Ocneanu, Pimsner-Popa, Wasserman [60]. It would seem to me that the notion Jones inclusion includes them all so that various names would correspond to different concrete realizations of the inclusions conjugate under outer automorphisms.

1. According to [60] for inclusions with  $\mathcal{M} : \mathcal{N} \leq 4$  (with  $A_1^{(1)}$  excluded) there exists a countable infinity of sub-factors which are pairwise non inner conjugate but conjugate to  $\mathcal{N}$ .
2. Also for any finite group  $G$  and its outer action there exists uncountably many sub-factors which are pairwise non inner conjugate but conjugate to the fixed point algebra of  $G$  [60]. For any amenable group  $G$  the the inclusion is also unique apart from outer automorphism [74].

Thus it seems that not only Jones inclusions but also more general inclusions are unique apart from outer automorphism.

Any \*-endomorphism  $\sigma$ , which is unit preserving, faithful, and weakly continuous, defines a sub-factor of type II<sub>1</sub> factor [60]. The construction of Jones leads to a standard inclusion sequence  $\mathcal{N} \subset \mathcal{M} \subset \mathcal{M}^1 \subset \dots$ . This sequence means addition of projectors  $e_i$ ,  $i < 0$ , having visualization as an addition of braid strand in braid picture. This hierarchy exists for all factors of type II. At the limit  $\mathcal{M}^\infty = \cup_i \mathcal{M}^i$  the braid sequence extends from  $-\infty$  to  $\infty$ . Inclusion hierarchy can be understood as a hierarchy of Connes tensor powers  $\mathcal{M} \otimes_{\mathcal{N}} \mathcal{M} \dots \otimes_{\mathcal{N}} \mathcal{M}$ . Also the ordinary tensor powers of hyper-finite factors of type II<sub>1</sub> (HFF) as well as their tensor products with finite-dimensional matrix algebras are isomorphic to the original HFF so that these objects share the magic of fractals.

Under certain assumptions the hierarchy can be continued also in opposite direction. For a finite index an infinite inclusion hierarchy of factors results with the same value of index.  $\sigma$  is said to be basic if it can be extended to \*-endomorphisms from  $\mathcal{M}^1$  to  $\mathcal{M}$ . This means that the hierarchy of inclusions can be continued in the opposite direction: this means elimination of strands in the braid picture. For finite factors (as opposed to hyper-finite ones) there are no basic \*-endomorphisms of  $\mathcal{M}$  having fixed point algebra of non-abelian  $G$  as a sub-factor [60].

### 1. Jones inclusions

For hyper-finite factors of type II<sub>1</sub> Jones inclusions allow basic \*-endomorphism. They exist for all values of  $\mathcal{M} : \mathcal{N} = r$  with  $r \in \{4\cos^2(\pi/n) | n \geq 3\} \cap [4, \infty)$  [60]. They are defined for an algebra defined by projectors  $e_i$ ,  $i \geq 1$ . All but nearest neighbor projectors commute.  $\lambda = 1/r$  appears in the relations for the generators of the algebra given by  $e_i e_j e_i = \lambda e_i$ ,  $|i - j| = 1$ .  $\mathcal{N} \subset \mathcal{M}$  is identified as the double commutator of algebra generated by  $e_i$ ,  $i \geq 2$ .

This means that principal graph and its dual are equivalent and the braid defined by projectors can be continued not only to  $-\infty$  but that also the dropping of arbitrary number of strands is possible [60]. It would seem that ADE property of the principal graph meaning single root length codes for the duality in the case of  $r \leq 4$  inclusions.

Irreducibility holds true for  $r < 4$  in the sense that the intersection of  $Q' \cap P = P' \cap P = C$ . For  $r \geq 4$  one has  $\dim(Q' \cap P) = 2$ . The operators commuting with  $Q$  contain besides identify operator of  $Q$  also the identify operator of  $P$ .  $Q$  would contain a single finite-dimensional matrix factor less than  $P$  in this case. Basic \*-endomorphisms with  $\sigma(P) = Q$  is  $\sigma(e_i) = e_{i+1}$ . The difference between genuine symmetries of quantum TGD and symmetries which can be mimicked by TGD could relate to the irreducibility for  $r < 4$  and raise these inclusions in a unique position. This difference could partially justify the hypothesis that only the groups  $G_a \times G_b \subset SU(2) \times SU(2) \subset SL(2, C) \times SU(3)$  define orbifold coverings of  $H_\pm = CD \times CP_2 \rightarrow H_\pm/G_a \times G_b$ .

### 2. Wasserman's inclusion

Wasserman's construction of  $r = 4$  factors clarifies the role of the subgroup of  $G \subset SU(2)$  for these inclusions. Also now  $r = 4$  inclusion is characterized by a discrete subgroup  $G \subset SU(2)$  and is given by  $(1 \otimes \mathcal{M})^G \subset (M_2(C) \times \mathcal{M})^G$ . According to [60] Jones inclusions are irreducible also for  $r = 4$ . The definition of Wasserman inclusion for  $r = 4$  seems however to imply that the identity matrices of both  $\mathcal{M}^G$  and  $(M(2, C) \otimes \mathcal{M})^G$  commute with  $\mathcal{M}^G$  so that the inclusion should be reducible for  $r = 4$ .

Note that  $G$  leaves both the elements of  $\mathcal{N}$  and  $\mathcal{M}$  invariant whereas  $SU(2)$  leaves the elements of  $\mathcal{N}$  invariant.  $M(2, C)$  is effectively replaced with the orbifold  $M(2, C)/G$ , with  $G$  acting as automorphisms. The space of these orbits has complex dimension  $d = 4$  for finite  $G$ .

For  $r < 4$  inclusion is defined as  $\mathcal{M}^G \subset \mathcal{M}$ . The representation of  $G$  as outer automorphism must change step by step in the inclusion sequence  $\dots \subset \mathcal{N} \subset \mathcal{M} \subset \dots$  since otherwise  $G$  would act trivially as one proceeds in the inclusion sequence. This is true since each step brings in additional finite-dimensional tensor factor in which  $G$  acts as automorphisms so that although  $\mathcal{M}$  can be invariant under  $G_{\mathcal{M}}$  it is not invariant under  $G_{\mathcal{N}}$ .

These two inclusions might accompany each other in TGD based physics. One could consider  $r < 4$  inclusion  $\mathcal{N} = \mathcal{M}^G \subset \mathcal{M}$  with  $G$  acting non-trivially in  $\mathcal{M}/\mathcal{N}$  quantum Clifford algebra.  $\mathcal{N}$  would decompose by  $r = 4$  inclusion to  $\mathcal{N}_1 \subset \mathcal{N}$  with  $SU(2)$  taking the role of  $G$ .  $\mathcal{N}/\mathcal{N}_1$  quantum Clifford algebra would transform non-trivially under  $SU(2)$  but would be  $G$  singlet.

In TGD framework the  $G$ -invariance for  $SU(2)$  representations means a reduction of  $S^2$  to the orbifold  $S^2/G$ . The coverings  $H_\pm \rightarrow H_\pm/G_a \times G_b$  should relate to these double inclusions and  $SU(2)$  inclusion could mean Kac-Moody type gauge symmetry for  $\mathcal{N}$ . Note that the presence of the factor containing only unit matrix should relate directly to the generator  $d$  in the generator set of affine algebra in the McKay construction. The physical interpretation of the fact that almost all ADE type

extended diagrams ( $D_n^{(1)}$  must have  $n \geq 4$ ) are allowed for  $r = 4$  inclusions whereas  $D_{2n+1}$  and  $E_6$  are not allowed for  $r < 4$ , remains open.

### 12.8.2 Generalization from $SU(2)$ to arbitrary compact group

The inclusions with index  $\mathcal{M} : \mathcal{N} < 4$  have one-dimensional relative commutant  $\mathcal{N}' \cup \mathcal{M}$ . The most obvious conjecture that  $\mathcal{M} : \mathcal{N} \geq 4$  corresponds to a non-trivial relative commutant is wrong. The index for Jones inclusion is identifiable as the square of quantum dimension of the fundamental representation of  $SU(2)$ . This identification generalizes to an arbitrary representation of arbitrary compact Lie group.

In his thesis Wenzl [127] studied the representations of Hecke algebras  $H_n(q)$  of type  $A_n$  obtained from the defining relations of symmetric group by the replacement  $e_i^2 = (q-1)e_i + q$ .  $H_n$  is isomorphic to complex group algebra of  $S_n$  if  $q$  is not a root of unity and for  $q = 1$  the irreducible representations of  $H_n(q)$  reduce trivially to Young's representations of symmetric groups. For primitive roots of unity  $q = \exp(i2\pi/l)$ ,  $l = 4, 5, \dots$ , the representations of  $H_n(\infty)$  give rise to inclusions for which index corresponds to a quantum dimension of any irreducible representation of  $SU(k)$ ,  $k \geq 2$ . For  $SU(2)$  also the value  $l = 3$  is allowed for spin  $1/2$  representation.

The inclusions are obtained by dropping the first  $m$  generators  $e_k$  from  $H_\infty(q)$  and taking double commutant of both  $H_\infty$  and the resulting algebra. The relative commutant corresponds to  $H_m(q)$ . By reducing by the minimal projection to relative commutant one obtains an inclusion with a trivial relative commutant. These inclusions are analogous to a discrete states superposed in continuum. Thus the results of Jones generalize from the fundamental representation of  $SU(2)$  to all representations of all groups  $SU(k)$ , and in fact to those of general compact groups as it turns out.

The generalization of the formula for index to square of quantum dimension of an irreducible representation of  $SU(k)$  reads as

$$\mathcal{M} : \mathcal{N} = \prod_{1 \leq r < s \leq k} \frac{\sin^2((\lambda_r - \lambda_s + s - r)\pi/l)}{\sin^2((s - r)n/l)}. \quad (12.8.1)$$

Here  $\lambda_r$  is the number of boxes in the  $r^{\text{th}}$  row of the Yang diagram with  $n$  boxes characterizing the representations and the condition  $1 \leq k \leq l - 1$  holds true. Only Young diagrams satisfying the condition  $l - k = \lambda_1 - \lambda_{r_{\text{max}}}$  are allowed.

The result would allow to restrict the generalization of the imbedding space in such a manner that only cyclic group  $Z_n$  appears in the covering of  $M^4 \rightarrow M^4/G_a$  or  $CP_2 \rightarrow CP_2/G_b$  factor. Be as it may, it seems that quantum representations of any compact Lie group can be realized using the generalization of the imbedding space. In the case of  $SU(2)$  the interpretation of higher-dimensional quantum representations in terms of Connes tensor products of 2-dimensional fundamental representations is highly suggestive.

The groups  $SO(3, 1) \times SU(3)$  and  $SL(2, C) \times U(2)_{ew}$  have a distinguished position both in physics and quantum TGD and the vision about physics as a generalized number theory implies them. Also the general pattern for inclusions selects these groups, and one can say that the condition that all possible statistics are realized is guaranteed by the choice  $M^4 \times CP_2$ .

1.  $n > 2$  for the quantum counterparts of the fundamental representation of  $SU(2)$  means that braid statistics for Jones inclusions cannot give the usual fermionic statistics. That Fermi statistics cannot "emerge" conforms with the role of infinite- $D$  Clifford algebra as a canonical representation of HFF of type  $II_1$ .  $SO(3, 1)$  as isometries of  $H$  gives  $Z_2$  statistics via the action on spinors of  $M^4$  and  $U(2)$  holonomies for  $CP_2$  realize  $Z_2$  statistics in  $CP_2$  degrees of freedom.
2.  $n > 3$  for more general inclusions in turn excludes  $Z_3$  statistics as braid statistics in the general case.  $SU(3)$  as isometries induces a non-trivial  $Z_3$  action on quark spinors but trivial action at the imbedding space level so that  $Z_3$  statistics would be in question.

## Chapter 13

# Quantum Hall effect and Hierarchy of Planck Constants

### 13.1 Introduction

Quantum Hall effect [15, 13, 16] occurs in 2-dimensional systems, typically a slab carrying a longitudinal voltage  $V$  causing longitudinal current  $j$ . A magnetic field orthogonal to the slab generates a transversal current component  $j_T$  by Lorentz force.  $j_T$  is proportional to the voltage  $V$  along the slab and the dimensionless coefficient is known as transversal conductivity. Classically the coefficient is proportional  $ne/B$ , where  $n$  is 2-dimensional electron density and should have a continuous spectrum. The finding that came as surprise was that the change of the coefficient as a function of parameters like magnetic field strength and temperature occurred as discrete steps of same size. In integer quantum Hall effect the coefficient is quantized to  $2\nu\alpha$ ,  $\alpha = e^2/4\pi$ , such that  $\nu$  is integer.

Later came the finding that also smaller steps corresponding to the filling fraction  $\nu = 1/3$  of the basic step were present and could be understood if the charge of electron would have been replaced with  $\nu = 1/3$  of its ordinary value. Later also QH effect with wide large range of filling fractions of form  $\nu = k/m$  was observed.

The model explaining the QH effect is based on pseudo particles known as anyons [69] , [15] . According to the general argument of [9] anyons have fractional charge  $\nu e$ . Also the TGD based model for fractionization to be discussed later suggests that the anyon charge should be  $\nu e$  quite generally. The braid statistics of anyon is believed to be fractional so that anyons are neither bosons nor fermions. Non-fractional statistics is absolutely essential for the vacuum degeneracy used to represent logical qubits.

In the case of Abelian anyons the gauge potential corresponds to the vector potential of the divergence free velocity field or equivalently of incompressible anyon current. For non-Abelian anyons the field theory defined by Chern-Simons action is free field theory and in well-defined sense trivial although it defines knot invariants. For non-Abelian anyons situation would be different. They would carry non-Abelian gauge charges possibly related to a symmetry breaking to a discrete subgroup  $H$  of gauge group [69] each of them defining an incompressible hydrodynamical flow. According to [52] the anyons associated with the filling fraction  $\nu = 5/2$  are a good candidate for non-Abelian anyons and in this case the charge of electron is reduced to  $Q = e/4$  rather than being  $Q = \nu e$  [14] . This finding favors non-Abelian models [16] .

Non-Abelian anyons [15, 17] are always created in pairs since they carry a conserved topological charge. In the model of [52] this charge should have values in 4-element group  $Z_4$  so that it is conserved only modulo 4 so that charges +2 and -2 are equivalent as are also charges 3 and -1. The state of  $n$  anyon pairs created from vacuum can be show to possess  $2^{n-1}$ -dimensional vacuum degeneracy [18] . When two anyons fuse the  $2^{n-1}$ -dimensional state space decomposes to  $2^{n-2}$ -dimensional tensor factors corresponding to anyon Cooper pairs with topological charges 2 and 0. The topological "spin" is ideal for representing logical qubits. Since free topological charges are not possible the notion of physical qubit does not make sense (note the analogy with quarks). The measurement of topological qubit reduces to a measurement of whether anyon Cooper pair has vanishing topological charge or not.

Topological quantum computation is perhaps the most promising application of anyons [52, 51, 37, 36, 43, 44], [17]. I have already earlier proposed the explanation of FQHE, anyons, and fractionization of quantum numbers in terms of hierarchy of Planck constants realized as a generalization of the imbedding space  $H = M^4 \times CP_2$  to a book like structure [27]. The book like structure applies separately to  $CP_2$  and to causal diamonds ( $CD \subset M^4$ ) defined as intersections of future and past directed light-cones. The pages of the Big Book correspond to singular coverings and factor spaces of  $CD$  ( $CP_2$ ) glued along 2-D subspace of  $CD$  ( $CP_2$ ) and are labeled by the values of Planck constants assignable to  $CD$  and  $CP_2$  and appearing in Lie algebra commutation relations. The observed Planck constant  $\hbar$ , whose square defines the scale of  $M^4$  metric corresponds to the ratio of these Planck constants. The key observation is that fractional filling factor results for ordinary integer QHE if  $\hbar$  is scaled up by a rational number.

In this chapter I try to formulate more precisely this idea. The outcome is a rather detailed view about anyons on one hand, and about the Kähler structure of the generalized imbedding space on the other hand.

1. Fundamental role is played by the assumption that the Kähler gauge potential of  $CP_2$  contains a gauge part with no physical implications in the context of gauge theories but contributing to physics in TGD framework since  $U(1)$  gauge transformations are representations of symplectic transformations of  $CP_2$ . Also in the case of  $CD$  it makes also sense to speak about Kähler gauge potential. The gauge part codes for Planck constants of  $CD$  and  $CP_2$  and leads to the identification of anyons as states associated with partonic 2-surfaces surrounding the tip of  $CD$  and fractionization of quantum numbers. Explicit formulas relating fractionized charges to the coefficients characterizing the gauge parts of Kähler gauge potentials of  $CD$  and  $CP_2$  are proposed based on some empirical input.
2. One important implication is that Poincare and Lorentz invariance are broken inside given  $CD$  although they remain exact symmetries at the level of the geometry of world of classical worlds (WCW). The interpretation is as a breaking of symmetries forced by the selection of quantization axis.
3. Anyons would basically correspond to matter at 2-dimensional "partonic" surfaces of macroscopic size surrounding the tip of the light-cone boundary of  $CD$  and could be regarded as gigantic elementary particle states with very large quantum numbers and by charge fractionization confined around the tip of  $CD$ . Charge fractionization and anyons would be basic characteristic of dark matter (dark only in relative sense). Hence it is not surprising that anyons would have applications going far beyond condensed matter physics. Anyonic dark matter concentrated at 2-dimensional surfaces would play key key role in the the physics of stars and black holes, and also in the formation of planetary system via the condensation of the ordinary matter around dark matter. This assumption was the basic starting point leading to the discovery of the hierarchy of Planck constants [27]. In living matter membrane like structures would represent a key example of anyonic systems as the model of DNA as topological quantum computer indeed assumes [26].
4. One of the basic questions has been whether TGD forces the hierarchy of Planck constants realized in terms of generalized imbedding space or not. The condition that the choice of quantization axes has a geometric correlate at the imbedding space level motivated by quantum classical correspondence of course forces the hierarchy: this has been clear from the beginning. It is now clear that also the first principle description of anyons requires the hierarchy in TGD Universe. The hierarchy reveals also new light to the huge vacuum degeneracy of TGD and reduces it dramatically at pages for which  $CD$  corresponds to a non-trivial covering or factor space, which suggests that mathematical existence of the theory necessitates the hierarchy of Planck constants. Also the proposed manifestation of Equivalence Principle at the level of symplectic fusion algebras as a duality between descriptions relying on the symplectic structures of  $CD$  and  $CP_2$  [13] forces the hierarchy of Planck constants.

The first sections of the chapter contain summary about theories of quantum Hall effect appearing already in [81]. Second section is a slightly modified version of the description of the generalized imbedding space, which has appeared already in [27, 81, 26] and containing brief description of how

to understand QHE in this framework. The third section represents the basic new results about the Kähler structure of generalized imbedding space and represents the resulting model of QHE.

## 13.2 About theories of quantum Hall effect

The most elegant models of quantum Hall effect are in terms of anyons regarded as singularities due to the symmetry breaking of gauge group  $G$  down to a finite sub-group  $H$ , which can be also non-Abelian. Concerning the description of the dynamics of topological degrees of freedom topological quantum field theories based on Chern-Simons action are the most promising approach.

### 13.2.1 Quantum Hall effect as a spontaneous symmetry breaking down to a discrete subgroup of the gauge group

The system exhibiting quantum Hall effect is effectively 2-dimensional. Fractional statistics suggests that topological defects, anyons, allowing a description in terms of the representations of the homotopy group of  $((\mathbb{R}^2)^n - D)/S_n$ . The gauge theory description would be in terms of spontaneous symmetry breaking of the gauge group  $G$  to a finite subgroup  $H$  by a Higgs mechanism [69], [15]. This would make all gauge degrees of freedom massive and leave only topological degrees of freedom. What is unexpected that also non-Abelian topological degrees of freedom are in principle possible. Quantum Hall effect is Abelian or non-Abelian depending on whether the group  $H$  has this property.

In the symmetry breaking  $G \rightarrow H$  the non-Abelian gauge fluxes defined as non-integrable phase factors  $P \exp(i \oint A_\mu dx^\mu)$  around large circles (surrounding singularities (so that field approaches a pure gauge configuration) are elements of the first homotopy group of  $G/H$ , which is  $H$  in the case that  $H$  is discrete group and  $G$  is simple. An idealized manner to model the situation [15] is to assume that the connection is pure gauge and defined by an  $H$ -valued function which is many-valued such that the values for different branches are related by a gauge transformation in  $H$ . In the general case a gauge transformation of a non-trivial gauge field by a multi-valued element of the gauge group would give rise to a similar situation.

One can characterize a given topological singularity magnetically by an element in conjugacy class  $C$  of  $H$  representing the transformation of  $H$  induced by a  $2\pi$  rotation around singularity. The elements of  $C$  define states in given magnetic representation. Electrically the particles are characterized by an irreducible representations of the subgroup of  $H_C \subset H$  which commutes with an arbitrarily chosen element of the conjugacy class  $C$ .

The action of  $h(B)$  resulting on particle A when it makes a closed turn around B reduces in magnetic degrees of freedom to translation in conjugacy class combined with the action of element of  $H_C$  in electric degrees of freedom. Closed paths correspond to elements of the braid group  $B_n(X^2)$  identifiable as the mapping class group of the punctured 2-surface  $X^2$  and this means that symmetry breaking  $G \rightarrow H$  defines a representation of the braid group. The construction of these representations is discussed in [15] and leads naturally via the group algebra of  $H$  to the so called quantum double  $D(H)$  of  $H$ , which is a quasi-triangular Hopf algebra allowing non-trivial representations of braid group.

Anyons could be singularities of gauge fields, perhaps even non-Abelian gauge fields, and the latter ones could be modelled by these representations. In particular, braid operations could be represented using anyons.

### 13.2.2 Witten-Chern-Simons action and topological quantum field theories

The Wess-Zumino-Witten action used to model 2-dimensional critical systems consists of a 2-dimensional conformally invariant term for the chiral field having values in group  $G$  combined with 2+1-dimensional term defined as the integral of Chern-Simons 3-form over a 3-space containing 2-D space as its boundary. This term is purely topological and identifiable as winding number for the map from 3-dimensional space to  $G$ . The coefficient of this term is integer  $k$  in suitable normalization.  $k$  gives the value of central extension of the Kac-Moody algebra defined by the theory.

One can couple the chiral field  $g(x)$  to gauge potential defined for some subgroup of  $G_1$  of  $G$ . If the  $G_1$  coincides with  $G$ , the chiral field can be gauged away by a suitable gauge transformation and the theory becomes purely topological Witten-Chern-Simons theory. Pure gauge field configuration

represented either as flat gauge fields with non-trivial holonomy over homotopically non-trivial paths or as multi-valued gauge group elements however remain and the remaining degrees of freedom correspond to the topological degrees of freedom.

Witten-Chern-Simons theories are labelled by a positive integer  $k$  giving the value of central extension of the Kac-Moody algebra defined by the theory. The connection with Wess-Zumino-Witten theory come from the fact that the highest weight states associated with the representations of the Kac-Moody algebra of WZW theory are in one-one correspondence with the representations  $R_i$  possible for Wilson loops in the topological quantum field theory.

In the Abelian case case 2+1-dimensional Chern-Simons action density is essentially the inner product  $A \wedge dA$  of the vector potential and magnetic field known as helicity density and the theory in question is a free field theory. In the non-Abelian case the action is defined by the 3-form

$$\frac{k}{4\pi} \text{Tr} \left( A \wedge (dA + \frac{2}{3} A \wedge A) \right)$$

and contains also interaction term so that the field theory defined by the exponential of the interaction term is non-trivial.

In topological quantum field theory the usual  $n$ -point correlation functions defined by the functional integral are replaced by the functional averages for  $\text{Diff}^3$  invariant quantities defined in terms of non-integrable phase factors defined by ordered exponentials over closed loops. One can consider arbitrary number of loops which can be knotted, linked, and braided. These quantities define both knot and 3-manifold invariants (the functional integral for zero link in particular). The perturbative calculation of the quantum averages leads directly to the Gaussian linking numbers and infinite number of perturbative link and not invariants.

The experience gained from topological quantum field theories defined by Chern-Simons action has led to a very elegant and surprisingly simple category theoretical approach to the topological quantum field theory [94, 112] allowing to assign invariants to knots, links, braids, and tangles and also to 3-manifolds for which braids as morphisms are replaced with cobordisms. The so called modular Hopf algebras, in particular quantum groups  $Sl(2)_q$  with  $q$  a root of unity, are in key role in this approach. Also the connection between links and 3-manifolds can be understood since closed, oriented, 3-manifolds can be constructed from each other by surgery based on links [7].

Witten's article [128] "Quantum Field Theory and the Jones Polynomial" is full of ingenious constructions, and for a physicist it is the easiest and certainly highly enjoyable manner to learn about knots and 3-manifolds. For these reasons a little bit more detailed sum up is perhaps in order.

1. Witten discusses first the quantization of Chern-Simons action at the weak coupling limit  $k \rightarrow \infty$ . First it is shown how the functional integration around flat connections defines a topological invariant for 3-manifolds in the case of a trivial Wilson loop. Next a canonical quantization is performed in the case  $X^3 = \Sigma^2 \times R^1$ : in the Coulomb gauge  $A_3 = 0$  the action reduces to a sum of  $n = \dim(G)$  Abelian Chern-Simons actions with a non-linear constraint expressing the vanishing of the gauge field. The configuration space consists thus of flat non-Abelian connections, which are characterized by their holonomy groups and allows Kähler manifold structure.
2. Perhaps the most elegant quantal element of the approach is the decomposition of the 3-manifold to two pieces glued together along 2-manifold implying the decomposition of the functional integral to a product of functional integrals over the pieces. This together with the basic properties of Hilbert of complex numbers (to which the partition functions defined by the functional integrals over the two pieces belong) allows almost a miracle like deduction of the basic results about the behavior of 3-manifold and link invariants under a connected sum, and leads to the crucial skein relations allowing to calculate the invariants by decomposing the link step by step to a union of unknotted, unlinked Wilson loops, which can be calculated exactly for  $SU(N)$ . The decomposition by skein relations gives rise to a partition function like representation of invariants and allows to understand the connection between knot theory and statistical physics [56]. A direct relationship with conformal field theories and Wess-Zumino-Witten model emerges via Wilson loops associated with the highest weight representations for Kac Moody algebras.
3. A similar decomposition procedure applies also to the calculation of 3-manifold invariants using link surgery to transform 3-manifolds to each other, with 3-manifold invariants being defined as

Wilson loops associated with the homology generators of these (solid) tori using representations  $R_i$  appearing as highest weight representations of the loop algebra of torus. Surgery operations are represented as mapping class group operations acting in the Hilbert space defined by the invariants for representations  $R_i$  for the original 3-manifold. The outcome is explicit formulas for the invariants of trivial knots and 3-manifold invariant of  $S^3$  for  $G = SU(N)$ , in terms of which more complex invariants are expressible.

4. For  $SU(N)$  the invariants are expressible as functions of the phase  $q = \exp(i2\pi/(k + N))$  associated with quantum groups [7]. Note that for  $SU(2)$  and  $k = 3$ , the invariants are expressible in terms of Golden Ratio. The central charge  $k = 3$  is in a special position since it gives rise to  $k + 1 = 4$ -vertex representing naturally 2-gate physically. Witten-Chern-Simons theories define universal unitary modular functors characterizing quantum computations [51].

### 13.2.3 Chern-Simons action for anyons

In the case of quantum Hall effect the Chern-Simons action has been deduced from a model of electrons as a 2-dimensional incompressible fluid [13]. Incompressibility requires that the electron current has a vanishing divergence, which makes it analogous to a magnetic field. The expressibility of the current as a curl of a vector potential  $b$ , and a detailed study of the interaction Lagrangian leads to the identification of an Abelian Chern-Simons for  $b$  as a low energy effective action. This action is Abelian, whereas the anyonic realization of quantum computation would suggest a non-Abelian Chern-Simons action.

Non-Abelian Chern-Simons action could result in the symmetry breaking of a non-Abelian gauge group  $G$ , most naturally electro-weak gauge group, to a non-Abelian discrete subgroup  $H$  [69] so that states would be labelled by representations of  $H$  and anyons would be characterized magnetically  $H$ -valued non-Abelian magnetic fluxes each of them defining its own incompressible hydro-dynamical flow. As will be found, TGD predicts a non-Abelian Chern-Simons term associated with electroweak long range classical fields.

### 13.2.4 Topological quantum computation using braids and anyons

By the general mathematical results braids are able to code all quantum logic operations [44]. In particular, braids allow to realize any quantum circuit consisting of single particle gates acting on qubits and two particle gates acting on pairs of qubits. The coding of braid requires a classical computation which can be done in polynomial time. The coding requires that each dancer is able to remember its dancing history by coding it into its own state.

The general ideas are following.

1. The ground states of anyonic system characterize the logical qubits, One assumes non-Abelian anyons with  $Z_4$ -valued topological charge so that a system of  $n$  anyon pairs created from vacuum allows  $2^{n-1}$ -fold anyon degeneracy [18]. The system is decomposed into blocks containing one anyonic Cooper pair with  $Q_T \in \{2, 0\}$  and two anyons with such topological charges that the net topological charge vanishes. One can say that the states  $(0, 1 - 1)$  and  $(0, -1, +1)$  represent logical qubit 0 whereas the states  $(2, -1, -1)$  and  $(2, +1, +1)$  represent logical qubit 1. This would suggest  $2^2$ -fold degeneracy but actually the degeneracy is 2-fold.

Free physical qubits are not possible and at least four particles are indeed necessarily in order to represent logical qubit. The reason is that the conservation of  $Z^4$  charge would not allow mixing of qubits 1 and 0, in particular the Hadamard 1-gate generating square root of qubit would break the conservation of topological charge. The square root of qubit can be generated only if 2 units of topological charge is transferred between anyon and anyon Cooper pair. Thus qubits can be represented as entangled states of anyon Cooper pair and anyon and the fourth anyon is needed to achieve vanishing total topological charge in the batch.

2. In the initial state of the system the anyonic Cooper pairs have  $Q_T = 0$  and the two anyons have opposite topological charges inside each block. The initial state codes no information unlike in ordinary computation but the information is represented by the braid. Of course, also more general configurations are possible. Anyons are assumed to evolve like free particles except during swap operations and their time evolution is described by single particle Hamiltonians.

Free particle approximation fails when the anyons are too near to each other as during braid operations. The space of logical qubits is realized as  $k$ -code defined by the  $2^{n-1}$  ground states, which are stable against local single particle perturbations for  $k = 3$  Witten-Chern-Simons action. In the more general case the stability against  $n$ -particle perturbations with  $n < [k/2]$  is achieved but the gates would become  $[k/2]$ -particle gates (for  $k = 5$  this would give 6-particle vertices).

3. Anyonic system provides a unitary modular functor as the S-matrix associated with the anyon system whose time evolution is fixed by the pre-existing braid structure. What this means that the S-matrices associated with the braids can be multiplied and thus a unitary representation for the group formed by braids results. The vacuum degeneracy of anyon system makes this representation non-trivial. By the NP complexity of braids it is possible to code any quantum logic operation by a particular braid [36]. There exists a powerful approximation theorem allowing to achieve this coding classically in polynomial time [44]. From the properties of the R-matrices inducing gate operations it is indeed clear that two gates can be realized. The Hadamard 1-gate could be realized as 2-gate in the system formed by anyon Cooper pair and anyon.
4. In [52] the time evolution is regarded as a discrete sequence of modifications of single anyon Hamiltonians induced by swaps [37]. If the modifications define a closed loop in the space of Hamiltonians the resulting unitary operators define a representation of braid group in a dense discrete sub-group of  $U(2^n)$ . The swap operation is 2-local operation acting like a 2-gate and induces quantum logical operation modifying also single particle Hamiltonians. What is important that this modification maps the space of the ground states to a new one and only if the modifications correspond to a closed loop the final state is in the same code space as the initial state. What time evolution does is to affect the topological charges of anyon Cooper pairs representing qubits inside the 4-anyon batches defined by the braids.

In quantum field theory the analog but not equivalent of this description would be following. Quite generally, a given particle in the final state has suffered a unitary transformation, which is an ordered product consisting of two kinds of unitary operators. Unitary single particle operators  $U_n = Pexp(i \int_{t_n}^{t_{n+1}} H_0 dt)$  are analogs of operators describing single qubit gate and play the role of anyon propagators during no-swap periods. Two-particle unitary operators  $U_{swap} = Pexp(i \int H_{swap} dt)$  are analogous to four-particle interactions and describe the effect of braid operations inducing entanglement of states having opposite values of topological charge but conserving the net topological charge of the anyon pair. This entanglement is completely analogous to spin entanglement. In particular, the braid operation mixes different states of the anyon. The unitary time development operator generating entangled state of anyons and defined by the braid structure represents the operation performed by the quantum circuit and the quantum measurement in the final state selects a particular final state.

5. Formally the computation halts with a measurement of the topological charge of the left-most anyon Cooper pair when the outcome is just single bit. If decay occurs with sufficiently high probability it is concluded that the value of the computed bit is 0, otherwise 1.

### 13.3 Hierarchy of Planck constants and the generalization of the notion of imbedding space

In the following the recent view about structure of imbedding space forced by the quantization of Planck constant is summarized. The question is whether it might be possible in some sense to replace  $H$  or its Cartesian factors by their necessarily singular multiple coverings and factor spaces. One can consider two options: either  $M^4$  or the causal diamond  $CD$ . The latter one is the more plausible option from the point of view of WCW geometry.

#### 13.3.1 The evolution of physical ideas about hierarchy of Planck constants

The evolution of the physical ideas related to the hierarchy of Planck constants and dark matter as a hierarchy of phases of matter with non-standard value of Planck constants was much faster than the

evolution of mathematical ideas and quite a number of applications have been developed during last five years.

1. The starting point was the proposal of Nottale [10] that the orbits of inner planets correspond to Bohr orbits with Planck constant  $\hbar_{gr} = GMm/v_0$  and outer planets with Planck constant  $\hbar_{gr} = 5GMm/v_0$ ,  $v_0/c \simeq 2^{-11}$ . The basic proposal [64, 55] was that ordinary matter condenses around dark matter which is a phase of matter characterized by a non-standard value of Planck constant whose value is gigantic for the space-time sheets mediating gravitational interaction. The interpretation of these space-time sheets could be as magnetic flux quanta or as massless extremals assignable to gravitons.
2. Ordinary particles possibly residing at these space-time sheet have enormous value of Compton length meaning that the density of matter at these space-time sheets must be very slowly varying. The string tension of string like objects implies effective negative pressure characterizing dark energy so that the interpretation in terms of dark energy might make sense [65]. TGD predicted a one-parameter family of Robertson-Walker cosmologies with critical or over-critical mass density and the "pressure" associated with these cosmologies is negative.
3. The quantization of Planck constant does not make sense unless one modifies the view about standard space-time is. Particles with different Planck constant must belong to different worlds in the sense local interactions of particles with different values of  $\hbar$  are not possible. This inspires the idea about the book like structure of the imbedding space obtained by gluing almost copies of  $H$  together along common "back" and partially labeled by different values of Planck constant.
4. Darkness is a relative notion in this framework and due to the fact that particles at different pages of the book like structure cannot appear in the same vertex of the generalized Feynman diagram. The phase transitions in which partonic 2-surface  $X^2$  during its travel along  $X_l^3$  leaks to another page of book are however possible and change Planck constant. Particle (say photon -) exchanges of this kind allow particles at different pages to interact. The interactions are strongly constrained by charge fractionization and are essentially phase transitions involving many particles. Classical interactions are also possible. It might be that we are actually observing dark matter via classical fields all the time and perhaps have even photographed it [75].
5. The realization that non-standard values of Planck constant give rise to charge and spin fractionization and anyonization led to the precise identification of the prerequisites of anyonic phase. If the partonic 2-surface, which can have even astrophysical size, surrounds the tip of  $CD$ , the matter at the surface is anyonic and particles are confined at this surface. Dark matter could be confined inside this kind of light-like 3-surfaces around which ordinary matter condenses. If the radii of the basic pieces of these nearly spherical anyonic surfaces - glued to a connected structure by flux tubes mediating gravitational interaction - are given by Bohr rules, the findings of Nottale [10] can be understood. Dark matter would resemble to a high degree matter in black holes replaced in TGD framework by light-like partonic 2-surfaces with a minimum size of order Schwarzschild radius  $r_S$  of order scaled up Planck length  $l_{Pl} = \sqrt{\hbar_{gr}G} = GM$ . Black hole entropy is inversely proportional to  $\hbar$  and predicted to be of order unity so that dramatic modification of the picture about black holes is implied.
6. Perhaps the most fascinating applications are in biology. The anomalous behavior ionic currents through cell membrane (low dissipation, quantal character, no change when the membrane is replaced with artificial one) has a natural explanation in terms of dark supra currents. This leads to a vision about how dark matter and phase transitions changing the value of Planck constant could relate to the basic functions of cell, functioning of DNA and aminoacids, and to the mysteries of bio-catalysis. This leads also a model for EEG interpreted as a communication and control tool of magnetic body containing dark matter and using biological body as motor instrument and sensory receptor. One especially amazing outcome is the emergence of genetic code of vertebrates from the model of dark nuclei as nuclear strings [47, 75], [47].

### 13.3.2 The most general option for the generalized imbedding space

Simple physical arguments pose constraints on the choice of the most general form of the imbedding space.

1. The fundamental group of the space for which one constructs a non-singular covering space or factor space should be non-trivial. This is certainly not possible for  $M^4$ ,  $CD$ ,  $CP_2$ , or  $H$ . One can however construct singular covering spaces. The fixing of the quantization axes implies a selection of the sub-space  $H_4 = M^2 \times S^2 \subset M^4 \times CP_2$ , where  $S^2$  is geodesic sphere of  $CP_2$ .  $\hat{M}^4 = M^4 \setminus M^2$  and  $\hat{CP}_2 = CP_2 \setminus S^2$  have fundamental group  $Z$  since the codimension of the excluded sub-manifold is equal to two and homotopically the situation is like that for a punctured plane. The exclusion of these sub-manifolds defined by the choice of quantization axes could naturally give rise to the desired situation.
2.  $CP_2$  allows two geodesic spheres which left invariant by  $U(2)$  resp.  $SO(3)$ . The first one is homologically non-trivial. For homologically non-trivial geodesic sphere  $H_4 = M^2 \times S^2$  represents a straight cosmic string which is non-vacuum extremal of Kähler action (not necessarily preferred extremal). One can argue that the many-valuedness of  $\hbar$  is un-acceptable for non-vacuum extremals so that only homologically trivial geodesic sphere  $S^2$  would be acceptable. One could go even further. If the extremals in  $M^2 \times CP_2$  can be preferred non-vacuum extremals, the singular coverings of  $M^4$  are not possible. Therefore only the singular coverings and factor spaces of  $CP_2$  over the homologically trivial geodesic sphere  $S^2$  would be possible. This however looks a non-physical outcome.
  - (a) The situation changes if the extremals of type  $M^2 \times Y^2$ ,  $Y^2$  a holomorphic surface of  $CP_3$ , fail to be hyperquaternionic. The tangent space  $M^2$  represents hypercomplex sub-space and the product of the modified gamma matrices associated with the tangent spaces of  $Y^2$  should belong to  $M^2$  algebra. This need not be the case in general.
  - (b) The situation changes also if one reinterprets the gluing procedure by introducing scaled up coordinates for  $M^4$  so that metric is continuous at  $M^2 \times CP_2$  but  $CD$ s with different size have different sizes differing by the ratio of Planck constants and would thus have only piece of lower or upper boundary in common.
3. For the more general option one would have four different options corresponding to the Cartesian products of singular coverings and factor spaces. These options can be denoted by  $C-C$ ,  $C-F$ ,  $F-C$ , and  $F-F$ , where  $C$  ( $F$ ) signifies for covering (factor space) and first (second) letter signifies for  $CD$  ( $CP_2$ ) and correspond to the spaces  $(\hat{CD} \hat{\times} G_a) \times (CP_2 \hat{\times} G_b)$ ,  $(\hat{CD} \hat{\times} G_a) \times CP_2/G_b$ ,  $\hat{CD}/G_a \times (CP_2 \hat{\times} G_b)$ , and  $\hat{CD}/G_a \times \hat{CP}_2/G_b$ .
4. The groups  $G_i$  could correspond to cyclic groups  $Z_n$ . One can also consider an extension by replacing  $M^2$  and  $S^2$  with its orbit under more general group  $G$  (say tetrahedral, octahedral, or icosahedral group). One expects that the discrete subgroups of  $SU(2)$  emerge naturally in this framework if one allows the action of these groups on the singular sub-manifolds  $M^2$  or  $S^2$ . This would replace the singular manifold with a set of its rotated copies in the case that the subgroups have genuinely 3-dimensional action (the subgroups which corresponds to exceptional groups in the ADE correspondence). For instance, in the case of  $M^2$  the quantization axes for angular momentum would be replaced by the set of quantization axes going through the vertices of tetrahedron, octahedron, or icosahedron. This would bring non-commutative homotopy groups into the picture in a natural manner.

### 13.3.3 About the phase transitions changing Planck constant

There are several non-trivial questions related to the details of the gluing procedure and phase transition as motion of partonic 2-surface from one sector of the imbedding space to another one.

1. How the gluing of copies of imbedding space at  $M^2 \times CP_2$  takes place? It would seem that the covariant metric of  $CD$  factor proportional to  $\hbar^2$  must be discontinuous at the singular manifold since only in this manner the idea about different scaling factor of  $CD$  metric can make sense. On the other hand, one can always scale the  $M^4$  coordinates so that the metric is continuous but the sizes of  $CD$ s with different Planck constants differ by the ratio of the Planck constants.

2. One might worry whether the phase transition changing Planck constant means an instantaneous change of the size of partonic 2-surface in  $M^4$  degrees of freedom. This is not the case. Light-likeness in  $M^2 \times S^2$  makes sense only for surfaces  $X^1 \times D^2 \subset M^2 \times S^2$ , where  $X^1$  is light-like geodesic. The requirement that the partonic 2-surface  $X^2$  moving from one sector of  $H$  to another one is light-like at  $M^2 \times S^2$  irrespective of the value of Planck constant requires that  $X^2$  has single point of  $M^2$  as  $M^2$  projection. Hence no sudden change of the size  $X^2$  occurs.
3. A natural question is whether the phase transition changing the value of Planck constant can occur purely classically or whether it is analogous to quantum tunneling. Classical non-vacuum extremals of Chern-Simons action have two-dimensional  $CP_2$  projection to homologically non-trivial geodesic sphere  $S^2_I$ . The deformation of the entire  $S^2_I$  to homologically trivial geodesic sphere  $S^2_{II}$  is not possible so that only combinations of partonic 2-surfaces with vanishing total homology charge (Kähler magnetic charge) can in principle move from sector to another one, and this process involves fusion of these 2-surfaces such that  $CP_2$  projection becomes single homologically trivial 2-surface. A piece of a non-trivial geodesic sphere  $S^2_I$  of  $CP_2$  can be deformed to that of  $S^2_{II}$  using 2-dimensional homotopy flattening the piece of  $S^2$  to curve. If this homotopy cannot be chosen to be light-like, the phase transitions changing Planck constant take place only via quantum tunnelling. Obviously the notions of light-like homotopies (cobordisms) are very relevant for the understanding of phase transitions changing Planck constant.

### 13.3.4 How one could fix the spectrum of Planck constants?

The question how the observed Planck constant relates to the integers  $n_a$  and  $n_b$  defining the covering and factors spaces, is far from trivial and I have considered several options. The basic physical inputs are the condition that scaling of Planck constant must correspond to the scaling of the metric of  $CD$  (that is Compton lengths) on one hand and the scaling of the gauge coupling strength  $g^2/4\pi\hbar$  on the other hand.

1. One can assign to Planck constant to both  $CD$  and  $CP_2$  by assuming that it appears in the commutation relations of corresponding symmetry algebras. Algebraist would argue that Planck constants  $\hbar(CD)$  and  $\hbar(CP_2)$  must define a homomorphism respecting multiplication and division (when possible) by  $G_i$ . This requires  $r(X) = \hbar(X)\hbar_0 = n$  for covering and  $r(X) = 1/n$  for factor space or vice versa.
2. If one assumes that  $\hbar^2(X)$ ,  $X = M^4$ ,  $CP_2$  corresponds to the scaling of the covariant metric tensor  $g_{ij}$  and performs an over-all scaling of  $H$ -metric allowed by the Weyl invariance of Kähler action by dividing metric with  $\hbar^2(CP_2)$ , one obtains the scaling of  $M^4$  covariant metric by  $r^2 \equiv \hbar^2/\hbar_0^2 = \hbar^2(M^4)/\hbar^2(CP_2)$  whereas  $CP_2$  metric is not scaled at all.
3. The condition that  $\hbar$  scales as  $n_a$  is guaranteed if one has  $\hbar(CD) = n_a\hbar_0$ . This does not fix the dependence of  $\hbar(CP_2)$  on  $n_b$  and one could have  $\hbar(CP_2) = n_b\hbar_0$  or  $\hbar(CP_2) = \hbar_0/n_b$ . The intuitive picture is that  $n_b$ - fold covering gives in good approximation rise to  $n_a n_b$  sheets and multiplies YM action action by  $n_a n_b$  which is equivalent with the  $\hbar = n_a n_b \hbar_0$  if one effectively compresses the covering to  $CD \times CP_2$ . One would have  $\hbar(CP_2) = \hbar_0/n_b$  and  $\hbar = n_a n_b \hbar_0$ . Note that the descriptions using ordinary Planck constant and coverings and scaled Planck constant but contracting the covering would be alternative descriptions.

This gives the following formulas  $r \equiv \hbar/\hbar_0 = r(M^4)/r(CP_2)$  in various cases.

$$\begin{array}{cccccc}
 & C - C & F - C & C - F & F - F & \\
 \hline
 r & n_a n_b & \frac{n_a}{n_b} & \frac{n_b}{n_a} & \frac{1}{n_a n_b} & 
 \end{array}$$

### 13.3.5 Preferred values of Planck constants

Number theoretic considerations favor the hypothesis that the integers corresponding to Fermat polygons constructible using only ruler and compass and given as products  $n_F = 2^k \prod_s F_s$ , where  $F_s = 2^{2^s} + 1$  are distinct Fermat primes, are favored. The reason would be that quantum phase  $q = \exp(i\pi/n)$  is in this case expressible using only iterated square root operation by starting from

rationals. The known Fermat primes correspond to  $s = 0, 1, 2, 3, 4$  so that the hypothesis is very strong and predicts that p-adic length scales have satellite length scales given as multiples of  $n_F$  of fundamental p-adic length scale.  $n_F = 2^{11}$  corresponds in TGD framework to a fundamental constant expressible as a combination of Kähler coupling strength,  $CP_2$  radius and Planck length appearing in the expression for the tension of cosmic strings, and the powers of  $2^{11}$  seem to be especially favored as values of  $n_a$  in living matter [24].

### 13.3.6 How Planck constants are visible in Kähler action?

$\hbar(M^4)$  and  $\hbar(CP_2)$  appear in the commutation and anticommutation relations of various superconformal algebras. Only the ratio of  $M^4$  and  $CP_2$  Planck constants appears in Kähler action and is due to the fact that the  $M^4$  and  $CP_2$  metrics of the imbedding space sector with given values of Planck constants are proportional to the corresponding Planck constants. This implies that Kähler function codes for radiative corrections to the classical action, which makes possible to consider the possibility that higher order radiative corrections to functional integral vanish as one might expect at quantum criticality. For a given p-adic length scale space-time sheets with all allowed values of Planck constants are possible. Hence the spectrum of quantum critical fluctuations could in the ideal case correspond to the spectrum of  $\hbar$  coding for the scaled up values of Compton lengths and other quantal lengths and times. If so, large  $\hbar$  phases could be crucial for understanding of quantum critical superconductors, in particular high  $T_c$  superconductors.

### 13.3.7 Could the dynamics of Kähler action predict the hierarchy of Planck constants?

The original justification for the hierarchy of Planck constants came from the indications that Planck constant could have large values in both astrophysical systems involving dark matter and also in biology. The realization of the hierarchy in terms of the singular coverings and possibly also factor spaces of  $CD$  and  $CP_2$  emerged from consistency conditions. The formula for the Planck constant involves heuristic guess work and physical plausibility arguments. There are good arguments in favor of the hypothesis that only coverings are possible. Only a finite number of pages of the Big Book correspond to a given value of Planck constant, biological evolution corresponds to a gradual dispersion to the pages of the Big Book with larger Planck constant, and a connection with the hierarchy of infinite primes and p-adicization program based on the mathematical realization of finite measurement resolution emerges.

One can however ask whether this hierarchy could emerge directly from the basic quantum TGD rather than as a separate hypothesis. The following arguments suggest that this might be possible. One finds also a precise geometric interpretation of preferred extremal property interpreted as criticality in zero energy ontology.

#### 1-1 correspondence between canonical momentum densities and time derivatives fails for Kähler action

The basic motivation for the geometrization program was the observation that canonical quantization for TGD fails. To see what is involved let us try to perform a canonical quantization in zero energy ontology at the 3-D surfaces located at the light-like boundaries of  $CD \times CP_2$ .

1. In canonical quantization canonical momentum densities  $\pi_k^0 \equiv \pi_k = \partial L_K / \partial(\partial_0 h^k)$ , where  $\partial_0 h^k$  denotes the time derivative of imbedding space coordinate, are the physically natural quantities in terms of which to fix the initial values: once their value distribution is fixed also conserved charges are fixed. Also the weak form of electric-magnetic duality given by  $J^{03} \sqrt{g_4} = 4\pi\alpha_K J_{12}$  and a mild generalization of this condition to be discussed below can be interpreted as a manner to fix the values of conserved gauge charges (not Noether charges) to their quantized values since Kähler magnetic flux equals to the integer giving the homology class of the (wormhole) throat. This condition alone need not characterize criticality, which requires an infinite number of deformations of  $X^4$  for which the second variation of the Kähler action vanishes and implies infinite number conserved charges. This in fact gives hopes of replacing  $\pi_k$  with these conserved Noether charges.

2. Canonical quantization requires that  $\partial_0 h^k$  in the energy is expressed in terms of  $\pi_k$ . The equation defining  $\pi_k$  in terms of  $\partial_0 h^k$  is however highly non-linear although algebraic. By taking squares the equations reduces to equations for rational functions of  $\partial_0 h^k$ .  $\partial_0 h^k$  appears in contravariant and covariant metric at most quadratically and in the induced Kähler electric field linearly and by multiplying the equations by  $\det(g_4)^3$  one can transform the equations to a polynomial form so that in principle  $\partial_0 h^k$  can be obtained as a solution of polynomial equations.
3. One can always eliminate one half of the coordinates by choosing 4 imbedding space coordinates as the coordinates of the spacetime surface so that the initial value conditions reduce to those for the canonical momentum densities associated with the remaining four coordinates. For instance, for space-time surfaces representable as map  $M^4 \rightarrow CP_2$   $M^4$  coordinates are natural and the time derivatives  $\partial_0 s^k$  of  $CP_2$  coordinates are multivalued. One would obtain four polynomial equations with  $\partial_0 s^k$  as unknowns. In regions where  $CP_2$  projection is 4-dimensional -in particular for the deformations of  $CP_2$  vacuum extremals the natural coordinates are  $CP_2$  coordinates and one can regard  $\partial_0 m^k$  as unknowns. For the deformations of cosmic strings, which are of form  $X^4 = X^2 \times Y^2 \subset M^4 \times CP_2$ , one can use coordinates of  $M^2 \times S^2$ , where  $S^2$  is geodesic sphere as natural coordinates and regard as unknowns  $E^2$  coordinates and remaining  $CP_2$  coordinates.
4. One can imagine solving one of the four polynomial equations for time derivatives in terms of other obtaining  $N$  roots. Then one would substitute these roots to the remaining 3 conditions to obtain algebraic equations from which one solves then second variable. Obviously situation is very complex without additional symmetries. The criticality of the preferred extremals might however give additional conditions allowing simplifications. The reasons for giving up the canonical quantization program was following. For the vacuum extremals of Kähler action  $\pi_k$  are however identically vanishing and this means that there is an infinite number of value distributions for  $\partial_0 h^k$ . For small deformations of vacuum extremals one might however hope a finite number of solutions to the conditions and thus finite number of space-time surfaces carrying same conserved charges.

If one assumes that physics is characterized by the values of the conserved charges one must treat the many-valuedness of  $\partial_0 h^k$ . The most obvious guess is that one should replace the space of space-like 4-surfaces corresponding to different roots  $\partial_0 h^k = F^k(\pi_l)$  with four-surfaces in the covering space of  $CD \times CP_2$  corresponding to different branches of the many-valued function  $\partial_0 h^k = F(\pi_l)$  co-inciding at the ends of  $CD$ .

**Do the coverings forced by the many-valuedness of  $\partial_0 h^k$  correspond to the coverings associated with the hierarchy of Planck constants?**

The obvious question is whether this covering space actually corresponds to the covering spaces associated with the hierarchy of Planck constants. This would conform with quantum classical correspondence. The hierarchy of Planck constants and hierarchy of covering spaces was introduced to cure the failure of the perturbation theory at quantum level. At classical level the multivaluedness of  $\partial_0 h^k$  means a failure of perturbative canonical quantization and forces the introduction of the covering spaces. The interpretation would be that when the density of matter becomes critical the space-time surface splits to several branches so that the density at each branches is sub-critical. It is of course not at all obvious whether the proposed structure of the Big Book is really consistent with this hypothesis and one also consider modifications of this structure if necessary. The manner to proceed is by making questions.

1. The proposed picture would give only single integer characterizing the covering. Two integers assignable to  $CD$  and  $CP_2$  degrees of freedom are however needed. How these two coverings could emerge?
  - (a) One should fix also the values of  $\pi_k^n = \partial L_K / \partial h_n^k$ , where  $n$  refers to space-like normal coordinate at the wormhole throats. If one requires that charges do not flow between regions with different signatures of the metric the natural condition is  $\pi_k^n = 0$  and allows also multi-valued solution. Since wormhole throats carry magnetic charge and since weak form of electric-magnetic duality is assumed, one can assume that  $CP_2$  projection is four-dimensional so that one can use  $CP_2$  coordinates and regard  $\partial_0 m^k$  as unknowns. The basic

idea about topological condensation in turn suggests that  $M^4$  projection can be assumed to be 4-D inside space-like 3-surfaces so that here  $\partial_0 s^k$  are the unknowns. At partonic 2-surfaces one would have conditions for both  $\pi_k^0$  and  $\pi_k^n$ . One might hope that the numbers of solutions are finite for preferred extremals because of their symmetries and given by  $n_a$  for  $\partial_0 m^k$  and by  $n_b$  for  $\partial_0 s^k$ . The optimistic guess is that  $n_a$  and  $n_b$  corresponds to the numbers of sheets for singular coverings of  $CD$  and  $CP_2$ . The covering could be visualized as replacement of space-time surfaces with space-time surfaces which have  $n_a n_b$  branches.  $n_b$  branches would degenerate to single branch at the ends of diagrams of the generated Feynman graph and  $n_a$  branches would degenerate to single one at wormhole throats.

- (b) This picture is not quite correct yet. The fixing of  $\pi_k^0$  and  $\pi_k^n$  should relate closely to the effective 2-dimensionality as an additional condition perhaps crucial for criticality. One could argue that both  $\pi_k^0$  and  $\pi_k^n$  must be fixed at  $X^3$  and  $X_l^3$  in order to effectively bring in dynamics in two directions so that  $X^3$  could be interpreted as a an orbit of partonic 2-surface in space-like direction and  $X_l^3$  as its orbit in light-like direction. The additional conditions could be seen as gauge conditions made possible by symplectic and Kac-Moody type conformal symmetries. The conditions for  $\pi_0^k$  would give  $n_b$  branches in  $CP_2$  degrees of freedom and the conditions for  $\pi_k^n$  would split each of these branches to  $n_a$  branches.
- (c) The existence of these two kinds of conserved charges (possibly vanishing for  $\pi_k^n$ ) could relate also very closely to the slicing of the space-time sheets by string world sheets and partonic 2-surfaces.
2. Should one then treat these branches as separate space-time surfaces or as a single space-time surface? The treatment as a single surface seems to be the correct thing to do. Classically the conserved changes would be  $n_a n_b$  times larger than for single branch. Kähler action need not (but could!) be same for different branches but the total action is  $n_a n_b$  times the average action and this effectively corresponds to the replacement of the  $\hbar_0/g_K^2$  factor of the action with  $\hbar/g_K^2$ ,  $r \equiv \hbar/\hbar_0 = n_a n_b$ . Since the conserved quantum charges are proportional to  $\hbar$  one could argue that  $r = n_a n_b$  tells only that the charge conserved charge is  $n_a n_b$  times larger than without multi-valuedness.  $\hbar$  would be only effectively  $n_a n_b$  fold. This is of course poor man's argument but might catch something essential about the situation.
  3. How could one interpret the condition  $J^{03} \sqrt{g_4} = 4\pi \alpha_K J_{12}$  and its generalization to be discussed below in this framework? The first observation is that the total Kähler electric charge is by  $\alpha_K \propto 1/(n_a n_b)$  same always. The interpretation would be in terms of charge fractionization meaning that each branch would carry Kähler electric charge  $Q_K = n g_K / n_a n_b$ . I have indeed suggested explanation of charge fractionization and quantum Hall effect based on this picture.
  4. The vision about the hierarchy of Planck constants involves also assumptions about imbedding space metric. The assumption that the  $M^4$  covariant metric is proportional to  $\hbar^2$  follows from the physical idea about  $\hbar$  scaling of quantum lengths as what Compton length is. One can always introduce scaled  $M^4$  coordinates bringing  $M^4$  metric into the standard form by scaling up the  $M^4$  size of  $CD$ . It is not clear whether the scaling up of  $CD$  size follows automatically from the proposed scenario. The basic question is why the  $M^4$  size scale of the critical extremals must scale like  $n_a n_b$ ? This should somehow relate to the weak self-duality conditions implying that Kähler field at each branch is reduced by a factor  $1/r$  at each branch. Field equations should possess a dynamical symmetry involving the scaling of  $CD$  by integer  $k$  and  $J^{0\beta} \sqrt{g_4}$  and  $J^{n\beta} \sqrt{g_4}$  by  $1/k$ . The scaling of  $CD$  should be due to the scaling up of the  $M^4$  time interval during which the branched light-like 3-surface returns back to a non-branched one.
  5. The proposed view about hierarchy of Planck constants is that the singular coverings reduce to single-sheeted coverings at  $M^2 \subset M^4$  for  $CD$  and to  $S^2 \subset CP_2$  for  $CP_2$ . Here  $S^2$  is any homologically trivial geodesic sphere of  $CP_2$  and has vanishing Kähler form. Weak self-duality condition is indeed consistent with any value of  $\hbar$  and implies that the vacuum property for the partonic 2-surface implies vacuum property for the entire space-time sheet as holography indeed requires. This condition however generalizes. In weak self-duality conditions the value of  $\hbar$  is free for any 2-D Lagrangian sub-manifold of  $CP_2$ .

The branching along  $M^2$  would mean that the branches of preferred extremals always collapse to single branch when their  $M^4$  projection belongs to  $M^2$ . Magnetically charged light-light-like

throats cannot have  $M^4$  projection in  $M^2$  so that self-duality conditions for different values of  $\hbar$  do not lead to inconsistencies. For spacelike 3-surfaces at the boundaries of  $CD$  the condition would mean that the  $M^4$  projection becomes light-like geodesic. Straight cosmic strings would have  $M^2$  as  $M^4$  projection. Also  $CP_2$  type vacuum extremals for which the random light-like projection in  $M^4$  belongs to  $M^2$  would represent this of situation. One can ask whether the degeneration of branches actually takes place along any string like object  $X^2 \times Y^2$ , where  $X^2$  defines a minimal surface in  $M^4$ . For these the weak self-duality condition would imply  $\hbar = \infty$  at the ends of the string. It is very plausible that string like objects feed their magnetic fluxes to larger space-times sheets through wormhole contacts so that these conditions are not encountered.

### Connection with the criticality of preferred extremals

Also a connection with quantum criticality and the criticality of the preferred extremals suggests itself. Criticality for the preferred extremals must be a property of space-like 3-surfaces and light-like 3-surfaces with degenerate 4-metric and the degeneration of the  $n_a n_b$  branches of the space-time surface at the its ends and at wormhole throats is exactly what happens at criticality. For instance, in catastrophe theory roots of the polynomial equation giving extrema of a potential as function of control parameters co-incide at criticality. If this picture is correct the hierarchy of Planck constants would be an outcome of criticality and of preferred extremal property and preferred extremals would be just those multi-branched space-time surfaces for which branches co-incide at the the boundaries of  $CD \times CP_2$  and at the throats.

## 13.4 Weak form electric-magnetic duality and its implications

The notion of electric-magnetic duality [10] was proposed first by Olive and Montonen and is central in  $\mathcal{N} = 4$  supersymmetric gauge theories. It states that magnetic monopoles and ordinary particles are two different phases of theory and that the description in terms of monopoles can be applied at the limit when the running gauge coupling constant becomes very large and perturbation theory fails to converge. The notion of electric-magnetic self-duality is more natural since for  $CP_2$  geometry Kähler form is self-dual and Kähler magnetic monopoles are also Kähler electric monopoles and Kähler coupling strength is by quantum criticality renormalization group invariant rather than running coupling constant. The notion of electric-magnetic (self-)duality emerged already two decades ago in the attempts to formulate the Kähler geometric of world of classical worlds. Quite recently a considerable step of progress took place in the understanding of this notion [17]. What seems to be essential is that one adopts a weaker form of the self-duality applying at partonic 2-surfaces. What this means will be discussed in the sequel.

Every new idea must be of course taken with a grain of salt but the good sign is that this concept leads to precise predictions. The point is that elementary particles do not generate monopole fields in macroscopic length scales: at least when one considers visible matter. The first question is whether elementary particles could have vanishing magnetic charges: this turns out to be impossible. The next question is how the screening of the magnetic charges could take place and leads to an identification of the physical particles as string like objects identified as pairs magnetic charged wormhole throats connected by magnetic flux tubes.

1. The first implication is a new view about electro-weak massivation reducing it to weak confinement in TGD framework. The second end of the string contains particle having electroweak isospin neutralizing that of elementary fermion and the size scale of the string is electro-weak scale would be in question. Hence the screening of electro-weak force takes place via weak confinement realized in terms of magnetic confinement.
2. This picture generalizes to the case of color confinement. Also quarks correspond to pairs of magnetic monopoles but the charges need not vanish now. Rather, valence quarks would be connected by flux tubes of length of order hadron size such that magnetic charges sum up to zero. For instance, for baryonic valence quarks these charges could be  $(2, -1, -1)$  and could be proportional to color hyper charge.

3. The highly non-trivial prediction making more precise the earlier stringy vision is that elementary particles are string like objects in electro-weak scale: this should become manifest at LHC energies.
4. The weak form electric-magnetic duality together with Beltrami flow property of Kähler leads to the reduction of Kähler action to Chern-Simons action so that TGD reduces to almost topological QFT and that Kähler function is explicitly calculable. This has enormous impact concerning practical calculability of the theory.
5. One ends up also to a general solution ansatz for field equations from the condition that the theory reduces to almost topological QFT. The solution ansatz is inspired by the idea that all isometry currents are proportional to Kähler current which is integrable in the sense that the flow parameter associated with its flow lines defines a global coordinate. The proposed solution ansatz would describe a hydrodynamical flow with the property that isometry charges are conserved along the flow lines (Beltrami flow). A general ansatz satisfying the integrability conditions is found. The solution ansatz applies also to the extremals of Chern-Simons action and to the conserved currents associated with the modified Dirac equation defined as contractions of the modified gamma matrices between the solutions of the modified Dirac equation. The strongest form of the solution ansatz states that various classical and quantum currents flow along flow lines of the Beltrami flow defined by Kähler current (Kähler magnetic field associated with Chern-Simons action). Intuitively this picture is attractive. A more general ansatz would allow several Beltrami flows meaning multi-hydrodynamics. The integrability conditions boil down to two scalar functions: the first one satisfies massless d'Alembert equation in the induced metric and the the gradients of the scalar functions are orthogonal. The interpretation in terms of momentum and polarization directions is natural.
6. The general solution ansatz works for induced Kähler Dirac equation and Chern-Simons Dirac equation and reduces them to ordinary differential equations along flow lines. The induced spinor fields are simply constant along flow lines of induced spinor field for Dirac equation in suitable gauge. Also the generalized eigen modes of the modified Chern-Simons Dirac operator can be deduced explicitly if the throats and the ends of space-time surface at the boundaries of  $CD$  are extremals of Chern-Simons action. Chern-Simons Dirac equation reduces to ordinary differential equations along flow lines and one can deduce the general form of the spectrum and the explicit representation of the Dirac determinant in terms of geometric quantities characterizing the 3-surface (eigenvalues are inversely proportional to the lengths of strands of the flow lines in the effective metric defined by the modified gamma matrices).

### 13.4.1 Could a weak form of electric-magnetic duality hold true?

Holography means that the initial data at the partonic 2-surfaces should fix the configuration space metric. A weak form of this condition allows only the partonic 2-surfaces defined by the wormhole throats at which the signature of the induced metric changes. A stronger condition allows all partonic 2-surfaces in the slicing of space-time sheet to partonic 2-surfaces and string world sheets. Number theoretical vision suggests that hyper-quaternionicity *resp.* co-hyperquaternionicity constraint could be enough to fix the initial values of time derivatives of the imbedding space coordinates in the space-time regions with Minkowskian *resp.* Euclidian signature of the induced metric. This is a condition on modified gamma matrices and hyper-quaternionicity states that they span a hyper-quaternionic sub-space.

#### Definition of the weak form of electric-magnetic duality

One can also consider alternative conditions possibly equivalent with this condition. The argument goes as follows.

1. The expression of the matrix elements of the metric and Kähler form of  $WCW$  in terms of the Kähler fluxes weighted by Hamiltonians of  $\delta M_{\pm}^4$  at the partonic 2-surface  $X^2$  looks very attractive. These expressions however carry no information about the 4-D tangent space of the partonic 2-surfaces so that the theory would reduce to a genuinely 2-dimensional theory, which

cannot hold true. One would like to code to the WCW metric also information about the electric part of the induced Kähler form assignable to the complement of the tangent space of  $X^2 \subset X^4$ .

2. Electric-magnetic duality of the theory looks a highly attractive symmetry. The trivial manner to get electric magnetic duality at the level of the full theory would be via the identification of the flux Hamiltonians as sums of of the magnetic and electric fluxes. The presence of the induced metric is however troublesome since the presence of the induced metric means that the simple transformation properties of flux Hamiltonians under symplectic transformations -in particular color rotations- are lost.
3. A less trivial formulation of electric-magnetic duality would be as an initial condition which eliminates the induced metric from the electric flux. In the Euclidian version of 4-D YM theory this duality allows to solve field equations exactly in terms of instantons. This approach involves also quaternions. These arguments suggest that the duality in some form might work. The full electric magnetic duality is certainly too strong and implies that space-time surface at the partonic 2-surface corresponds to piece of  $CP_2$  type vacuum extremal and can hold only in the deep interior of the region with Euclidian signature. In the region surrounding wormhole throat at both sides the condition must be replaced with a weaker condition.
4. To formulate a weaker form of the condition let us introduce coordinates  $(x^0, x^3, x^1, x^2)$  such  $(x^1, x^2)$  define coordinates for the partonic 2-surface and  $(x^0, x^3)$  define coordinates labeling partonic 2-surfaces in the slicing of the space-time surface by partonic 2-surfaces and string world sheets making sense in the regions of space-time sheet with Minkowskian signature. The assumption about the slicing allows to preserve general coordinate invariance. The weakest condition is that the generalized Kähler electric fluxes are apart from constant proportional to Kähler magnetic fluxes. This requires the condition

$$J^{03}\sqrt{g_4} = K J_{12} . \quad (13.4.1)$$

A more general form of this duality is suggested by the considerations of [35] reducing the hierarchy of Planck constants to basic quantum TGD and also reducing Kähler function for preferred extremals to Chern-Simons terms [1] at the boundaries of  $CD$  and at light-like wormhole throats. This form is following

$$J^{n\beta}\sqrt{g_4} = K\epsilon \times \epsilon^{n\beta\gamma\delta} J_{\gamma\delta}\sqrt{g_4} . \quad (13.4.2)$$

Here the index  $n$  refers to a normal coordinate for the space-like 3-surface at either boundary of  $CD$  or for light-like wormhole throat.  $\epsilon$  is a sign factor which is opposite for the two ends of  $CD$ . It could be also opposite of opposite at the opposite sides of the wormhole throat. Note that the dependence on induced metric disappears at the right hand side and this condition eliminates the potentials singularity due to the reduction of the rank of the induced metric at wormhole throat.

5. Information about the tangent space of the space-time surface can be coded to the configuration space metric with loosing the nice transformation properties of the magnetic flux Hamiltonians if Kähler electric fluxes or sum of magnetic flux and electric flux satisfying this condition are used and  $K$  is symplectic invariant. Using the sum

$$J_e + J_m = (1 + K)J_{12} , \quad (13.4.3)$$

where  $J$  denotes the Kähler magnetic flux, , makes it possible to have a non-trivial configuration space metric even for  $K = 0$ , which could correspond to the ends of a cosmic string like solution carrying only Kähler magnetic fields. This condition suggests that it can depend only on Kähler

magnetic flux and other symplectic invariants. Whether local symplectic coordinate invariants are possible at all is far from obvious, If the slicing itself is symplectic invariant then  $K$  could be a non-constant function of  $X^2$  depending on string world sheet coordinates. The light-like radial coordinate of the light-cone boundary indeed defines a symplectically invariant slicing and this slicing could be shifted along the time axis defined by the tips of  $CD$ .

### Electric-magnetic duality physically

What could the weak duality condition mean physically? For instance, what constraints are obtained if one assumes that the quantization of electro-weak charges reduces to this condition at classical level?

1. The first thing to notice is that the flux of  $J$  over the partonic 2-surface is analogous to magnetic flux

$$Q_m = \frac{e}{\hbar} \oint B dS = n .$$

$n$  is non-vanishing only if the surface is homologically non-trivial and gives the homology charge of the partonic 2-surface.

2. The expressions of classical electromagnetic and  $Z^0$  fields in terms of Kähler form [2] , [2] read as

$$\begin{aligned} \gamma &= \frac{eF_{em}}{\hbar} = 3J - \sin^2(\theta_W)R_{03} , \\ Z^0 &= \frac{g_Z F_Z}{\hbar} = 2R_{03} . \end{aligned} \quad (13.4.4)$$

Here  $R_{03}$  is one of the components of the curvature tensor in vielbein representation and  $F_{em}$  and  $F_Z$  correspond to the standard field tensors. From this expression one can deduce

$$J = \frac{e}{3\hbar} F_{em} + \sin^2(\theta_W) \frac{g_Z}{6\hbar} F_Z . \quad (13.4.5)$$

3. The weak duality condition when integrated over  $X^2$  implies

$$\begin{aligned} \frac{e^2}{3\hbar} Q_{em} + \frac{g_Z^2 p}{6} Q_{Z,V} &= K \oint J = Kn , \\ Q_{Z,V} &= \frac{I_V^3}{2} - Q_{em} , \quad p = \sin^2(\theta_W) . \end{aligned} \quad (13.4.6)$$

Here the vectorial part of the  $Z^0$  charge rather than as full  $Z^0$  charge  $Q_Z = I_L^3 + \sin^2(\theta_W)Q_{em}$  appears. The reason is that only the vectorial isospin is same for left and right handed components of fermion which are in general mixed for the massive states.

The coefficients are dimensionless and expressible in terms of the gauge coupling strengths and using  $\hbar = r\hbar_0$  one can write

$$\begin{aligned} \alpha_{em} Q_{em} + p \frac{\alpha_Z}{2} Q_{Z,V} &= \frac{3}{4\pi} \times rnK , \\ \alpha_{em} &= \frac{e^2}{4\pi\hbar_0} , \quad \alpha_Z = \frac{g_Z^2}{4\pi\hbar_0} = \frac{\alpha_{em}}{p(1-p)} . \end{aligned} \quad (13.4.7)$$

4. There is a great temptation to assume that the values of  $Q_{em}$  and  $Q_Z$  correspond to their quantized values and therefore depend on the quantum state assigned to the partonic 2-surface. The linear coupling of the modified Dirac operator to conserved charges implies correlation between the geometry of space-time sheet and quantum numbers assigned to the partonic 2-surface. The assumption of standard quantized values for  $Q_{em}$  and  $Q_Z$  would be also seen as the identification of the fine structure constants  $\alpha_{em}$  and  $\alpha_Z$ . This however requires weak isospin invariance.

**The value of  $K$  from classical quantization of Kähler electric charge**

The value of  $K$  can be deduced by requiring classical quantization of Kähler electric charge.

1. The condition that the flux of  $F^{03} = (\hbar/g_K)J^{03}$  defining the counterpart of Kähler electric field equals to the Kähler charge  $g_K$  would give the condition  $K = g_K^2/\hbar$ , where  $g_K$  is Kähler coupling constant which should invariant under coupling constant evolution by quantum criticality. Within experimental uncertainties one has  $\alpha_K = g_K^2/4\pi\hbar_0 = \alpha_{em} \simeq 1/137$ , where  $\alpha_{em}$  is finite structure constant in electron length scale and  $\hbar_0$  is the standard value of Planck constant.
2. The quantization of Planck constants makes the condition highly non-trivial. The most general quantization of  $r$  is as rationals but there are good arguments favoring the quantization as integers corresponding to the allowance of only singular coverings of  $CD$  and  $CP_2$ . The point is that in this case a given value of Planck constant corresponds to a finite number pages of the "Big Book". The quantization of the Planck constant implies a further quantization of  $K$  and would suggest that  $K$  scales as  $1/r$  unless the spectrum of values of  $Q_{em}$  and  $Q_Z$  allowed by the quantization condition scales as  $r$ . This is quite possible and the interpretation would be that each of the  $r$  sheets of the covering carries (possibly same) elementary charge. Kind of discrete variant of a full Fermi sphere would be in question. The interpretation in terms of anyonic phases [57] supports this interpretation.
3. The identification of  $J$  as a counterpart of  $eB/\hbar$  means that Kähler action and thus also Kähler function is proportional to  $1/\alpha_K$  and therefore to  $\hbar$ . This implies that for large values of  $\hbar$  Kähler coupling strength  $g_K^2/4\pi$  becomes very small and large fluctuations are suppressed in the functional integral. The basic motivation for introducing the hierarchy of Planck constants was indeed that the scaling  $\alpha \rightarrow \alpha/r$  allows to achieve the convergence of perturbation theory: Nature itself would solve the problems of the theoretician. This of course does not mean that the physical states would remain as such and the replacement of single particles with anyonic states in order to satisfy the condition for  $K$  would realize this concretely.
4. The condition  $K = g_K^2/\hbar$  implies that the Kähler magnetic charge is always accompanied by Kähler electric charge. A more general condition would read as

$$K = n \times \frac{g_K^2}{\hbar}, n \in Z . \tag{13.4.8}$$

This would apply in the case of cosmic strings and would allow vanishing Kähler charge possible when the partonic 2-surface has opposite fermion and antifermion numbers (for both leptons and quarks) so that Kähler electric charge should vanish. For instance, for neutrinos the vanishing of electric charge strongly suggests  $n = 0$  besides the condition that abelian  $Z^0$  flux contributing to em charge vanishes.

It took a year to realize that this value of  $K$  is natural at the Minkowskian side of the wormhole throat. At the Euclidian side much more natural condition is

$$K = \frac{1}{\hbar} . \tag{13.4.9}$$

In fact, the self-duality of  $CP_2$  Kähler form favours this boundary condition at the Euclidian side of the wormhole throat. Also the fact that one cannot distinguish between electric and magnetic charges

in Euclidian region since all charges are magnetic can be used to argue in favor of this form. The same constraint arises from the condition that the action for  $CP_2$  type vacuum extremal has the value required by the argument leading to a prediction for gravitational constant in terms of the square of  $CP_2$  radius and  $\alpha_K$  the effective replacement  $g_K^2 \rightarrow 1$  would spoil the argument.

The boundary condition  $J_E = J_B$  for the electric and magnetic parts of Kähler form at the Euclidian side of the wormhole throat inspires the question whether all Euclidian regions could be self-dual so that the density of Kähler action would be just the instanton density. Self-duality follows if the deformation of the metric induced by the deformation of the canonically imbedded  $CP_2$  is such that in  $CP_2$  coordinates for the Euclidian region the tensor  $(g^{\alpha\beta}g^{\mu\nu} - g^{\alpha\nu}g^{\mu\beta})/\sqrt{g}$  remains invariant. This is certainly the case for  $CP_2$  type vacuum extremals since by the light-likeness of  $M^4$  projection the metric remains invariant. Also conformal scalings of the induced metric would satisfy this condition. Conformal scaling is not consistent with the degeneracy of the 4-metric at the wormhole

### Reduction of the quantization of Kähler electric charge to that of electromagnetic charge

The best manner to learn more is to challenge the form of the weak electric-magnetic duality based on the induced Kähler form.

1. Physically it would seem more sensible to pose the duality on electromagnetic charge rather than Kähler charge. This would replace induced Kähler form with electromagnetic field, which is a linear combination of induced Kähler field and classical  $Z^0$  field

$$\begin{aligned} \gamma &= 3J - \sin^2\theta_W R_{03} \ , \\ Z^0 &= 2R_{03} \ . \end{aligned} \tag{13.4.10}$$

Here  $Z_0 = 2R_{03}$  is the appropriate component of  $CP_2$  curvature form [2]. For a vanishing Weinberg angle the condition reduces to that for Kähler form.

2. For the Euclidian space-time regions having interpretation as lines of generalized Feynman diagrams Weinberg angle should be non-vanishing. In Minkowskian regions Weinberg angle could however vanish. If so, the condition guaranteeing that electromagnetic charge of the partonic 2-surfaces equals to the above condition stating that the em charge assignable to the fermion content of the partonic 2-surfaces reduces to the classical Kähler electric flux at the Minkowskian side of the wormhole throat. One can argue that Weinberg angle must increase smoothly from a vanishing value at both sides of wormhole throat to its value in the deep interior of the Euclidian region.
3. The vanishing of the Weinberg angle in Minkowskian regions conforms with the physical intuition. Above elementary particle length scales one sees only the classical electric field reducing to the induced Kähler form and classical  $Z^0$  fields and color gauge fields are effectively absent. Only in phases with a large value of Planck constant classical  $Z^0$  field and other classical weak fields and color gauge field could make themselves visible. Cell membrane could be one such system [59]. This conforms with the general picture about color confinement and weak massivation.

The GRT limit of TGD suggests a further reason for why Weinberg angle should vanish in Minkowskian regions.

1. The value of the Kähler coupling strength must be very near to the value of the fine structure constant in electron length scale and these constants can be assumed to be equal.
2. GRT limit of TGD with space-time surfaces replaced with abstract 4-geometries would naturally correspond to Einstein-Maxwell theory with cosmological constant which is non-vanishing only in Euclidian regions of space-time so that both Reissner-Nordström metric and  $CP_2$  are allowed as simplest possible solutions of field equations [77]. The extremely small value of the observed cosmological constant needed in GRT type cosmology could be equal to the large cosmological constant associated with  $CP_2$  metric multiplied with the 3-volume fraction of Euclidian regions.

3. Also at GRT limit quantum theory would reduce to almost topological QFT since Einstein-Maxwell action reduces to 3-D term by field equations implying the vanishing of the Maxwell current and of the curvature scalar in Minkowskian regions and curvature scalar + cosmological constant term in Euclidian regions. The weak form of electric-magnetic duality would guarantee also now the preferred extremal property and prevent the reduction to a mere topological QFT.
4. GRT limit would make sense only for a vanishing Weinberg angle in Minkowskian regions. A non-vanishing Weinberg angle would make sense in the deep interior of the Euclidian regions where the approximation as a small deformation of  $CP_2$  makes sense.

The weak form of electric-magnetic duality has surprisingly strong implications for the basic view about quantum TGD as following considerations show.

### 13.4.2 Magnetic confinement, the short range of weak forces, and color confinement

The weak form of electric-magnetic duality has surprisingly strong implications if one combines it with some very general empirical facts such as the non-existence of magnetic monopole fields in macroscopic length scales.

#### How can one avoid macroscopic magnetic monopole fields?

Monopole fields are experimentally absent in length scales above order weak boson length scale and one should have a mechanism neutralizing the monopole charge. How electroweak interactions become short ranged in TGD framework is still a poorly understood problem. What suggests itself is the neutralization of the weak isospin above the intermediate gauge boson Compton length by neutral Higgs bosons. Could the two neutralization mechanisms be combined to single one?

1. In the case of fermions and their super partners the opposite magnetic monopole would be a wormhole throat. If the magnetically charged wormhole contact is electromagnetically neutral but has vectorial weak isospin neutralizing the weak vectorial isospin of the fermion only the electromagnetic charge of the fermion is visible on longer length scales. The distance of this wormhole throat from the fermionic one should be of the order weak boson Compton length. An interpretation as a bound state of fermion and a wormhole throat state with the quantum numbers of a neutral Higgs boson would therefore make sense. The neutralizing throat would have quantum numbers of  $X_{-1/2} = \nu_L \bar{\nu}_R$  or  $X_{1/2} = \bar{\nu}_L \nu_R$ .  $\nu_L \bar{\nu}_R$  would not be neutral Higgs boson (which should correspond to a wormhole contact) but a super-partner of left-handed neutrino obtained by adding a right handed neutrino. This mechanism would apply separately to the fermionic and anti-fermionic throats of the gauge bosons and corresponding space-time sheets and leave only electromagnetic interaction as a long ranged interaction.
2. One can of course wonder what is the situation situation for the bosonic wormhole throats feeding gauge fluxes between space-time sheets. It would seem that these wormhole throats must always appear as pairs such that for the second member of the pair monopole charges and  $I_V^3$  cancel each other at both space-time sheets involved so that one obtains at both space-time sheets magnetic dipoles of size of weak boson Compton length. The proposed magnetic character of fundamental particles should become visible at TeV energies so that LHC might have surprises in store!

#### Magnetic confinement and color confinement

Magnetic confinement generalizes also to the case of color interactions. One can consider also the situation in which the magnetic charges of quarks (more generally, of color excited leptons and quarks) do not vanish and they form color and magnetic singlets in the hadronic length scale. This would mean that magnetic charges of the state  $q_{\pm 1/2} - X_{\mp 1/2}$  representing the physical quark would not vanish and magnetic confinement would accompany also color confinement. This would explain why free quarks are not observed. To how degree then quark confinement corresponds to magnetic confinement is an interesting question.

For quark and antiquark of meson the magnetic charges of quark and antiquark would be opposite and meson would correspond to a Kähler magnetic flux so that a stringy view about meson emerges. For valence quarks of baryon the vanishing of the net magnetic charge takes place provided that the magnetic net charges are  $(\pm 2, \mp 1, \mp 1)$ . This brings in mind the spectrum of color hyper charges coming as  $(\pm 2, \mp 1, \mp 1)/3$  and one can indeed ask whether color hyper-charge correlates with the Kähler magnetic charge. The geometric picture would be three strings connected to single vertex. Amusingly, the idea that color hypercharge could be proportional to color hyper charge popped up during the first year of TGD when I had not yet discovered  $CP_2$  and believed on  $M^4 \times S^2$ .

p-Adic length scale hypothesis and hierarchy of Planck constants defining a hierarchy of dark variants of particles suggest the existence of scaled up copies of QCD type physics and weak physics. For p-adically scaled up variants the mass scales would be scaled by a power of  $\sqrt{2}$  in the most general case. The dark variants of the particle would have the same mass as the original one. In particular, Mersenne primes  $M_k = 2^k - 1$  and Gaussian Mersennes  $M_{G,k} = (1 + i)^k - 1$  has been proposed to define zoomed copies of these physics. At the level of magnetic confinement this would mean hierarchy of length scales for the magnetic confinement.

One particular proposal is that the Mersenne prime  $M_{89}$  should define a scaled up variant of the ordinary hadron physics with mass scaled up roughly by a factor  $2^{(107-89)/2} = 512$ . The size scale of color confinement for this physics would be same as the weal length scale. It would look more natural that the weak confinement for the quarks of  $M_{89}$  physics takes place in some shorter scale and  $M_{61}$  is the first Mersenne prime to be considered. The mass scale of  $M_{61}$  weak bosons would be by a factor  $2^{(89-61)/2} = 2^{14}$  higher and about  $1.6 \times 10^4$  TeV.  $M_{89}$  quarks would have virtually no weak interactions but would possess color interactions with weak confinement length scale reflecting themselves as new kind of jets at collisions above TeV energies.

In the biologically especially important length scale range 10 nm -2500 nm there are as many as four Gaussian Mersennes corresponding to  $M_{G,k}$ ,  $k = 151, 157, 163, 167$ . This would suggest that the existence of scaled up scales of magnetic-, weak- and color confinement. An especially interesting possibly testable prediction is the existence of magnetic monopole pairs with the size scale in this range. There are recent claims about experimental evidence for magnetic monopole pairs [7].

### Magnetic confinement and stringy picture in TGD sense

The connection between magnetic confinement and weak confinement is rather natural if one recalls that electric-magnetic duality in super-symmetric quantum field theories means that the descriptions in terms of particles and monopoles are in some sense dual descriptions. Fermions would be replaced by string like objects defined by the magnetic flux tubes and bosons as pairs of wormhole contacts would correspond to pairs of the flux tubes. Therefore the sharp distinction between gravitons and physical particles would disappear.

The reason why gravitons are necessarily stringy objects formed by a pair of wormhole contacts is that one cannot construct spin two objects using only single fermion states at wormhole throats. Of course, also super partners of these states with higher spin obtained by adding fermions and anti-fermions at the wormhole throat but these do not give rise to graviton like states [29]. The upper and lower wormhole throat pairs would be quantum superpositions of fermion anti-fermion pairs with sum over all fermions. The reason is that otherwise one cannot realize graviton emission in terms of joining of the ends of light-like 3-surfaces together. Also now magnetic monopole charges are necessary but now there is no need to assign the entities  $X_{\pm}$  with gravitons.

Graviton string is characterized by some p-adic length scale and one can argue that below this length scale the charges of the fermions become visible. Mersenne hypothesis suggests that some Mersenne prime is in question. One proposal is that gravitonic size scale is given by electronic Mersenne prime  $M_{127}$ . It is however difficult to test whether graviton has a structure visible below this length scale.

What happens to the generalized Feynman diagrams is an interesting question. It is not at all clear how closely they relate to ordinary Feynman diagrams. All depends on what one is ready to assume about what happens in the vertices. One could of course hope that zero energy ontology could allow some very simple description allowing perhaps to get rid of the problematic aspects of Feynman diagrams.

1. Consider first the recent view about generalized Feynman diagrams which relies zero energy ontology. A highly attractive assumption is that the particles appearing at wormhole throats

are on mass shell particles. For incoming and outgoing elementary bosons and their super partners they would be positive it resp. negative energy states with parallel on mass shell momenta. For virtual bosons they the wormhole throats would have opposite sign of energy and the sum of on mass shell states would give virtual net momenta. This would make possible twistor description of virtual particles allowing only massless particles (in 4-D sense usually and in 8-D sense in TGD framework). The notion of virtual fermion makes sense only if one assumes in the interaction region a topological condensation creating another wormhole throat having no fermionic quantum numbers.

2. The addition of the particles  $X^\pm$  replaces generalized Feynman diagrams with the analogs of stringy diagrams with lines replaced by pairs of lines corresponding to fermion and  $X_{\pm 1/2}$ . The members of these pairs would correspond to 3-D light-like surfaces glued together at the vertices of generalized Feynman diagrams. The analog of 3-vertex would not be splitting of the string to form shorter strings but the replication of the entire string to form two strings with same length or fusion of two strings to single string along all their points rather than along ends to form a longer string. It is not clear whether the duality symmetry of stringy diagrams can hold true for the TGD variants of stringy diagrams.
3. How should one describe the bound state formed by the fermion and  $X^\pm$ ? Should one describe the state as superposition of non-parallel on mass shell states so that the composite state would be automatically massive? The description as superposition of on mass shell states does not conform with the idea that bound state formation requires binding energy. In TGD framework the notion of negentropic entanglement has been suggested to make possible the analogs of bound states consisting of on mass shell states so that the binding energy is zero [44]. If this kind of states are in question the description of virtual states in terms of on mass shell states is not lost. Of course, one cannot exclude the possibility that there is infinite number of this kind of states serving as analogs for the excitations of string like object.
4. What happens to the states formed by fermions and  $X_{\pm 1/2}$  in the internal lines of the Feynman diagram? Twistor philosophy suggests that only the higher on mass shell excitations are possible. If this picture is correct, the situation would not change in an essential manner from the earlier one.

The highly non-trivial prediction of the magnetic confinement is that elementary particles should have stringy character in electro-weak length scales and could behaving to become manifest at LHC energies. This adds one further item to the list of non-trivial predictions of TGD about physics at LHC energies [45].

#### Should $J + J_1$ appear in Kähler action?

The presence of the  $S^2$  Kähler form  $J_1$  in weak form of electric-magnetic duality was originally suggested by an erratic argument about the reduction to almost topological QFT to be described in the next subsection. In any case this argument raises the question whether one could replace  $J$  with  $J + J_1$  in the Kähler action. This would not affect the basic non-vacuum extremals but would modify the vacuum degeneracy of the Kähler action. Canonically imbedded  $M^4$  would become a monopole configuration with an infinite magnetic energy and Kähler action due to the monopole singularity at the line connecting tips of the  $CD$ . Action and energy can be made small by drilling a small hole around origin. This is however not consistent with the weak form of electro-weak duality. Amusingly, the modified Dirac equation reduces to ordinary massless Dirac equation in  $M^4$ .

This extremal can be transformed to a vacuum extremal by assuming that the solution is also a  $CP_2$  magnetic monopole with opposite contribution to the magnetic charge so that  $J + J_1 = 0$  holds true. This is achieved if one can regard space-time surface as a map  $M^4 \rightarrow CP_2$  reducing to a map  $(\Theta, \Phi) = (\theta, \pm\phi)$  with the sign chosen by properly projecting the homologically non-trivial  $r_M = \text{constant}$  spheres of  $CD$  to the homologically non-trivial geodesic sphere of  $CP_2$ . Symplectic transformations of  $S^2 \times CP_2$  produce new vacuum extremals of this kind. Using Darboux coordinates in which one has  $J = \sum_{k=1,2} P_k dQ^k$  and assuming that  $(P_1, Q_1)$  corresponds to the  $CP_2$  image of  $S^2$ , one can take  $Q_2$  to be arbitrary function of  $P^2$  which in turn is an arbitrary function of  $M^4$  coordinates to obtain even more general vacuum extremals with 3-D  $CP_2$  projection. Therefore the

spectrum of vacuum extremals, which is very relevant for the TGD based description of gravitation in long length scales because it allows to satisfy Einstein's equations as an additional condition, looks much richer than for the original option, and it is natural to ask whether this option might make sense.

An objection is that  $J_1$  is a radial monopole field and this breaks Lorentz invariance to  $SO(3)$ . Lorentz invariance is broken to  $SO(3)$  for a given  $CD$  also by the presence of the preferred time direction defined by the time-like line connecting the tips of the  $CD$  becoming carrying the monopole charge but is compensated since Lorentz boosts of  $CDs$  are possible. Could one consider similar compensation also now? Certainly the extremely small breaking of Lorentz invariance and the vanishing of the monopole charge for the vacuum extremals is all that is needed at the space-time level. No new gauge fields would be introduced since only the Kähler field part of photon and  $Z^0$  boson would receive an additional contribution.

The ultimate fate of the modification depends on whether it is consistent with the general relativistic description of gravitation. Since a breaking of spherical symmetry is involved, it is not at all clear whether one can find vacuum extremals which represent small deformations of the Reissner-Nordström metric and Robertson-Walker metric. The argument below shows that this option does not allow the imbedding of small deformations of physically plausible space-time metrics as vacuum extremals.

The basic vacuum extremal whose deformations should give vacuum extremals allowing interpretation as solutions of Einstein's equations is given by a map  $M^4 \rightarrow CP_2$  projecting the  $r_M$  constant spheres  $S^2$  of  $M^2$  to the homologically non-trivial geodesic sphere of  $CP_2$ . The winding number of this map is  $-1$  in order to achieve vanishing of the induced Kähler form  $J + J_1$ . For instance, the following two canonical forms of the map are possible

$$\begin{aligned} (\Theta, \Psi) &= (\theta_M, -\phi_M) , \\ (\Theta, \Psi) &= (\pi - \theta_M, \phi_M) . \end{aligned} \tag{13.4.11}$$

Here  $(\Theta, \Psi)$  refers to the geodesic sphere of  $CP_2$  and  $(\theta_M, \phi_M)$  to the sphere of  $M^4$ . The resulting space-time surface is not flat and Einstein tensor is non-vanishing. More complex metrics can be constructed from this metric by a deformation making the  $CP_2$  projection 3-dimensional.

Using the expression of the  $CP_2$  line element in Eguchi-Hanson coordinates [10]

$$\frac{ds^2}{R^2} = \frac{dr^2}{F^2} + \frac{r^2}{F} (d\Psi + \cos\Theta d\Phi)^2 + \frac{r^2}{4F} (d\Theta^2 + f r a c r^2 4 F \sin^2\Theta d\Phi^2) \tag{13.4.12}$$

and s the relationship  $r = \tan(\Theta)$ , one obtains following expression for the  $CP_2$  metric

$$\frac{ds^2}{R^2} = d\theta_M^2 + \sin^2(\theta_M) \left[ (d\phi_M + \cos(\theta) d\Phi)^2 + \frac{1}{4} (d\theta^2 + \sin^2(\theta) d\Phi^2) \right] . \tag{13.4.13}$$

The resulting metric is obtained from the metric of  $S^2$  by replacing  $d\phi^2$  which 3-D line element. The factor  $\sin^2(\theta_M)$  implies that the induced metric becomes singular at North and South poles of  $S^2$ . In particular, the gravitational potential is proportional to  $\sin^2(\theta_M)$  so that gravitational force in the radial direction vanishes at equators. It is very difficult to imagine any manner to produce a small deformation of Reissner-Nordström metric or Robertson-Walker metric. Hence it seems that the vacuum extremals produce by  $J + J_1$  option are not physical.

### 13.4.3 Could Quantum TGD reduce to almost topological QFT?

There seems to be a profound connection with the earlier unrealistic proposal that TGD reduces to almost topological quantum theory in the sense that the counterpart of Chern-Simons action assigned with the wormhole throats somehow dictates the dynamics. This proposal can be formulated also for the modified Dirac action action. I gave up this proposal but the following argument shows that

Kähler action with weak form of electric-magnetic duality effectively reduces to Chern-Simons action plus Coulomb term.

1. Kähler action density can be written as a 4-dimensional integral of the Coulomb term  $j_K^\alpha A_\alpha$  plus and integral of the boundary term  $J^{n\beta} A_\beta \sqrt{g_4}$  over the wormhole throats and of the quantity  $J^{0\beta} A_\beta \sqrt{g_4}$  over the ends of the 3-surface.
2. If the self-duality conditions generalize to  $J^{n\beta} = 4\pi\alpha_K \epsilon^{n\beta\gamma\delta} J_{\gamma\delta}$  at throats and to  $J^{0\beta} = 4\pi\alpha_K \epsilon^{0\beta\gamma\delta} J_{\gamma\delta}$  at the ends, the Kähler function reduces to the counterpart of Chern-Simons action evaluated at the ends and throats. It would have same value for each branch and the replacement  $\hbar_0 \rightarrow r\hbar_0$  would effectively describe this. Boundary conditions would however give  $1/r$  factor so that  $\hbar$  would disappear from the Kähler function! The original attempt to realize quantum TGD as an almost topological QFT was in terms of Chern-Simons action but was given up. It is somewhat surprising that Kähler action gives Chern-Simons action in the vacuum sector defined as sector for which Kähler current is light-like or vanishes.

Holography encourages to ask whether also the Coulomb interaction terms could vanish. This kind of dimensional reduction would mean an enormous simplification since TGD would reduce to an almost topological QFT. The attribute "almost" would come from the fact that one has non-vanishing classical Noether charges defined by Kähler action and non-trivial quantum dynamics in  $M^4$  degrees of freedom. One could also assign to space-time surfaces conserved four-momenta which is not possible in topological QFTs. For this reason the conditions guaranteeing the vanishing of Coulomb interaction term deserve a detailed analysis.

1. For the known extremals  $j_K^\alpha$  either vanishes or is light-like ("massless extremals" for which weak self-duality condition does not make sense [8] ) so that the Coulombic term vanishes identically in the gauge used. The addition of a gradient to  $A$  induces terms located at the ends and wormhole throats of the space-time surface but this term must be cancelled by the other boundary terms by gauge invariance of Kähler action. This implies that the  $M^4$  part of WCW metric vanishes in this case. Therefore massless extremals as such are not physically realistic: wormhole throats representing particles are needed.
2. The original naive conclusion was that since Chern-Simons action depends on  $CP_2$  coordinates only, its variation with respect to Minkowski coordinates must vanish so that the WCW metric would be trivial in  $M^4$  degrees of freedom. This conclusion is in conflict with quantum classical correspondence and was indeed too hasty. The point is that the allowed variations of Kähler function must respect the weak electro-magnetic duality which relates Kähler electric field depending on the induced 4-metric at 3-surface to the Kähler magnetic field. Therefore the dependence on  $M^4$  coordinates creeps via a Lagrange multiplier term

$$\int \Lambda_\alpha (J^{n\alpha} - K \epsilon^{n\alpha\beta\gamma} J_{\beta\gamma}) \sqrt{g_4} d^3x \quad (13.4.14)$$

The (1,1) part of second variation contributing to  $M^4$  metric comes from this term.

3. This erratic conclusion about the vanishing of  $M^4$  part WCW metric raised the question about how to achieve a non-trivial metric in  $M^4$  degrees of freedom. The proposal was a modification of the weak form of electric-magnetic duality. Besides  $CP_2$  Kähler form there would be the Kähler form assignable to the light-cone boundary reducing to that for  $r_M = constant$  sphere - call it  $J^1$ . The generalization of the weak form of self-duality would be  $J^{n\beta} = \epsilon^{n\beta\gamma\delta} K (J_{\gamma\delta} + \epsilon J_{\gamma\delta}^1)$ . This form implies that the boundary term gives a non-trivial contribution to the  $M^4$  part of the WCW metric even without the constraint from electric-magnetic duality. Kähler charge is not affected unless the partonic 2-surface contains the tip of  $CD$  in its interior. In this case the value of Kähler charge is shifted by a topological contribution. Whether this term can survive depends on whether the resulting vacuum extremals are consistent with the basic facts about classical gravitation.

4. The Coulombic interaction term is not invariant under gauge transformations. The good news is that this might allow to find a gauge in which the Coulomb term vanishes. The vanishing condition fixing the gauge transformation  $\phi$  is

$$j_K^\alpha \partial_\alpha \phi = -j^\alpha A_\alpha . \quad (13.4.15)$$

This differential equation can be reduced to an ordinary differential equation along the flow lines  $j_K$  by using  $dx^\alpha/dt = j_K^\alpha$ . Global solution is obtained only if one can combine the flow parameter  $t$  with three other coordinates- say those at the either end of  $CD$  to form space-time coordinates. The condition is that the parameter defining the coordinate differential is proportional to the covariant form of Kähler current:  $dt = \phi j_K$ . This condition in turn implies  $d^2t = d(\phi j_K) = d\phi \wedge j_K + \phi dj_K = 0$  implying  $j_K \wedge dj_K = 0$  or more concretely,

$$\epsilon^{\alpha\beta\gamma\delta} j_\beta^K \partial_\gamma j_\delta^K = 0 . \quad (13.4.16)$$

$j_K$  is a four-dimensional counterpart of Beltrami field [48] and could be called generalized Beltrami field.

The integrability conditions follow also from the construction of the extremals of Kähler action [8] . The conjecture was that for the extremals the 4-dimensional Lorentz force vanishes (no dissipation): this requires  $j_K \wedge J = 0$ . One manner to guarantee this is the topologization of the Kähler current meaning that it is proportional to the instanton current:  $j_K = \phi j_I$ , where  $j_I = *(J \wedge A)$  is the instanton current, which is not conserved for 4-D  $CP_2$  projection. The conservation of  $j_K$  implies the condition  $j_I^\alpha \partial_\alpha \phi = \partial_\alpha j^\alpha \phi$  and from this  $\phi$  can be integrated if the integrability condition  $j_I \wedge dj_I = 0$  holds true implying the same condition for  $j_K$ . By introducing at least 3 or  $CP_2$  coordinates as space-time coordinates, one finds that the contravariant form of  $j_I$  is purely topological so that the integrability condition fixes the dependence on  $M^4$  coordinates and this selection is coded into the scalar function  $\phi$ . These functions define families of conserved currents  $j_K^\alpha \phi$  and  $j_I^\alpha \phi$  and could be also interpreted as conserved currents associated with the critical deformations of the space-time surface.

5. There are gauge transformations respecting the vanishing of the Coulomb term. The vanishing condition for the Coulomb term is gauge invariant only under the gauge transformations  $A \rightarrow A + \nabla\phi$  for which the scalar function the integral  $\int j_K^\alpha \partial_\alpha \phi$  reduces to a total divergence a giving an integral over various 3-surfaces at the ends of  $CD$  and at throats vanishes. This is satisfied if the allowed gauge transformations define conserved currents

$$D_\alpha(j^\alpha \phi) = 0 . \quad (13.4.17)$$

As a consequence Coulomb term reduces to a difference of the conserved charges  $Q_\phi^e = \int j^0 \phi \sqrt{g_4} d^3x$  at the ends of the CD vanishing identically. The change of the imons type term is trivial if the total weighted Kähler magnetic flux  $Q_\phi^m = \sum \int J \phi dA$  over wormhole throats is conserved. The existence of an infinite number of conserved weighted magnetic fluxes is in accordance with the electric-magnetic duality. How these fluxes relate to the flux Hamiltonians central for WCW geometry is not quite clear.

6. The gauge transformations respecting the reduction to almost topological QFT should have some special physical meaning. The measurement interaction term in the modified Dirac interaction corresponds to a critical deformation of the space-time sheet and is realized as an addition of a gauge part to the Kähler gauge potential of  $CP_2$ . It would be natural to identify this gauge transformation giving rise to a conserved charge so that the conserved charges would provide a representation for the charges associated with the infinitesimal critical deformations not affecting Kähler action. The gauge transformed Kähler potential couples to the modified

Dirac equation and its effect could be visible in the value of Kähler function and therefore also in the properties of the preferred extremal. The effect on WCW metric would however vanish since  $K$  would transform only by an addition of a real part of a holomorphic function. Kähler function is identified as a Dirac determinant for Chern-Simons Dirac action and the spectrum of this operator should not be invariant under these gauge transformations if this picture is correct. This is achieved if the gauge transformation is carried only in the Dirac action corresponding to the Chern-Simons term: this assumption is motivated by the breaking of time reversal invariance induced by quantum measurements. The modification of Kähler action can be guessed to correspond just to the Chern-Simons contribution from the instanton term.

7. A reasonable looking guess for the explicit realization of the quantum classical correspondence between quantum numbers and space-time geometry is that the deformation of the preferred extremal due to the addition of the measurement interaction term is induced by a  $U(1)$  gauge transformation induced by a transformation of  $\delta CD \times CP_2$  generating the gauge transformation represented by  $\phi$ . This interpretation makes sense if the fluxes defined by  $Q_\phi^m$  and corresponding Hamiltonians affect only zero modes rather than quantum fluctuating degrees of freedom.

To sum up, one could understand the basic properties of WCW metric in this framework. Effective 2-dimensionality would result from the existence of an infinite number of conserved charges in two different time directions (genuine conservation laws plus gauge fixing). The infinite-dimensional symmetric space for given values of zero modes corresponds to the Cartesian product of the WCWs associated with the partonic 2-surfaces at both ends of  $CD$  and the generalized Chern-Simons term decomposes into a sum of terms from the ends giving single particle Kähler functions and to the terms from light-like wormhole throats giving interaction term between positive and negative energy parts of the state. Hence Kähler function could be calculated without any knowledge about the interior of the space-time sheets and TGD would reduce to almost topological QFT as speculated earlier. Needless to say this would have immense boost to the program of constructing WCW Kähler geometry.

#### 13.4.4 Kähler action for Euclidian regions as Kähler function and Kähler action for Minkowskian regions as Morse function?

One of the nasty questions about the interpretation of Kähler action relates to the square root of the metric determinant. If one proceeds completely straightforwardly, the only reason conclusion is that the square root is imaginary in Minkowskian space-time regions so that Kähler action would be complex. The Euclidian contribution would have a natural interpretation as positive definite Kähler function but how should one interpret the imaginary Minkowskian contribution? Certainly the path integral approach to quantum field theories supports its presence. For some mysterious reason I was able to forget this nasty question and serious consideration of the obvious answer to it. Only when I worked between possible connections between TGD and Floer homology [85] I realized that the Minkowskian contribution is an excellent candidate for Morse function whose critical points give information about WCW homology. This would fit nicely with the vision about TGD as almost topological QFT.

Euclidian regions would guarantee the convergence of the functional integral and one would have a mathematically well-defined theory. Minkowskian contribution would give the quantal interference effects and stationary phase approximation. The analog of Floer homology would represent quantum superpositions of critical points identifiable as ground states defined by the extrema of Kähler action for Minkowskian regions. Perturbative approach to quantum TGD would rely on functional integrals around the extrema of Kähler function. One would have maxima also for the Kähler function but only in the zero modes not contributing to the WCW metric.

There is a further question related to almost topological QFT character of TGD. Should one assume that the reduction to Chern-Simons terms occurs for the preferred extremals in *both* Minkowskian and Euclidian regions or only in Minkowskian regions?

1. All arguments for this have been represented for Minkowskian regions [28] involve local light-like momentum direction which does not make sense in the Euclidian regions. This does not however kill the argument: one can have non-trivial solutions of Laplacian equation in the region of  $CP_2$  bounded by wormhole throats: for  $CP_2$  itself only covariantly constant right-handed neutrino represents this kind of solution and at the same time supersymmetry. In the

general case solutions of Laplacian represent broken super-symmetries and should be in one-one correspondences with the solutions of the modified Dirac equation. The interpretation for the counterparts of momentum and polarization would be in terms of classical representation of color quantum numbers.

If the reduction occurs in Euclidian regions, it gives in the case of  $CP_2$  two 3-D terms corresponding to two 3-D gluing regions for three coordinate patches needed to define coordinates and spinor connection for  $CP_2$  so that one would have two Chern-Simons terms. Without any other contributions the first term would be identical with that from Minkowskian region apart from imaginary unit. Second Chern-Simons term would be however independent of this. For wormhole contacts the two terms could be assigned with opposite wormhole throats and would be identical with their Minkowskian cousins from imaginary unit. This looks a little bit strange.

2. There is however a very delicate issue involved. Quantum classical correspondence requires that the quantum numbers of partonic states must be coded to the space-time geometry, and this is achieved by adding to the action a measurement interaction term which reduces to what is almost a gauge term present only in Chern-Simons-Dirac equation but not at space-time interior [28]. This term would represent a coupling to Poincare quantum numbers at the Minkowskian side and to color and electro-weak quantum numbers at  $CP_2$  side. Therefore the net Chern-Simons contributions and would be different.
3. There is also a very beautiful argument stating that Dirac determinant for Chern-Simons-Dirac action equals to Kähler function, which would be lost if Euclidian regions would not obey holography. The argument obviously generalizes and applies to both Morse and Kähler function.

The Minkowskian contribution of Kähler action is imaginary due to the negative of the metric determinant and gives a phase factor to vacuum functional reducing to Chern-Simons terms at wormhole throats. Ground state degeneracy due to the possibility of having both signs for Minkowskian contribution to the exponent of vacuum functional provides a general view about the description of CP breaking in TGD framework.

1. In TGD framework path integral is replaced by inner product involving integral over WCV. The vacuum functional and its conjugate are associated with the states in the inner product so that the phases of vacuum functionals cancel if only one sign for the phase is allowed. Minkowskian contribution would have no physical significance. This of course cannot be the case. The ground state is actually degenerate corresponding to the phase factor and its complex conjugate since  $\sqrt{g}$  can have two signs in Minkowskian regions. Therefore the inner products between states associated with the two ground states define  $2 \times 2$  matrix and non-diagonal elements contain interference terms due to the presence of the phase factor. At the limit of full  $CP_2$  type vacuum extremal the two ground states would reduce to each other and the determinant of the matrix would vanish.
2. A small mixing of the two ground states would give rise to CP breaking and the first principle description of CP breaking in systems like  $K - \bar{K}$  and of CKM matrix should reduce to this mixing.  $K^0$  mesons would be CP even and odd states in the first approximation and correspond to the sum and difference of the ground states. Small mixing would be present having exponential sensitivity to the actions of  $CP_2$  type extremals representing wormhole throats. This might allow to understand qualitatively why the mixing is about 50 times larger than expected for  $B^0$  mesons.
3. There is a strong temptation to assign the two ground states with two possible arrows of geometric time. At the level of M-matrix the two arrows would correspond to state preparation at either upper or lower boundary of CD. Do long- and shortlived neutral K mesons correspond to almost fifty-fifty orthogonal superpositions for the two arrow of geometric time or almost completely to a fixed arrow of time induced by environment? Is the dominant part of the arrow same for both or is it opposite for long and short-lived neutral measons? Different lifetimes would suggest that the arrow must be the same and apart from small leakage that induced by environment. CP breaking would be induced by the fact that CP is performed only  $K^0$  but not for the environment in the construction of states. One can probably imagine also alternative interpretations.

*Remark:* The proportionality of Minkowskian and Euclidian contributions to the same Chern-Simons term implies that the critical points with respect to zero modes appear for both the phase and modulus of vacuum functional. The Kähler function property does not allow extrema for vacuum functional as a function of complex coordinates of WCW since this would mean Kähler metric with non-Euclidian signature. If this were not the case, the stationary values of phase factor and extrema of modulus of the vacuum functional would correspond to different configurations.

### 13.4.5 A general solution ansatz based on almost topological QFT property

The basic vision behind the ansatz is the reduction of quantum TGD to almost topological field theory. This requires that the flow parameters associated with the flow lines of isometry currents and Kähler current extend to global coordinates. This leads to integrability conditions implying generalized Beltrami flow and Kähler action for the preferred extremals reduces to Chern-Simons action when weak electro-weak duality is applied as boundary conditions. The strongest form of the hydrodynamical interpretation requires that all conserved currents are parallel to Kähler current. In the more general case one would have several hydrodynamic flows. Also the braidings (several of them for the most general ansatz) assigned with the light-like 3-surfaces are naturally defined by the flow lines of conserved currents. The independent behavior of particles at different flow lines can be seen as a realization of the complete integrability of the theory. In free quantum field theories on mass shell Fourier components are in a similar role but the geometric interpretation in terms of flow is of course lacking. This picture should generalize also to the solution of the modified Dirac equation.

#### Basic field equations

Consider first the equations at general level.

1. The breaking of the Poincare symmetry due to the presence of monopole field occurs and leads to the isometry group  $T \times SO(3) \times SU(3)$  corresponding to time translations, rotations, and color group. The Cartan algebra is four-dimensional and field equations reduce to the conservation laws of energy  $E$ , angular momentum  $J$ , color isospin  $I_3$ , and color hypercharge  $Y$ .
2. Quite generally, one can write the field equations as conservation laws for  $I, J, I_3$ , and  $Y$ .

$$D_\alpha [D_\beta (J^{\alpha\beta} H_A) - j_K^\alpha H^A + T^{\alpha\beta} j_A^l h_{kl} \partial_\beta h^l] = 0 . \quad (13.4.18)$$

The first term gives a contraction of the symmetric Ricci tensor with antisymmetric Kähler form and vanishes so that one has

$$D_\alpha [j_K^\alpha H^A - T^{\alpha\beta} j_A^k h_{kl} \partial_\beta h^l] = 0 . \quad (13.4.19)$$

For energy one has  $H_A = 1$  and energy current associated with the flow lines is proportional to the Kähler current. Its divergence vanishes identically.

3. One can express the divergence of the term involving energy momentum tensor as as sum of terms involving  $j_K^\alpha J_{\alpha\beta}$  and contraction of second fundamental form with energy momentum tensor so that one obtains

$$j_K^\alpha D_\alpha H^A = j_K^\alpha J_{\alpha\beta} j_\beta^A + T^{\alpha\beta} H_{\alpha\beta}^k j_k^A . \quad (13.4.20)$$

### Hydrodynamical solution ansatz

The characteristic feature of the solution ansatz would be the reduction of the dynamics to hydrodynamics analogous to that for a continuous distribution of particles initially at the end of  $X^3$  of the light-like 3-surface moving along flow lines defined by currents  $j_A$  satisfying the integrability condition  $j_A \wedge dj_A = 0$ . Field theory would reduce effectively to particle mechanics along flow lines with conserved charges defined by various isometry currents. The strongest condition is that all isometry currents  $j_A$  and also Kähler current  $j_K$  are proportional to the same current  $j$ . The more general option corresponds to multi-hydrodynamics.

Conserved currents are analogous to hydrodynamical currents in the sense that the flow parameter along flow lines extends to a global space-time coordinate. The conserved current is proportional to the gradient  $\nabla\Phi$  of the coordinate varying along the flow lines:  $J = \Psi\nabla\Phi$  and by a proper choice of  $\Psi$  one can allow to have conservation. The initial values of  $\Psi$  and  $\Phi$  can be selected freely along the flow lines beginning from either the end of the space-time surface or from wormhole throats.

If one requires hydrodynamics also for Chern-Simons action (effective 2-dimensionality is required for preferred extremals), the initial values of scalar functions can be chosen freely only at the partonic 2-surfaces. The freedom to choose the initial values of the charges conserved along flow lines at the partonic 2-surfaces means the existence of an infinite number of conserved charges so that the theory would be integrable and even in two different coordinate directions. The basic difference as compared to ordinary conservation laws is that the conserved currents are parallel and their flow parameter extends to a global coordinate.

1. The most general assumption is that the conserved isometry currents

$$J_A^\alpha = j_K^\alpha H^A - T^{\alpha\beta} j_A^k h_{kl} \partial_\beta h^l \quad (13.4.21)$$

and Kähler current are integrable in the sense that  $J_A \wedge J_A = 0$  and  $j_K \wedge j_K = 0$  hold true. One could imagine the possibility that the currents are not parallel.

2. The integrability condition  $dJ_A \wedge J_A = 0$  is satisfied if one one has

$$J_A = \Psi_A d\Phi_A . \quad (13.4.22)$$

The conservation of  $J_A$  gives

$$d * (\Psi_A d\Phi_A) = 0 . \quad (13.4.23)$$

This would mean separate hydrodynamics for each of the currents involved. In principle there is not need to assume any further conditions and one can imagine infinite basis of scalar function pairs  $(\Psi_A, \Phi_A)$  since criticality implies infinite number deformations implying conserved Noether currents.

3. The conservation condition reduces to d'Alembert equation in the induced metric if one assumes that  $\nabla\Psi_A$  is orthogonal with every  $d\Phi_A$ .

$$d * d\Phi_A = 0 , \quad d\Psi_A \cdot d\Phi_A = 0 . \quad (13.4.24)$$

Taking  $x = \Phi_A$  as a coordinate the orthogonality condition states  $g^{xj} \partial_j \Psi_A = 0$  and in the general case one cannot solve the condition by simply assuming that  $\Psi_A$  depends on the coordinates transversal to  $\Phi_A$  only. These conditions bring in mind  $p \cdot p = 0$  and  $p \cdot e$  condition for massless modes of Maxwell field having fixed momentum and polarization.  $d\Phi_A$  would correspond to  $p$

and  $d\Psi_A$  to polarization. The condition that each isometry current corresponds its own pair  $(\Psi_A, \Phi_A)$  would mean that each isometry current corresponds to independent light-like momentum and polarization. Ordinary free quantum field theory would support this view whereas hydrodynamics and QFT limit of TGD would support single flow.

These are the most general hydrodynamical conditions that one can assume. One can consider also more restricted scenarios.

1. The strongest ansatz is inspired by the hydrodynamical picture in which all conserved isometry charges flow along same flow lines so that one would have

$$J_A = \Psi_A d\Phi . \quad (13.4.25)$$

In this case same  $\Phi$  would satisfy simultaneously the d'Alembert type equations.

$$d * d\Phi = 0 , \quad d\Psi_A \cdot d\Phi = 0. \quad (13.4.26)$$

This would mean that the massless modes associated with isometry currents move in parallel manner but can have different polarizations. The spinor modes associated with light-light like 3-surfaces carry parallel four-momenta, which suggest that this option is correct. This allows a very general family of solutions and one can have a complete 3-dimensional basis of functions  $\Psi_A$  with gradient orthogonal to  $d\Phi$ .

2. Isometry invariance under  $T \times SO(3) \times SU(3)$  allows to consider the possibility that one has

$$J_A = k_A \Psi_A d\Phi_{G(A)} , \quad d * (d\Phi_{G(A)}) = 0 , \quad d\Psi_A \cdot d\Phi_{G(A)} = 0 . \quad (13.4.27)$$

where  $G(A)$  is  $T$  for energy current,  $SO(3)$  for angular momentum currents and  $SU(3)$  for color currents. Energy would thus flow along its own flux lines, angular momentum along its own flow lines, and color quantum numbers along their own flow lines. For instance, color currents would differ from each other only by a numerical constant. The replacement of  $\Psi_A$  with  $\Psi_{G(A)}$  would be too strong a condition since Killing vector fields are not related by a constant factor.

To sum up, the most general option is that each conserved current  $J_A$  defines its own integrable flow lines defined by the scalar function pair  $(\Psi_A, \Phi_A)$ . A complete basis of scalar functions satisfying the d'Alembert type equation guaranteeing current conservation could be imagined with restrictions coming from the effective 2-dimensionality reducing the scalar function basis effectively to the partonic 2-surface. The diametrically opposite option corresponds to the basis obtained by assuming that only single  $\Phi$  is involved.

The proposed solution ansatz can be compared to the earlier ansatz [35] stating that Kähler current is topologized in the sense that for  $D(CP_2) = 3$  it is proportional to the identically conserved instanton current (so that 4-D Lorentz force vanishes) and vanishes for  $D(CP_2) = 4$  (Maxwell phase). This hypothesis requires that instanton current is Beltrami field for  $D(CP_2) = 3$ . In the recent case the assumption that also instanton current satisfies the Beltrami hypothesis in strong sense (single function  $\Phi$ ) generalizes the topologization hypothesis for  $D(CP_2) = 3$ . As a matter fact, the topologization hypothesis applies to isometry currents also for  $D(CP_2) = 4$  although instanton current is not conserved anymore.

### Can one require the extremal property in the case of Chern-Simons action?

Effective 2-dimensionality is achieved if the ends and wormhole throats are extremals of Chern-Simons action. The strongest condition would be that space-time surfaces allow orthogonal slicings by 3-surfaces which are extremals of Chern-Simons action.

Also in this case one can require that the flow parameter associated with the flow lines of the isometry currents extends to a global coordinate. Kähler magnetic field  $B = *J$  defines a conserved current so that all conserved currents would flow along the field lines of  $B$  and one would have 3-D Beltrami flow. Note that in magnetohydrodynamics the standard assumption is that currents flow along the field lines of the magnetic field.

For wormhole throats light-likeness causes some complications since the induced metric is degenerate and the contravariant metric must be restricted to the complement of the light-like direction. This means that d'Alembert equation reduces to 2-dimensional Laplace equation. For space-like 3-surfaces one obtains the counterpart of Laplace equation with partonic 2-surfaces serving as sources. The interpretation in terms of analogs of Coulomb potentials created by 2-D charge distributions would be natural.

### 13.4.6 Hydrodynamic picture in fermionic sector

Super-symmetry inspires the conjecture that the hydrodynamical picture applies also to the solutions of the modified Dirac equation.

#### 4-dimensional modified Dirac equation and hydrodynamical picture

Consider first the solutions of of the induced spinor field in the interior of space-time surface.

1. The local inner products of the modes of the induced spinor fields define conserved currents

$$\begin{aligned} D_\alpha J_{mn}^\alpha &= 0 , \\ J_{mn}^\alpha &= \bar{u}_m \hat{\Gamma}^\alpha u_n , \\ \hat{\Gamma}^\alpha &= \frac{\partial L_K}{\partial(\partial_\alpha h^k)} \Gamma_k . \end{aligned} \tag{13.4.28}$$

The conjecture is that the flow parameters of also these currents extend to a global coordinate so that one would have in the completely general case the condition

$$\begin{aligned} J_{mn}^\alpha &= \Phi_{mn} d\Psi_{mn} , \\ d * (d\Phi_{mn}) &= 0 , \quad \nabla \Psi_{mn} \cdot \Phi_{mn} = 0 . \end{aligned} \tag{13.4.29}$$

The condition  $\Phi_{mn} = \Phi$  would mean that the massless modes propagate in parallel manner and along the flow lines of Kähler current. The conservation condition along the flow line implies tht the current component  $J_{mn}$  is constant along it. Everything would reduce to initial values at the ends of the space-time sheet boundaries of  $CD$  and 3-D modified Dirac equation would reduce everything to initial values at partonic 2-surfaces.

2. One might hope that the conservation of these super currents for all modes is equivalent with the modified Dirac equation. The modes  $u_n$  appearing in  $\Psi$  in quantized theory would be kind of "square roots" of the basis  $\Phi_{mn}$  and the challenge would be to deduce the modes from the conservation laws.
3. The quantization of the induced spinor field in 4-D sense would be fixed by those at 3-D space-like ends by the fact that the oscillator operators are carried along the flow lines as such so that the anti-commutator of the induced spinor field at the opposite ends of the flow lines at the light-like boundaries of  $CD$  is in principle fixed by the anti-commutations at the either end. The anti-commutations at 3-D surfaces cannot be fixed freely since one has 3-D Chern-Simons flow reducing the anti-commutations to those at partonic 2-surfaces.

The following argument suggests that induced spinor fields are in a suitable gauge simply constant along the flow lines of the Kähler current just as massless spinor modes are constant along the geodesic in the direction of momentum.

1. The modified gamma matrices are of form  $T_k^\alpha \Gamma^k$ ,  $T_k^\alpha = \partial L_K / \partial (\partial_\alpha h^k)$ . The H-vectors  $T_k^\alpha$  can be expressed as linear combinations of a subset of Killing vector fields  $j_A^k$  spanning the tangent space of  $H$ . For  $CP_2$  the natural choice are the 4 Lie-algebra generators in the complement of  $U(2)$  sub-algebra. For  $CD$  one can use generator time translation and three generators of rotation group  $SO(3)$ . The completeness of the basis defined by the subset of Killing vector fields gives completeness relation  $h_l^k = j^{Ak} j_{Ak}$ . This implies  $T^{\alpha k} = T^{\alpha k} j_k^A j_A^k = T^{\alpha A} j_A^k$ . One can define gamma matrices  $\Gamma_A$  as  $\Gamma_k j_A^k$  to get  $T_k^\alpha \Gamma^k = T^{\alpha A} \Gamma_A$ .
2. This together with the condition that all isometry currents are proportional to the Kähler current (or if this vanishes to some conserved current- say energy current) satisfying Beltrami flow property implies that one can reduce the modified Dirac equation to an ordinary differential equation along flow lines. The quantities  $T^{tA}$  are constant along the flow lines and one obtains

$$T^{tA} j_A D_t \Psi = 0 . \tag{13.4.30}$$

By choosing the gauge suitably the spinors are just constant along flow lines so that the spinor basis reduces by effective 2-dimensionality to a complete spinor basis at partonic 2-surfaces.

**Generalized eigen modes for the modified Chern-Simons Dirac equation and hydrodynamical picture**

Hydrodynamical picture helps to understand also the construction of generalized eigen modes of 3-D Chern-Simons Dirac equation.

*The general form of generalized eigenvalue equation for Chern-Simons Dirac action*

Consider first the the general form and interpretation of the generalized eigenvalue equation assigned with the modified Dirac equation for Chern-Simons action [15] . This is of course only an approximation since an additional contribution to the modified gamma matrices from the Lagrangian multiplier term guaranteeing the weak form of electric-magnetic duality must be included.

1. The modified Dirac equation for  $\Psi$  is consistent with that for its conjugate if the coefficient of the instanton term is real and one uses the Dirac action  $\bar{\Psi}(D^\rightarrow - D^\leftarrow)\Psi$  giving modified Dirac equation as

$$D_{C-S} \Psi + \frac{1}{2} (D_\alpha \hat{\Gamma}_{C-S}^\alpha) \Psi = 0 . \tag{13.4.31}$$

As noticed, the divergence  $D_\alpha \hat{\Gamma}_{C-S}^\alpha$  does not contain second derivatives in the case of Chern-Simons action. In the case of Kähler action they occur unless field equations equivalent with the vanishing of the divergence term are satisfied. The extremals of Chern-Simons action provide a natural manner to define effective 2-dimensionality.

Also the fermionic current is conserved in this case, which conforms with the idea that fermions flow along the light-like 3-surfaces. If one uses the action  $\bar{\Psi} D^\rightarrow \Psi$ ,  $\bar{\Psi}$  does not satisfy the Dirac equation following from the variational principle and fermion current is not conserved.

2. The generalized eigen modes of  $D_{C-S}$  should be such that one obtains the counterpart of Dirac propagator which is purely algebraic and does not therefore depend on the coordinates of the throat. This is satisfied if the generalized eigenvalues are expressible in terms of covariantly constant combinations of gamma matrices and here only  $M^4$  gamma matrices are possible. Therefore the eigenvalue equation would read as

$$D\Psi = \lambda^k \gamma_k \Psi, \quad D = D_{C-S} + \frac{1}{2} D_\alpha \hat{\Gamma}_{C-S}^\alpha, \quad D_{C-S} = \hat{\Gamma}_{C-S}^\alpha D_\alpha. \quad (13.4.32)$$

Here the covariant derivatives  $D_\alpha$  contain the measurement interaction term as an apparent gauge term. For extremals one has

$$D = D_{C-S}. \quad (13.4.33)$$

Covariant constancy allows to take the square of this equation and one has

$$(D^2 + [D, \lambda^k \gamma_k])\Psi = \lambda^k \lambda_k \Psi. \quad (13.4.34)$$

The commutator term is analogous to magnetic moment interaction.

3. The generalized eigenvalues correspond to  $\lambda = \sqrt{\lambda^k \lambda_k}$  and Dirac determinant is defined as a product of the eigenvalues and conjecture to give the exponent of Kähler action reducing to Chern-Simons term.  $\lambda$  is completely analogous to mass.  $\lambda_k$  cannot be however interpreted as ordinary four-momentum: for instance, number theoretic arguments suggest that  $\lambda_k$  must be restricted to the preferred plane  $M^2 \subset M^4$  interpreted as a commuting hyper-complex plane of complexified quaternions. For incoming lines this mass would vanish so that all incoming particles irrespective their actual quantum numbers would be massless in this sense and the propagator is indeed that for a massless particle. Note that the eigen-modes define the boundary values for the solutions of  $D_K \Psi = 0$  so that the values of  $\lambda$  indeed define the counterpart of the momentum space.

This transmutation of massive particles to effectively massless ones might make possible the application of the twistor formalism as such in TGD framework [82].  $N = 4$  SUSY is one of the very few gauge theory which might be UV finite but it is definitely unphysical due to the masslessness of the basic quanta. Could the resolution of the interpretational problems be that the four-momenta appearing in this theory do not directly correspond to the observed four-momenta?

## 2. Inclusion of the constraint term

As already noticed one must include also the constraint term due to the weak form of electric-magnetic duality and this changes somewhat the above simple picture.

1. At the 3-dimensional ends of the space-time sheet and at wormhole throats the 3-dimensionality allows to introduce a coordinate varying along the flow lines of Kähler magnetic field  $B = *J$ . In this case the integrability conditions state that the flow is Beltrami flow. Note that the value of  $B^\alpha$  along the flow line defining magnetic flux appearing in anti-commutation relations is constant. This suggests that the generalized eigenvalue equation for the Chern-Simons action reduces to a collection of ordinary apparently independent differential equations associated with the flow lines beginning from the partonic 2-surface. This indeed happens when the  $CP_2$  projection is 2-dimensional. In this case it however seems that the basis  $u_n$  is not of much help.
2. The conclusion is wrong: the variations of Chern-Simons action are subject to the constraint that electric-magnetic duality holds true expressible in terms of Lagrange multiplier term

$$\int \Lambda_\alpha (J^{n\alpha} - K \epsilon^{n\alpha\beta\gamma} J_{\beta\gamma}) \sqrt{g_4} d^3x. \quad (13.4.35)$$

This gives a constraint force to the field equations and also a dependence on the induced 4-metric so that one has only almost topological QFT. This term also guarantees the  $M^4$  part of WCW Kähler metric is non-trivial. The condition that the ends of space-time sheet and wormhole throats are extrema of Chern-Simons action subject to the electric-magnetic duality constraint is strongly suggested by the effective 2-dimensionality. Without the constraint term Chern-Simons action would vanish for its extremals so that Kähler function would be identically zero.

This term implies also an additional contribution to the modified gamma matrices besides the contribution coming from Chern-Simons action so that the first guess for the modified Dirac operator would not be quite correct. This contribution is of exactly of the same general form as the contribution for any general coordinate invariant action. The dependence of the induced metric on  $M^4$  degrees of freedom guarantees that also  $M^4$  gamma matrices are present. In the following this term will not be considered.

3. When the contribution of the constraint term to the modified gamma matrices is neglected, the explicit expression of the modified Dirac operator  $D_{C-S}$  associated with the Chern-Simons term is given by

$$\begin{aligned}
D &= \hat{\Gamma}^\mu D_\mu + \frac{1}{2} D_\mu \hat{\Gamma}^\mu , \\
\hat{\Gamma}^\mu &= \frac{\partial L_{C-S}}{\partial_\mu h^k} \Gamma_k = \epsilon^{\mu\alpha\beta} [2J_{kl} \partial_\alpha h^l A_\beta + J_{\alpha\beta} A_k] \Gamma^k D_\mu , \\
D_\mu \hat{\Gamma}^\mu &= B_K^\alpha (J_{k\alpha} + \partial_\alpha A_k) , \\
B_K^\alpha &= \epsilon^{\alpha\beta\gamma} J_{\beta\gamma} , \quad J_{k\alpha} = J_{kl} \partial_\alpha s^l , \quad \hat{\epsilon}^{\alpha\beta\gamma} = \epsilon^{\alpha\beta\gamma} \sqrt{g_3} .
\end{aligned} \tag{13.4.36}$$

For the extremals of Chern-Simons action one has  $D_\alpha \hat{\Gamma}^\alpha = 0$ . Analogous condition holds true when the constraining contribution to the modified gamma matrices is added.

### 3. Generalized eigenvalue equation for Chern-Simons Dirac action

Consider now the Chern-Simons Dirac equation in more detail assuming that the inclusion of the constraint contribution to the modified gamma matrices does not induce any complications. Assume also extremal property for Chern-Simons action with constraint term and Beltrami flow property.

1. For the extremals the Chern-Simons Dirac operator (constraint term not included) reduces to a one-dimensional Dirac operator

$$D_{C-S} = \hat{\epsilon}^{r\alpha\beta} [2J_{k\alpha} A_\beta + J_{\alpha\beta} A_k] \Gamma^k D_r . \tag{13.4.37}$$

Constraint term implies only a modification of the modified gamma matrices but the form of the operator remains otherwise same when extrema are in question so that one has  $D_\alpha \hat{\Gamma}^\alpha = 0$ .

2. For the extremals of Chern-Simons action the general solution of the modified Chern-Simons Dirac equation ( $\lambda^k = 0$ ) is covariantly constant with respect to the coordinate  $r$ :

$$D_r \Psi = 0 . \tag{13.4.38}$$

The solution to this condition can be written immediately in terms of a non-integrable phase factor  $P \exp(i \int A_r dr)$ , where integration is along curve with constant transversal coordinates. If  $\hat{\Gamma}^v$  is light-like vector field also  $\hat{\Gamma}^v \Psi_0$  defines a solution of  $D_{C-S}$ . This solution corresponds to a zero mode for  $D_{C-S}$  and does not contribute to the Dirac determinant (suggested to give rise to

the exponent of Kähler function identified as Kähler action). Note that the dependence of these solutions on transversal coordinates of  $X_l^3$  is arbitrary which conforms with the hydrodynamic picture. The solutions of Chern-Simons-Dirac are obtained by similar integration procedure also when extremals are not in question.

The formal solution associated with a general eigenvalue  $\lambda$  can be constructed by integrating the eigenvalue equation separately along all coordinate curves. This makes sense if  $r$  indeed assigned to possibly light-like flow lines of  $B^\alpha$  or more general Beltrami field possible induced by the constraint term. There are very strong consistency conditions coming from the conditions that  $\Psi$  in the interior is constant along the flow lines of Kähler current and continuous at the ends and throats (call them collectively boundaries), where  $\Psi$  has a non-trivial variation along the flow lines of  $B^\alpha$ .

1. This makes sense only if the flow lines of the Kähler current are transversal to the boundaries so that the spinor modes at boundaries dictate the modes of the spinor field in the interior. Effective 2-dimensionality means that the spinor modes in the interior can be calculated either by starting from the throats or from the ends so that the data at either upper or lower partonic 2-surfaces dictates everything in accordance with zero energy ontology.
2. This gives an infinite number of commuting diagrams stating that the flow-line time evolution along flow lines along wormhole throats from lower partonic 2-surface to the upper one is equivalent with the flow-line time evolution along the lower end of space-time surface to interior, then along interior to the upper end of the space-time surface and then back to the upper partonic 2-surface. If the space-time surface allows a slicing by partonic 2-surfaces these conditions can be assumed for any pair of partonic 2-surfaces connected by Chern-Simons flow evolution.
3. Since the time evolution along interior keeps the spinor field as constant in the proper gauge and since the flow evolutions at the lower and upper ends are in a reverse direction, there is a strong attemptation to assume that the spinor field at the ends of the of the flow lines of Kähler magnetic field are identical apart from a gauge transformation. This leads to a particle-in-box quantization of the values of the pseudo-mass (periodic boundary conditions). These conditions will be assumed in the sequel.

These assumptions lead to the following picture about the generalized eigen modes.

1. By choosing the gauge so that covariant derivative reduces to ordinary derivative and using the constancy of  $\hat{\Gamma}^r$ , the solution of the generalized eigenvalue equation can be written as

$$\begin{aligned} \Psi &= \exp(iL(r)\hat{\Gamma}^r\lambda^k\Gamma_k)\Psi_0 , \\ L(r) &= \int_0^r \frac{1}{\sqrt{\hat{g}^{rr}}} dr . \end{aligned} \quad (13.4.39)$$

$L(r)$  can be regarded as the along flux line as defined by the effective metric defined by modified gamma matrices. If  $\lambda_k$  is linear combination of  $\Gamma^0$  and  $\Gamma^{rM}$  it anti-commutes with  $\Gamma^r$  which contains only  $CP_2$  gamma matrices so that the pseudo-momentum is a priori arbitrary.

2. When the constraint term taking care of the electric-magnetic duality is included, also  $M^4$  gamma matrices are present. If they are in the orthogonal complement of a preferred plane  $M^2 \subset M^4$ , anti-commutativity is achieved. This assumption cannot be fully justified yet but conforms with the general physical vision. There is an obvious analogy with the condition that polarizations are in a plane orthogonal to  $M^2$ . The condition indeed states that only transversal deformations define quantum fluctuating WCW degrees of freedom contributing to the WCW Kähler metric. In  $M^8-H$  duality the preferred plane  $M^2$  is interpreted as a hyper-complex plane belonging to the tangent space of the space-time surface and defines the plane of non-physical polarizations. Also a generalization of this plane to an integrable distribution of planes  $M^2(x)$  has been proposed and one must consider also now the possibility of a varying plane  $M^2(x)$  for the pseudo-momenta. The scalar function  $\Phi$  appearing in the general solution ansatz for the field equations satisfies massless d'Alembert equation and its gradient defines a local light-like

direction at space-time-level and hence a 2-D plane of the tangent space. Maybe the projection of this plane to  $M^4$  could define the preferred  $M^2$ . The minimum condition is that these planes are defined only at the ends of space-time surface and at wormhole throats.

3. If one accepts this hypothesis, one can write

$$\begin{aligned}\Psi &= \left[ \cos(L(r)\lambda) + i \sin(\lambda(r)) \hat{\Gamma}^r \lambda^k \Gamma_k \right] \Psi_0 , \\ \lambda &= \sqrt{\lambda_k \lambda^k} .\end{aligned}\tag{13.4.40}$$

4. Boundary conditions should fix the spectrum of masses. If the the flow lines of Kähler current coincide with the flow lines of Kähler magnetic field or more general Beltrami current at wormhole throats one ends up with difficulties since the induced spinor fields must be constant along flow lines and only trivial eigenvalues are possible. Hence it seems that the two Beltrami fields must be transversal. This requires that at the partonic 2-surfaces the value of the induced spinor mode in the interior coincides with its value at the throat. Since the induced spinor fields in interior are constant along flow lines, one must have

$$\exp(i\lambda L(r_{max})) = 1 .\tag{13.4.41}$$

This implies that one has essentially particle in a box with size defined by the effective metric

$$\lambda_n = \frac{n2\pi}{L(r_{max})} .\tag{13.4.42}$$

5. This condition cannot however hold true simultaneously for all points of the partonic 2-surfaces since  $L(r_{max})$  depends on the point of the surface. In the most general case one can consider only a subset consisting of the points for which the values of  $L(r_{max})$  are rational multiples of the value of  $L(r_{max})$  at one of the points -call it  $L_0$ . This implies the notion of number theoretical braid. Induced spinor fields are localized to the points of the braid defined by the flow lines of the Kähler magnetic field (or equivalently, any conserved current- this resolves the longstanding issue about the identification of number theoretical braids). The number of the included points depends on measurement resolution characterized somehow by the number rationals which are allowed. Only finite number of harmonics and sub-harmonics of  $L_0$  are possible so that for integer multiples the number of points is finite. If  $n_{max}L_0$  and  $L_0/n_{min}$  are the largest and smallest lengths involved, one can argue that the rationals  $n_{max}/n$ ,  $n = 1, \dots, n_{max}$  and  $n/n_{min}$ ,  $n = 1, \dots, n_{min}$  are the natural ones.
6. One can consider also algebraic extensions for which  $L_0$  is scaled from its reference value by an algebraic number so that the mass scale  $m$  must be scaled up in similar manner. The spectrum comes also now in integer multiples. p-Adic mass calculations predicts mass scales to the inverses of square roots of prime and this raises the expectation that  $\sqrt{n}$  harmonics and sub-harmonics of  $L_0$  might be necessary. Notice however that pseudo-momentum spectrum is in question so that this argument is on shaky grounds.

There is also the question about the allowed values of  $(\lambda_0, \lambda_3)$  for a given value of  $\lambda$ . This issue will be discussed in the next section devoted to the attempt to calculate the Dirac determinant assignable to this spectrum: suffice it to say that integer valued spectrum is the first guess implying that the pseudo-momenta satisfy  $n_0^2 - n_3^2 = n^2$  and therefore correspond to Pythagorean triangles. What is remarkable that the notion of number theoretic braid pops up automatically from the Beltrami flow hypothesis.

## 13.5 How to define Dirac determinant?

The basic challenge is to define Dirac determinant hoped to give rise to the exponent of Kähler action associated with the preferred extremal. The reduction to almost topological QFT gives this kind of expression in terms of Chern-Simons action and one might hope of obtaining even more concrete expression from the Chern-Simons Dirac determinant. The calculation of the previous section allowed to calculate the most general spectrum of the modified Dirac operator. If the number of the eigenvalues is infinite as the naive expectation is then Dirac determinant diverges if calculated as the product of the eigenvalues and one must calculate it by using some kind of regularization procedure. Zeta function regularization is the natural manner to do this.

The following arguments however lead to a concrete vision how the regularization could be avoided and a connection with infinite primes. In fact, the manifestly finite option and the option involving zeta function regularization give Kähler functions differing only by a scaling factor and only the manifestly finite option satisfies number theoretical constraints coming from p-adicization. An explicit expression for the Dirac determinant in terms of geometric data of the orbit of the partonic 2-surface emerges.

Arithmetic quantum field theory defined by infinite primes emerges naturally. The lines of the generalized Feynman graphs are characterized by infinite primes and the selection rules correlating the geometries of the lines of the generalized Feynman graphs corresponds to the conservation of the sum of number theoretic momenta  $\log(p_i)$  assignable to sub-braids corresponding to different primes  $p_i$  assignable to the orbit of parton. This conforms with the vision that infinite primes indeed characterize the geometry of light-like 3-surfaces and therefore also of space-time sheets. The eigenvalues of the modified Dirac operator are proportional  $1/\sqrt{p_i}$  where  $p_i$  are the primes appearing in the definition of the p-adic prime and the interpretation as analogs of Higgs vacuum expectation values makes sense and is consistent with p-adic length scale hypothesis and p-adic mass calculations. It must be emphasized that all this is essentially due to single basic hypothesis, namely the reduction of quantum TGD to almost topological QFT guaranteed by the Beltrami ansatz for field equations and by the weak form of electric-magnetic duality.

### 13.5.1 Dirac determinant when the number of eigenvalues is infinite

At first sight the general spectrum looks the only reasonable possibility but if the eigenvalues correlate with the geometry of the partonic surface as quantum classical correspondence suggests, this conclusion might be wrong. The original hope was the number of eigenvalues would be finite so that also determinant would be finite automatically. There were some justifications for this hope in the definition of Dirac determinant based on the dimensional reduction of  $D_K$  as  $D_K = D_{K,3} + D_1$  and the identification of the generalized eigenvalues as those assigned to  $D_{K,3}$  as analogs of energy eigenvalues assignable to the light-like 3-surface. It will be found that number theoretic input could allow to achieve a manifest finiteness in the case of  $D_{C-S}$  and that this option is the only possible one if number theoretic universality is required.

If there are no constraints on the eigenvalue spectrum of  $D_{C-S}$  for a given partonic orbit, the naive definition of the determinant gives an infinite result and one must define Dirac determinant using  $\zeta$  function regularization implying that Kähler function reduces to the derivative of the zeta function  $\zeta_D(s)$  -call it Dirac Zeta- associated with the eigenvalue spectrum.

Consider now the situation when the number of eigenvalues is infinite.

1. In this kind of situation zeta function regularization is the standard manner to define the Dirac determinant. What one does is to assign zeta function to the spectrum- let us call it Dirac zeta function and denote by  $\zeta_D(s)$ - as

$$\zeta_D(s) = \sum_k \lambda_k^{-s} . \quad (13.5.1)$$

If the eigenvalue  $\lambda_k$  has degeneracy  $g_k$  it appears  $g_k$  times in the sum. In the case of harmonic oscillator one obtains Riemann zeta for which sum representation converges only for  $Re(s) \geq 1$ . Riemann zeta can be however analytically continued to the entire complex plane and the idea is that this can be done also in the more general case.

2. By the basic conjecture Kähler function corresponds to the logarithm of the Dirac determinant and equals to the sum of the logarithms of the eigenvalues

$$K = \log\left(\prod \lambda_k\right) = -\frac{d\zeta_D}{ds} \Big|_{s=0} . \quad (13.5.2)$$

The expression on the left hand side diverges if taken as such but the expression on the right had side based on the analytical continuation of the zeta function is completely well-defined and finite quantity. Note that the replacement of eigenvalues  $\lambda_k$  by their powers  $\lambda_k^n$  -or equivalently the increase of the degeneracy by a factor  $n$  - brings in only a factor  $n$  to  $K$ :  $K \rightarrow nK$ .

3. Dirac determinant involves in the minimal situation only the integer multiples of pseudo-mass scale  $\lambda = 2\pi/L_{min}$ . One can consider also rational and even algebraic multiples  $qL_{min} < L_{max}$ ,  $q \geq 1$ , of  $L_{min}$  so that one would have several integer spectra simultaneously corresponding to different braids. Here  $L_{min}$  and  $L_{max}$  are the extrema of the braid strand length determined in terms of the effective metric as  $L = \int (\hat{g}^{rr})^{-1/2} dr$ . The question what multiples are involved will be needed later.
4. Each rational or algebraic multiple of  $L_{min}$  gives to the zeta function a contribution which is of same form so that one has

$$\zeta_D = \sum_q \zeta(\log(qx)s) , \quad x = \frac{L_{min}}{R} , \quad 1 \leq q < \frac{L_{max}}{L_{min}} . \quad (13.5.3)$$

Kähler function can be expressed as

$$K = \sum_n \log(\lambda_n) = -\frac{d\zeta_D(s)}{ds} = -\sum_q \log(qx) \frac{d\zeta(s)}{ds} \Big|_{s=0} , \quad x = \frac{L_{min}}{R} . \quad (13.5.4)$$

What is remarkable that the number theoretical details of  $\zeta_D$  determine only the overall scaling factor of Kähler function and thus the value of Kähler coupling strength, which would be purely number theoretically determined if the hypothesis about the role of infinite primes is correct. Also the value of  $R$  is irrelevant since it does not affect the Kähler metric.

5. The dependence of Kähler function on WCW degrees of freedom would be coded completely by the dependence of the length scales  $qL_{min}$  on the complex coordinates of WCW: note that this dependence is different for each scale. This is reminiscent of the coding of the shape of the drum (or more generally - manifold) by the spectrum of its eigen frequencies. Now Kähler geometry would code for the dependence of the spectrum on the shape of the drum defined by the partonic 2-surface and the 4-D tangent space distribution associated with it.

What happens at the limit of vacuum extremals serves as a test for the identification of Kähler function as Dirac determinant. The weak form of electric magnetic duality implies that all components of the induced Kähler field vanish simultaneously if Kähler magnetic field cancels. In the modified Chern-Simons Dirac equation one obtains  $L = \int (\hat{g}^{rr})^{-1/2} dr$ . The modified gamma matrix  $\hat{\Gamma}^r$  approaches a finite limit when Kähler magnetic field vanishes

$$\hat{\Gamma}^r = \epsilon^{r\beta\gamma} (2J_{\beta k} A_\gamma + J_{\beta\gamma} A_k) \Gamma^k \rightarrow 2\epsilon^{r\beta\gamma} J_{\beta k} \Gamma^k . \quad (13.5.5)$$

The relevant component of the effective metric is  $\hat{g}^{rr}$  and is given by

$$\hat{g}^{rr} = (\hat{\Gamma}^r)^2 = 4\epsilon^{r\beta\gamma} \epsilon^{r\mu\nu} J_{\beta k} J_\mu{}^k A_\gamma A_\nu . \quad (13.5.6)$$

The limit is non-vanishing in general and therefore the eigenvalues remain finite also at this limit as also the parameter  $L_{min} = \int (\hat{g}^{rr})^{-1/2} dr$  defining the minimum of the length of the braid strand defined by Kähler magnetic flux line in the effective metric unless  $\hat{g}^{rr}$  goes to zero everywhere inside the partonic surface. Chern-Simons action and Kähler action vanish for vacuum extremals so that in this case one could require that Dirac determinant approaches to unity in a properly chosen gauge. Dirac determinant should approach to unit for vacuum extremals indeed approaches to unity since there are no finite eigenvalues at the limit  $\hat{g}^{rr} = 0$ .

### 13.5.2 Hyper-octonionic primes

Before detailed discussion of the hyper-octonionic option it is good to consider the basic properties of hyper-octonionic primes.

1. Hyper-octonionic primes are of form

$$\Pi_p = (n_0, n_3, n_1, n_2, \dots, n_7) , \quad \Pi_p^2 = n_0^2 - \sum_i n_i^2 = p \text{ or } p^2 . \quad (13.5.7)$$

2. Hyper-octonionic primes have a standard representation as hyper-complex primes. The Minkowski norm squared factorizes into a product as

$$n_0^2 - n_3^2 = (n_0 + n_3)(n_0 - n_3) . \quad (13.5.8)$$

If one has  $n_3 \neq 0$ , the prime property implies  $n_0 - n_3 = 1$  so that one obtains  $n_0 = n_3 + 1$  and  $2n_3 + 1 = p$  giving

$$(n_0, n_3) = ((p+1)/2, (p-1)/2) . \quad (13.5.9)$$

Note that one has  $(p+1)/2$  odd for  $p \bmod 4 = 1$  and  $(p+1)/2$  even for  $p \bmod 4 = 3$ . The difference  $n_0 - n_3 = 1$  characterizes prime property.

If  $n_3$  vanishes the prime property implies equivalence with ordinary prime and one has  $n_0^2 = p^2$ . These hyper-octonionic primes represent particles at rest.

3. The action of a discrete subgroup  $G(p)$  of the octonionic automorphism group  $G_2$  generates form hyper-complex primes with  $n_3 \neq 0$  further hyper-octonionic primes  $\Pi(p, k)$  corresponding to the same value of  $n_0$  and  $p$  and for these the integer valued projection to  $M^2$  satisfies  $n_0^2 - n_3^2 = n > p$ . It is also possible to have a state representing the system at rest with  $(n_0, n_3) = ((p+1)/2, 0)$  so that the pseudo-mass varies in the range  $[\sqrt{p}, (p+1)/2]$ . The subgroup  $G(n_0, n_3) \subset SU(3)$  leaving invariant the projection  $(n_0, n_3)$  generates the hyper-octonionic primes corresponding to the same value of mass for hyper-octonionic primes with same Minkowskian length  $p$  and pseudo-mass  $\lambda = n \geq \sqrt{p}$ .
4. One obtains two kinds of primes corresponding to the lengths of pseudo-momenta equal to  $p$  or  $\sqrt{p}$ . The first kind of particles are always at rest whereas the second kind of particles can be brought at rest only if one interprets the pseudo-momentum as  $M^2$  projection. This brings in mind the secondary p-adic length scales assigned to causal diamonds (CDs) and the primary p-adic lengths scales assigned to particles.

If the  $M^2$  projections of hyper-octonionic primes with length  $\sqrt{p}$  characterize the allowed basic momenta,  $\zeta_D$  is sum of zeta functions associated with various projections which must be in the limits dictated by the geometry of the orbit of the partonic surface giving upper and lower bounds  $L_{max}$  and  $L_{min}$  on the length  $L$ .  $L_{min}$  is scaled up to  $\sqrt{n_0^2 - n_3^2} L_{min}$  for a given projection  $(n_0, n_3)$ . In general a given  $M^2$  projection  $(n_0, n_3)$  corresponds to several hyper-octonionic primes since  $SU(3)$  rotations give a new hyper-octonionic prime with the same  $M^2$  projection. This leads to an inconsistency unless one has a good explanation for why some basic momentum can appear several times. One might argue that the spinor mode is degenerate due to the possibility to perform discrete color rotations of the state. For hyper complex representatives there is no such problem and it seems favored. In any case, one can look how the degeneracy factors for given projection can be calculated.

1. To calculate the degeneracy factor  $D(n)$  associated with given pseudo-mass value  $\lambda = n$  one must find all hyper-octonionic primes  $\Pi$ , which can have projection in  $M^2$  with length  $n$  and sum up the degeneracy factors  $D(n, p)$  associated with them:

$$\begin{aligned}
 D(n) &= \sum_p D(n, p) \ , \\
 D(n, p) &= \sum_{n_0^2 - n_3^2 = p} D(p, n_0, n_3) \ , \\
 n_0^2 - n_3^2 &= n \ , \ \Pi_p^2(n_0, n_3) = n_0^2 - n_3^2 - \sum_i n_i^2 = n - \sum_i n_i^2 = p \ .
 \end{aligned}
 \tag{13.5.10}$$

2. The condition  $n_0^2 - n_3^2 = n$  allows only Pythagorean triangles and one must find the discrete subgroup  $G(n_0, n_3) \subset SU(3)$  producing hyper-octonions with integer valued components with length  $p$  and components  $(n_0, n_3)$ . The points at the orbit satisfy the condition

$$\sum n_i^2 = p - n \ .
 \tag{13.5.11}$$

The degeneracy factor  $D(p, n_0, n_3)$  associated with given mass value  $n$  is the number of elements of in the coset space  $G(n_0, n_3, p)/H(n_0, n_3, p)$ , where  $H(n_0, n_3, p)$  is the isotropy group of given hyper-octonionic prime obtained in this manner. For  $n_0^2 - n_3^2 = p^2$   $D(n_0, n_3, p)$  obviously equals to unity.

### 13.5.3 Three basic options for the pseudo-momentum spectrum

The calculation of the scaling factor of the Kähler function requires the knowledge of the degeneracies of the mass squared eigen values. There are three options to consider.

#### First option: all pseudo-momenta are allowed

If the degeneracy for pseudo-momenta in  $M^2$  is same for all mass values- and formally characterizable by a number  $N$  telling how many 2-D pseudo-momenta reside on mass shell  $n_0^2 - n_3^2 = m^2$ . In this case zeta function would be proportional to a sum of Riemann Zetas with scaled arguments corresponding to scalings of the basic mass  $m$  to  $m/q$ .

$$\zeta_D(s) = N \sum_q \zeta(\log(qx)s) \ , \ x = \frac{L_{min}}{R} \ .
 \tag{13.5.12}$$

This option provides no idea about the possible values of  $1 \leq q \leq L_{max}/L_{min}$ . The number  $N$  is given by the integral of relativistic density of states  $\int dk/2\sqrt{k^2 + m^2}$  over the hyperbola and is logarithmically divergent so that the normalization factor  $N$  of the Kähler function would be infinite.

### Second option: All integer valued pseudomomenta are allowed

Second option is inspired by number theoretic vision and assumes integer valued components for the momenta using  $m_{max} = 2\pi/L_{min}$  as mass unit. p-Adicization motivates also the assumption that momentum components using  $m_{max}$  as mass scale are integers. This would restrict the choice of the number theoretical braids.

Integer valuedness together with masses coming as integer multiples of  $m_{max}$  implies  $(\lambda_0, \lambda_3) = (n_0, n_3)$  with on mass shell condition  $n_0^2 - n_3^2 = n^2$ . Note that the condition is invariant under scaling. These integers correspond to Pythagorean triangles plus the degenerate situation with  $n_3 = 0$ . There exists a finite number of pairs  $(n_0, n_3)$  satisfying this condition as one finds by expressing  $n_0$  as  $n_0 = n_3 + k$  giving  $2n_3k + k^2 = p^2$  giving  $n_3 < n^2/2, n_0 < n^2/2 + 1$ . This would be enough to have a finite degeneracy  $D(n) \geq 1$  for a given value of mass squared and  $\zeta_D$  would be well defined.  $\zeta_D$  would be a modification of Riemann zeta given by

$$\begin{aligned}\zeta_D &= \sum_q \zeta_1(\log(qx)s) , \quad x = \frac{L_{min}}{R} , \\ \zeta_1(s) &= \sum g_n n^{-s} , \quad g_n \geq 1 .\end{aligned}\tag{13.5.13}$$

For generalized Feynman diagrams this option allows conservation of pseudo-momentum and for loops no divergences are possible since the integral over two-dimensional virtual momenta is replaced with a sum over discrete mass shells containing only a finite number of points. This option looks thus attractive but requires a regularization. On the other hand, the appearance of a zeta function having a strong resemblance with Riemann zeta could explain the finding that Riemann zeta is closely related to the description of critical systems. This point will be discussed later.

### Third option: Infinite primes code for the allowed mass scales

According to the proposal of [70] , [8] the hyper-complex parts of hyper-octonionic primes appearing in their infinite counterparts correspond to the  $M^2$  projections of real four-momenta. This hypothesis suggests a very detailed map between infinite primes and standard model quantum numbers and predicts a universal mass spectrum [70] . Since pseudo-momenta are automatically restricted to the plane  $M^2$ , one cannot avoid the question whether they could actually correspond to the hyper-octonionic primes defining the infinite prime. These interpretations need not of course exclude each other. This option allows several variants and at this stage it is not possible to exclude any of these options.

1. One must choose between two alternatives for which pseudo-momentum corresponds to hyper-complex prime serving as a canonical representative of a hyper-octonionic prime or a projection of hyper-octonionic prime to  $M^2$ .
2. One must decide whether one allows a) only the momenta corresponding to hyper-complex primes, b) also their powers (p-adic fractality), or c) all their integer multiples ("Riemann option").

One must also decide what hyper-octonionic primes are allowed.

1. The first guess is that all hyper-complex/hyper-octonionic primes defining length scale  $\sqrt{p}L_{min} \leq L_{max}$  or  $pL_{min} \leq L_{max}$  are allowed. p-Adic fractality suggests that also the higher p-adic length scales  $p^{n/2}L_{min} < L_{max}$  and  $p^n L_{min} < L_{max}$ ,  $n \geq 1$ , are possible.

It can however happen that no primes are allowed by this criterion. This would mean vanishing Kähler function which is of course also possible since Kähler action can vanish (for instance, for massless extremals). It seems therefore safer to allow also the scale corresponding to the trivial prime  $(n_0, n_3) = (1, 0)$  (1 is formally prime because it is not divisible by any prime different from 1) so that at least  $L_{min}$  is possible. This option also allows only rather small primes unless the partonic 2-surface contains vacuum regions in which case  $L_{max}$  is infinite: in this case all primes would be allowed and the exponent of Kähler function would vanish.

2. The hypothesis that only the hyper-complex or hyper-octonionic primes appearing in the infinite hyper-octonionic prime are possible looks more reasonable since large values of  $p$  would be possible and could be identified in terms of the p-adic length scale hypothesis. All hyper-octonionic primes appearing in infinite prime would be possible and the geometry of the orbit of the partonic 2-surface would define an infinite prime. This would also give a concrete physical interpretation for the earlier hypothesis that hyper-octonionic primes appearing in the infinite prime characterize partonic 2-surfaces geometrically. One can also identify the fermionic and purely bosonic primes appearing in the infinite prime as braid strands carrying fermion number and purely bosonic quantum numbers. This option will be assumed in the following.

### 13.5.4 Expression for the Dirac determinant for various options

The expressions for the Dirac determinant for various options can be deduced in a straightforward manner. Numerically Riemann option and manifestly finite option do not differ much but their number theoretic properties are totally different.

#### Riemann option

All integer multiples of these basic pseudo-momenta would be allowed for Riemann option so that  $\zeta_D$  would be sum of Riemann zetas with arguments scaled by the basic pseudo-masses coming as inverses of the basic length scales for braid strands. For the option involving only hyper-complex primes the formula for  $\zeta_D$  reads as

$$\zeta_D = \zeta(\log(x_{min}s)) + \sum_{i,n} \zeta(\log(x_{i,n}s)) + \sum_{i,n} \zeta(\log(y_{i,n}s)) ,$$

$$x_{i,n} = p_i^{n/2} x_{min} \leq x_{max} , \quad p_i \geq 3 , \quad y_{i,n} = p_i^n x_{min} \leq x_{max} \cdot p_i \geq 2 ,$$
(13.5.14)

$L_{max}$  resp.  $L_{min}$  is the maximal resp. minimal length  $L = \int (\hat{g}^{rr})^{-1/2} dr$  for the braid strand defined by the flux line of the Kähler magnetic field in the effective metric. The contributions correspond to the effective hyper-complex prime  $p_1 = (1, 0)$  and hyper-complex primes with Minkowski lengths  $\sqrt{p}$  ( $p \geq 3$ ) and  $p$ ,  $p \geq 2$ . If also higher p-adic length scales  $L_n = p^{n/2} L_{min} < L_{max}$  and  $L_n = p^n L_{min} < L_{max}$ ,  $n > 1$ , are allowed there is no further restriction on the summation. For the restricted option only  $L_n$ ,  $n = 0, 2$  is allowed.

The expressions for the Kähler function and its exponent reads as

$$K = k(\log(x_{min}) + \sum_i \log(x_i) + \sum_i \log(y_i)) ,$$

$$\exp(K) = \left(\frac{1}{x_{min}}\right)^k \times \prod_i \left(\frac{1}{x_i}\right)^k \times \prod_i \left(\frac{1}{y_i}\right)^k ,$$

$$x_i \leq x_{max} , \quad y_i \leq x_{max} , \quad k = -\frac{d\zeta(s)}{ds} \Big|_{s=0} = \frac{1}{2} \log(2\pi) \simeq .9184 .$$
(13.5.15)

From the point of view of p-adicization program the appearance of strongly transcendental numbers in the normalization factor of  $\zeta_D$  is not a well-come property.

If the scaling of the WCW Kähler metric by  $1/k$  is a legitimate procedure it would allow to get rid of the transcendental scaling factor  $k$  and this scaling would cancel also the transcendental from the exponent of Kähler function. The scaling is not however consistent with the view that Kähler coupling strength determines the normalization of the WCW metric.

This formula generalizes in a rather obvious manner to the cases when one allows  $M^2$  projections of hyper-octonionic primes.

### Manifestly finite options

The options for which one does not allow summation over all integer multiples of the basic momenta characterized by the canonical representatives of hyper-complex primes or their projections to  $M^2$  are manifestly finite. They differ from the Riemann option only in that the normalization factor  $k \simeq .9184$  defined by the derivative Riemann Zeta at origin is replaced with  $k = 1$ . This would mean manifest finiteness of  $\zeta_D$ . Kähler function and its exponent are given by

$$\begin{aligned}
 K &= k(\log(x_{min}) + \sum_i \log(x_i) + \sum_i \log(y_i)) , \quad x_i \leq x_{max} , \quad y_i \leq x_{max} , \\
 exp(K) &= \frac{1}{x_{min}} \times \prod_i \frac{1}{x_i} \times \prod_i \frac{1}{y_i} .
 \end{aligned}
 \tag{13.5.16}$$

Numerically the Kähler functions do not differ much since their ratio is .9184. Number theoretically these functions are however completely different. The resulting dependence involves only square roots of primes and is an algebraic function of the lengths  $p_i$  and rational function of  $x_{min}$ . p-Adicization program would require rational values of the lengths  $x_{min}$  in the intersection of the real and p-adic worlds if one allows algebraic extension containing the square roots of the primes involved. Note that in p-adic context this algebraic extension involves two additional square roots for  $p > 2$  if one does not want square root of  $p$ . Whether one should allow for  $R_p$  also extension based on  $\sqrt{p}$  is not quite clear. This would give 8-D extension.

For the more general option allowing all projections of hyper-complex primes to  $M^2$  the general form of Kähler function is same. Instead of pseudo-masses coming as primes and their square roots one has pseudomasses coming as square roots of some integers  $n \leq p$  or  $n \leq p^2$  for each  $p$ . In this case the conservation laws are not so strong.

Note that in the case of vacuum extremals  $x_{min} = \infty$  holds true so that there are no primes satisfying the condition and Kähler function vanishes as it indeed should.

### More concrete picture about the option based on infinite primes

The identification of pseudo-momenta in terms of infinite primes suggests a rather concrete connection between number theory and physics.

1. One could assign the finite hyper-octonionic primes  $\Pi_i$  making the infinite prime to the sub-braids identified as Kähler magnetic flux lines with the same length  $L$  in the effective metric. The primes assigned to the finite part of the infinite prime correspond to single fermion and some number of bosons. The primes assigned to the infinite part correspond to purely bosonic states assignable to the purely bosonic braid strands. Purely bosonic state would correspond to the action of a WCW Hamiltonian to the state.

This correspondence can be expanded to include all quantum numbers by using the pair of infinite primes corresponding to the "vacuum primes"  $X \pm 1$ , where  $X$  is the product of all finite primes [70]. The only difference with respect to the earlier proposal is that physical momenta would be replaced by pseudo-momenta.

2. Different primes  $p_i$  appearing in the infinite prime would correspond to their own sub-braids. For each sub-braid there is a  $N$ -fold degeneracy of the generalized eigen modes corresponding to the number  $N$  of braid strands so that many particle states are possible as required by the braid picture.
3. The correspondence of infinite primes with the hierarchy of Planck constants could allow to understand the fermion-many boson states and many boson states assigned with a given finite prime in terms of many-particle states assigned to  $n_a$  and  $n_b$ -sheeted singular covering spaces of  $CD$  and  $CP_2$  assignable to the two infinite primes. This interpretation requires that only single p-adic prime  $p_i$  is realized as quantum state meaning that quantum measurement always selects a particular p-adic prime  $p_i$  (and corresponding sub-braid) characterizing the p-adicity of the quantum state. This selection of number field behind p-adic physics responsible for cognition looks very plausible.

4. The correspondence between pairs of infinite primes and quantum states [70] allows to interpret color quantum numbers in terms of the states associated with the representations of a finite subgroup of  $SU(3)$  transforming hyper-octonionic primes to each other and preserving the  $M^2$  pseudo-momentum. Same applies to  $SO(3)$ . The most natural interpretation is in terms of wave functions in the space of discrete  $SU(3)$  and  $SO(3)$  transforms of the partonic 2-surface. The dependence of the pseudo-masses on these quantum numbers is natural so that the projection hypothesis finds support from this interpretation.
5. The infinite prime characterizing the orbit of the partonic 2-surface would thus code which multiples of the basic mass  $2\pi/L_{min}$  are possible. Either the  $M^2$  projections of hyper-octonionic primes or their hyper-complex canonical representatives would fix the basic  $M^2$  pseudo-momenta for the corresponding number theoretic braid associated. In the reverse direction the knowledge of the light-like 3-surface, the  $CD$  and  $CP_2$  coverings, and the number of the allowed discrete  $SU(3)$  and  $SU(2)$  rotations of the partonic 2-surface would dictate the infinite prime assignable to the orbit of the partonic 2-surface.

One would also like to understand whether there is some kind of conservation laws associated with the pseudo-momenta at vertices. The arithmetic QFT assignable to infinite primes would indeed predict this kind of conservation laws.

1. For the manifestly finite option the ordinary conservation of pseudo-momentum conservation at vertices is not possible since the addition of pseudo-momenta does not respect the condition  $n_0 - n_3 = 1$ . In fact, this difference in the sum of hyper-complex prime momenta tells how many momenta are present. If one applies the conservation law to the sum of the pseudo-momenta corresponding to different primes and corresponding braids, one can have reactions in which the number of primes involved is conserved. This would give the selection rule  $\sum_1^N p_i = \sum_1^N p_f$ . These reactions have interpretation in terms of the geometry of the 3-surface representing the line of the generalized Feynman diagram.
2. Infinite primes define an arithmetic quantum field theory in which the total momentum defined as  $\sum n_i \log(p_i)$  is a conserved quantity. As matter fact, each prime  $p_i$  would define a separately conserved momentum so that there would be an infinite number of conservation laws. If the sum  $\sum_i \log(p_i)$  is conserved in the vertex, the primes  $p_i$  associated with the incoming particle are shared with the outgoing particles so that also the total momentum is conserved. This looks the most plausible option and would give very powerful number theoretical selection rules at vertices since the collection of primes associated with incoming line would be union of the collections associated with the outgoing lines and also total pseudo-momentum would be conserved.
3. For the both Riemann zeta option and manifestly finite options the arithmetic QFT associated with infinite primes would be realized at the level of pseudo-momenta meaning very strong selection rules at vertices coding for how the geometries of the partonic lines entering the vertex correlate. WCW integration would reduce for the lines of Feynman diagram to a sum over light-like 3-surfaces characterized by  $(x_{min}, x_{max})$  with a suitable weighting factor and the exponent of Kähler function would give an exponential damping as a function of  $x_{min}$ .

### Which option to choose?

One should be able to make two choices. One must select between hyper-complex representations and the projections of hyper-octonionic primes and between the manifestly finite options and the one producing Riemann zeta?

Hyper-complex option seems to be slightly favored over the projection option.

1. The appearance of the scales  $\sqrt{p_i} x_{min}$  and possibly also their  $p^n$  multiples brings in mind p-adic length scales coming as  $\sqrt{p^n}$  multiples of  $CP_2$  length scale. The scales  $p_i x_{min}$  associated with hyper-complex primes reducing to ordinary primes in turn bring in mind the size scales assignable to  $CD$ s. The hierarchy of Planck constants implies also  $\hbar/\hbar_0 = \sqrt{n_a n_b}$  multiples of these length scales but mass scales would not depend on  $n_a$  and  $n_b$  [71]. For large values of  $p$  the pseudo-momenta are almost light-like for hyper-complex option whereas the projection option allows also states at rest.

2. Hyper-complex option predicts that only the p-adic pseudo-mass scales appear in the partition function and is thus favored by the p-adic length scale hypothesis. Projection option predicts also the possibility of the mass scales (not all of them) coming as  $1/\sqrt{n}$ . These mass scales are however not predicted by the hierarchy of Planck constants.
3. The same pseudo-mass scale can appear several times for the projection option. This degeneracy corresponds to the orbit of the hyper-complex prime under the subgroup of  $SU(3)$  respecting integer property. Similar statement holds true in the case of  $SO(3)$ : these groups are assigned to the two infinite primes characterizing parton. The natural assignment of this degeneracy is to the discrete color rotational and rotational degrees associated with the partonic 2-surface itself rather than spinor modes at fixed partonic 2-surface. That the pseudo-mass would depend on color and angular momentum quantum numbers would make sense.

Consider next the arguments in favor of the manifestly finite option.

1. The manifestly finite option is admittedly more elegant than the one based on Riemann zeta and also guarantees that no additional loop summations over pseudo-momenta are present. The strongest support for the manifestly finite option comes from number theoretical universality.
2. One could however argue that the restriction of the pseudo-momenta to a finite number is not consistent with the modified Dirac-Chern-Simons equation. Quantum classical correspondence however implies correlation between the geometry of the partonic orbits and the pseudo-momenta and the summation over all prime valued pseudo-momenta is present but with a weighting factor coming from Kähler function implying exponential suppression.

The Riemann zeta option could be also defended.

1. The numerical difference of the normalization factors of the Kähler function is however only about 8 per cent and quantum field theorists might interpret the replacement the length scales  $x_i$  and  $y_i$  with  $x_i^d$  and  $y_i^d$ ,  $d \simeq .9184$ , in terms of an anomalous dimension of these length scales. Could one say that radiative corrections mean the scaling of the original preferred coordinates so that one could still have consistency with number theoretic universality?
2. Riemann zeta with a non-vanishing argument could have also other applications in quantum TGD. Riemann zeta has interpretation as a partition function and the zeros of partition functions have interpretation in terms of phase transitions. The quantum criticality of TGD indeed corresponds to a phase transition point. There is also experimental evidence that the distribution of zeros of zeta corresponds to the distribution of energies of quantum critical systems in the sense that the energies correspond to the imaginary parts of the zeros of zeta [38] .

The first explanation would be in terms of the analogs of the harmonic oscillator coherent states with integer multiple of the basic momentum taking the role of occupation number of harmonic oscillator and the zeros  $s = 1/2 + iy$  of  $\zeta$  defining the values of the complex coherence parameters. TGD inspired strategy for the proof of Riemann hypothesis indeed leads to the identification of the zeros as coherence parameters rather than energies as in the case of Hilbert-Polya hypothesis [63] and the vanishing of the zeta at zero has interpretation as orthogonality of the state with respect to the state defined by a vanishing coherence parameter interpreted as a tachyon. One should demonstrate that the energies of quantum states can correspond to the imaginary parts of the coherence parameters.

Second interpretation could be in terms of quantum critical zero energy states for which the "complex square root of density matrix" defines time-like entanglement coefficients of  $M$ -matrix. The complex square roots of the probabilities defined by the coefficient of harmonic oscillator states (perhaps identifiable in terms of the multiples of pseudo-momentum) in the coherent state defined by the zero of  $\zeta$  would define the  $M$ -matrix in this situation. Energy would correspond also now to the imaginary part of the coherence parameter. The norm of the state would be completely well-defined.

### Representation of configuration Kähler metric in terms of eigenvalues of $D_{C-S}$

A surprisingly concrete connection of the configuration space metric in terms of generalized eigenvalue spectrum of  $D_{C-S}$  results. From the general expression of Kähler metric in terms of Kähler function

$$G_{k\bar{l}} = \partial_k \partial_{\bar{l}} K = \frac{\partial_k \partial_{\bar{l}} \exp(K)}{\exp(K)} - \frac{\partial_k \exp(K)}{\exp(K)} \frac{\partial_{\bar{l}} \exp(K)}{\exp(K)}, \quad (13.5.17)$$

and from the expression of  $\exp(K) = \prod_i \lambda_i$  as the product of finite number of eigenvalues of  $D_{C-S}$ , the expression

$$G_{k\bar{l}} = \sum_i \frac{\partial_k \partial_{\bar{l}} \lambda_i}{\lambda_i} - \frac{\partial_k \lambda_i}{\lambda_i} \frac{\partial_{\bar{l}} \lambda_i}{\lambda_i} \quad (13.5.18)$$

for the configuration space metric follows. Here complex coordinates refer to the complex coordinates of configuration space. Hence the knowledge of the eigenvalue spectrum of  $D_{C-S}(X^3)$  as function of some complex coordinates of configuration space allows to deduce the metric to arbitrary accuracy. If the above arguments are correct the calculation reduces to the calculation of the derivatives of  $\log(\sqrt{p}L_{min}/R)$ , where  $L_{min}$  is the length of the Kähler magnetic flux line between partonic 2-surfaces with respect to the effective metric defined by the anti-commutators of the modified gamma matrices. Note that these length scales have different dependence on WCW coordinates so that one cannot reduce everything to  $L_{min}$ . Therefore one would have explicit representation of the basic building brick of WCW Kähler metric in terms of the geometric data associated with the orbit of the partonic 2-surface.

### The formula for the Kähler action of $CP_2$ type vacuum extremals is consistent with the Dirac determinant formula

The first killer test for the formula of Kähler function in terms of the Dirac determinant based on infinite prime hypothesis is provided by the action of  $CP_2$  type vacuum extremals. One of the first attempts to make quantitative predictions in TGD framework was the prediction for the gravitational constant. The argument went as follows.

1. For dimensional reasons gravitational constant must be proportional to p-adic length scale squared, where  $p$  characterizes the space-time sheet of the graviton. It must be also proportional to the square of the vacuum function for the graviton representing a line of generalized Feynman diagram and thus to the exponent  $\exp(-2K)$  of Kähler action for topologically condensed  $CP_2$  type vacuum extremals with very long projection. If topological condensation does not reduce much of the volume of  $CP_2$  type vacuum extremal, the action is just Kähler action for  $CP_2$  itself. This gives

$$\hbar_0 G = L_p^2 \exp(2L_K(CP_2)) = pR^2 \exp(2L_K(CP_2)). \quad (13.5.19)$$

2. Using as input the constraint  $\alpha_K \simeq \alpha_{em} \sim 1/137$  for Kähler coupling strengths coming from the comparison of the TGD prediction for the rotation velocity of distant galaxies around galactic nucleus and the p-adic mass calculation for the electron mass, one obtained the result

$$\exp(2L_K(CP_2)) = \frac{1}{p \times \prod_{p_i \leq 23} p_i}. \quad (13.5.20)$$

The product contains the product of all primes smaller than 24 ( $p_i \in \{2, 3, 5, 7, 11, 13, 17, 19, 23\}$ ). The expression for the Kähler function would be just of the form predicted by the Dirac determinant formula with  $L_{min}$  replaced with  $CP_2$  length scale. As a matter fact, this was the first indication that particles are characterized by several p-adic primes but that only one of them is "active". As explained, the number theoretical state function reduction explains this.

3. The same formula for the gravitational constant would result for any prime  $p$  but the value of Kähler coupling strength would depend on prime  $p$  logarithmically for this option. I indeed proposed that this formula fixes the discrete evolution of the Kähler coupling strength as function of p-adic prime from the condition that gravitational constant is renormalization group invariant quantity but gave up this hypothesis later. It is wisest to keep an agnostic attitude to this issue.
4. I also made numerous brave attempts to deduce an explicit formula for Kähler coupling strength. The general form of the formula is

$$\frac{1}{\alpha_K} = k \log(K^2), \quad K^2 = p \times 2 \times 3 \times 5 \dots \times 23 \quad . \quad (13.5.21)$$

The problem is the exact value of  $k$  cannot be known precisely and the guesses for its value depend on what one means with number theoretical universality. Should Kähler action be a rational number? Or is it Kähler function which is rational number (it is for the Dirac determinant option in this particular case). Is Kähler coupling strength  $g_K^2/4\pi$  or  $g_K^2$  a rational number? Some of the guesses were  $k = \pi/4$  and  $k = 137/107$ . The facts that the value of Kähler action for the line of a generalized diagram is not exactly  $CP_2$  action and the value of  $\alpha_K$  is not known precisely makes these kind of attempts hopeless in absence of additional ideas.

Also other elementary particles -in particular exchanged bosons- should involve the exponent of Kähler action for  $CP_2$  type vacuum extremal. Since the values of gauge couplings are gigantic as compared to the expression of the gravitational constant the value of Kähler action must be rather small form them.  $CP_2$  type vacuum extremals must be short in the sense that  $L_{min}$  in the effective metric is very short. Note however that the p-adic prime characterizing the particle according to p-adic mass calculations would be large also now. One can of course ask whether this p-adic prime characterizes the gravitational space-time sheets associated with the particle and not the particle itself. The assignment of p-adic mass calculations with thermodynamics at gravitational space-time sheets of the particle would be indeed natural. The value of  $\alpha_K$  would depend on  $p$  in logarithmic manner for this option. The topological condensation of could also eat a lot of  $CP_2$  volume for them.

### Eigenvalues of $D_{C-S}$ as vacuum expectations of Higgs field?

Infinite prime hypothesis implies the analog of p-adic length scale hypothesis but since pseudo-momenta are in question, this need not correspond to the p-adic length scale hypothesis for the actual masses justified by p-adic thermodynamics. Note also that  $L_{min}$  does not correspond to  $CP_2$  length scale. This is actually not a problem since the effective metric is not  $M^4$  metric and one can quite well consider the possibility that  $L_{min}$  corresponds to  $CP_2$  length scale in the the induced metric. The reason is that light-like 3- surface is in question the distance along the Kähler magnetic flux line reduces essentially to a distance along the partonic 2-surface having size scale of order  $CP_2$  length for the partonic 2-surfaces identified as wormhole throats. Therefore infinite prime can code for genuine p-adic length scales associated with the light-like 3-surface and quantum states would correspond by number theoretical state function reduction hypothesis to single ordinary prime.

Support for this identification comes also from the expression of gravitational constant deduced from p-adic length scale hypothesis. The result is that gravitational constant is assumed to be proportional to have the expression  $G = L_p^2 \exp(-2S_K(CP_2))$ , where  $p$  characterizes graviton or the space-time sheet mediating gravitational interaction and exponent gives Kähler action for  $CP_2$  type vacuum extremal representing graviton. The argument allows to identify the p-adic prime  $p = M_{127}$  associated with electron (largest Mersenne prime which does not correspond to super-astronomical length scale) as the p-adic prime characterizing also graviton. The exponent of Kähler action is proportional to  $1/p$  which conforms with the general expression for Kähler function. I have considered several identifications of the numerical factor and one of them has been as product of primes  $2 \leq p \leq 23$  assuming that somehow the primes  $\{2, \dots, 23, p\}$  characterize graviton. This guess is indeed consistent with the prediction of the infinite-prime hypothesis.

The first guess inspired by the p-adic mass calculations is that the squares  $\lambda_i^2$  of the eigenvalues of  $D_{C-S}$  could correspond to the conformal weights of ground states. Another natural physical

interpretation of  $\lambda$  is as an analog of the Higgs vacuum expectation. The instability of the Higgs=0 phase would correspond to the fact that  $\lambda = 0$  mode is not localized to any region in which electromagnetic field or induced Kähler field is non-vanishing. By the previous argument one would have order of magnitude estimate  $h_0 = \sqrt{2\pi/L_{min}}$ .

1. The vacuum expectation value of Higgs is only proportional to the scale of  $\lambda$ . Indeed, Higgs and gauge bosons as elementary particles correspond to wormhole contacts carrying fermion and anti-fermion at the two wormhole throats and must be distinguished from the space-time correlate of its vacuum expectation as something proportional to  $\lambda$ . For free fermions the vacuum expectation value of Higgs does not seem to be even possible since free fermions do not correspond to wormhole contacts between two space-time sheets but possess only single wormhole throat (p-adic mass calculations are consistent with this). If fermion suffers topological condensation as indeed assumed to do in interaction region, a wormhole contact is generated and makes possible the generation of Higgs vacuum expectation value.
2. Physical considerations suggest that the vacuum expectation of Higgs field corresponds to a particular eigenvalue  $\lambda_i$  of modified Chern-Simons Dirac operator so that the eigenvalues  $\lambda_i$  would define TGD counterparts for the minima of Higgs potential. For the minimal option one has only a finite number of pseudo-mass eigenvalues inversely proportional  $\sqrt{p}$  so that the identification as a Higgs vacuum expectation is consistent with the p-adic length scale hypothesis. Since the vacuum expectation of Higgs corresponds to a condensate of wormhole contacts giving rise to a coherent state, the vacuum expectation cannot be present for topologically condensed  $CP_2$  type vacuum extremals representing fermions since only single wormhole throat is involved. This raises a hen-egg question about whether Higgs contributes to the mass or whether Higgs is only a correlate for massivation having description using more profound concepts. From TGD point of view the most elegant option is that Higgs does not give rise to mass but Higgs vacuum expectation value accompanies bosonic states and is naturally proportional to  $\lambda_i$ . With this interpretation  $\lambda_i$  could give a contribution to both fermionic and bosonic masses.
3. If the coset construction for super-symplectic and super Kac-Moody algebra implying Equivalence Principle is accepted, one encounters what looks like a problem. p-Adic mass calculations require negative ground state conformal weight compensated by Super Virasoro generators in order to obtain massless states. The tachyonicity of the ground states would mean a close analogy with both string models and Higgs mechanism.  $\lambda_i^2$  is very natural candidate for the ground state conformal weights identified but would have wrong sign. Therefore it seems that  $\lambda_i^2$  can define only a deviation of the ground state conformal weight from negative value and is positive.
4. In accordance with this  $\lambda_i^2$  would give constant contribution to the ground state conformal weight. What contributes to the thermal mass squared is the deviation of the ground state conformal weight from half-odd integer since the negative integer part of the total conformal weight can be compensated by applying Virasoro generators to the ground state. The first guess motivated by cyclotron energy analogy is that the lowest conformal weights are of form  $h_c = -n/2 + \lambda_i^2$  where the negative contribution comes from Super Virasoro representation. The negative integer part of the net conformal weight can be canceled using Super Virasoro generators but  $\Delta h_c$  would give to mass squared a contribution analogous to Higgs contribution. The mapping of the real ground state conformal weight to a p-adic number by canonical identification involves some delicacies.
5. p-Adic mass calculations are consistent with the assumption that Higgs type contribution is vanishing (that is small) for fermions and dominates for gauge bosons. This requires that the deviation of  $\lambda_i^2$  with smallest magnitude from half-odd integer value in the case of fermions is considerably smaller than in the case of gauge bosons in the scale defined by p-adic mass scale  $1/L(k)$  in question. Somehow this difference could relate to the fact that bosons correspond to pairs of wormhole throats.

### Is there a connection between p-adic thermodynamics, hierarchy of Planck constants, and infinite primes

The following observations suggest that there might be an intrinsic connection between p-adic thermodynamics, hierarchy of Planck constants, and infinite primes.

1. p-Adic thermodynamics [41] is based on string mass formula in which mass squared is proportional to conformal weight having values which are integers apart from the contribution of the conformal weight of vacuum which can be non-integer valued. The thermal expectation in p-adic thermodynamics is obtained by replacing the Boltzman weight  $\exp(-E/T)$  of ordinary thermodynamics with p-adic conformal weight  $p^{n/T_p}$ , where  $n$  is the value of conformal weight and  $1/T_p = m$  is integer values inverse p-adic temperature. Apart from the ground state contribution and scale factor p-adic mass squared is essentially the expectation value

$$\langle n \rangle = \frac{\sum_n g(n) n p^{\frac{n}{T_p}}}{\sum_n g(n) p^{\frac{n}{T_p}}} . \quad (13.5.22)$$

$g(n)$  denotes the degeneracy of a state with given conformal weight and depends only on the number of tensor factors in the representations of Virasoro or Super-Virasoro algebra. p-Adic mass squared is mapped to its real counterpart by canonical identification  $\sum x_n p^n \rightarrow \sum x_n p^{-n}$ . The real counterpart of p-adic thermodynamics is obtained by the replacement  $p^{\frac{n}{T_p}}$  and gives under certain additional assumptions in an excellent accuracy the same results as the p-adic thermodynamics.

2. An intriguing observation is that one could interpret p-adic and real thermodynamics for mass squared also in terms of number theoretic thermodynamics for the number theoretic momentum  $\log(p^n) = n \log(p)$ . The expectation value for this differs from the expression for  $\langle n \rangle$  only by the factor  $\log(p)$ .
3. In the proposed characterization of the partonic orbits in terms of infinite primes the primes appearing in infinite prime are identified as p-adic primes. For minimal option the p-adic prime characterizes  $\sqrt{p}$ - or  $p$ - multiple of the minimum length  $L_{min}$  of braid strand in the effective metric defined by modified Chern-Simons gamma matrix. One can consider also  $(\sqrt{p})^n$  and  $p^n$  (p-adic fractality)- and even integer multiples of  $L_{min}$  if they are below  $L_{max}$ . If light-like 3-surface contains vacuum regions arbitrary large  $p$ :s are possible since for these one has  $L_{min} \rightarrow \infty$ . Number theoretic state function reduction implies that only single  $p$  can be realized -one might say "is active"- for a given quantum state. The powers  $p_i^n$  appearing in the infinite prime have interpretation as many particle states with total number theoretic momentum  $n_i \log(p)_i$ . For the finite part of infinite prime one has one fermion and  $n_i - 1$  bosons and for the bosonic part  $n_i$  bosons. The arithmetic QFT associated with infinite primes - in particular the conservation of the number theoretic momentum  $\sum n_i \log(p_i)$  - would naturally describe the correlations between the geometries of light-like 3-surfaces representing the incoming lines of the vertex of generalized Feynman diagram. As a matter fact, the momenta associated with different primes are separately conserved so that one has infinite number of conservation laws.
4. One must assign two infinite primes to given partonic two surface so that one has for a given prime  $p$  two integers  $n_+$  and  $n_-$ . Also the hierarchy of Planck constants assigns to a given page of the Big Book two integers and one has  $\hbar = n_a n_b \hbar_0$ . If one has  $n_a = n_+$  and  $n_b = n_-$  then the reactions in which given initial number theoretic momenta  $n_{\pm, i} \log(p_i)$  is shared between final states would have concrete interpretation in terms of the integers  $n_a, n_b$  characterizing the coverings of incoming and outgoing lines.

Note that one can also consider the possibility that the hierarchy of Planck constants emerges from the basic quantum TGD. Basically due to the vacuum degeneracy of Kähler action the canonical momentum densities correspond to several values of the time derivatives of the imbedding space coordinates so that for a given partonic 2-surface there are several space-time sheets with same conserved quantities defined by isometry currents and Kähler current. This forces the introduction of  $N$ -fold covering of  $CD \times CP_2$  in order to describe the situation. The splitting of the partonic 2-surface into  $N$  pieces implies a charge fractionization during its travel to the upper end of  $CD$ . One can also develop an argument suggesting that the coverings factorize to coverings of  $CD$  and  $CP_2$  so that the number of the sheets of the covering is  $N = n_a n_b$  [35] .

These observations make one wonder whether there could be a connection between p-adic thermodynamics, hierarchy of Planck constants, and infinite primes.

1. Suppose that one accepts the identification  $n_a = n_+$  and  $n_b = n_-$ . Could one perform a further identification of these integers as non-negative conformal weights characterizing physical states so that conservation of the number theoretic momentum for a given p-adic prime would correspond to the conservation of conformal weight. In p-adic thermodynamics this conformal weight is sum of conformal weights of 5 tensor factors of Super-Virasoro algebra. The number must be indeed five and one could assign them to the factors of the symmetry group. One factor for color symmetries and two factors of electro-weak  $SU(2)_L \times U(1)$  are certainly present. The remaining two factors could correspond to transversal degrees of freedom assignable to string like objects but one can imagine also other identifications [41].
2. If this interpretation is correct, a given conformal weight  $n = n_a = n_+$  (say) would correspond to all possible distributions of five conformal weights  $n_i, i = 1, \dots, 5$  between the  $n_a$  sheets of covering of  $CD$  satisfying  $\sum_{i=1}^5 n_i = n_a = n_+$ . Single sheet of covering would carry only unit conformal weight so that one would have the analog of fractionization also now and a possible interpretation would be in terms of the instability of states with conformal weight  $n > 1$ . Conformal thermodynamics would also mean thermodynamics in the space of states determined by infinite primes and in the space of coverings.
3. The conformal weight assignable to the  $CD$  would naturally correspond to mass squared but there is also the conformal weight assignable to  $CP_2$  and one can wonder what its interpretation might be. Could it correspond to the expectation of pseudo mass squared characterizing the generalized eigenstates of the modified Dirac operator? Note that one should allow in the spectrum also the powers of hyper-complex primes up to some maximum power  $p^{n_{max}/2} \leq L_{max}/L_{min}$  so that Dirac determinant would be non-vanishing and Kähler function finite. From the point of conformal invariance this is indeed natural.

## 13.6 Quantum Hall effect, charge fractionization, and hierarchy of Planck constants

In this section the most recent view about the relationship between dark matter hierarchy and quantum Hall effect is discussed. This discussion leads to a more realistic view about FQHE allowing to formulate precisely the conditions under which anyons emerge, describes the fractionization of electric and magnetic charges in terms of the delicacies of the Kähler gauge potential of generalized imbedding space, and relates the TGD based model to the original model of Laughlin. The discussion allows also to sharpen the vision about the formulation of quantum TGD itself.

### 13.6.1 Quantum Hall effect

Recall first the basic facts. Quantum Hall effect (QHE) [15, 2, 13] is an essentially 2-dimensional phenomenon and occurs at the end of current carrying region for the current flowing transversally along the end of the wire in external magnetic field along the wire. For quantum Hall effect transversal Hall conductance characterizing the 2-dimensional current flow is dimensionless and quantized and given by

$$\sigma_{xy} = 2\nu\alpha_{em} \ ,$$

$\nu$  is so called filling factor telling the number of filled Landau levels in the magnetic field. In the case of integer quantum Hall effect (IQHE)  $\nu$  is integer valued. For fractional quantum Hall effect (FQHE)  $\nu$  is rational number. Laughlin introduced his many-electron wave function predicting fractional quantum Hall effect for filling fractions  $\nu = 1/m$  [13]. The further attempts to understand FQHE led to the notion of anyon by Wilzeck [15]. Anyon has been compared to a vortex like excitation of a dense 2-D electron plasma formed by the current carriers.  $\nu$  is inversely proportional to the magnetic flux and the fractional filling factor can be also understood in terms of fractional magnetic flux.

The starting point of the quantum field theoretical models is the effective 2-dimensionality of the system implying that the projective representations for the permutation group of  $n$  objects are representations of braid group allowing fractional statistics. This is due to the non-trivial first homotopy

group of 2-dimensional manifold containing punctures. Quantum field theoretical models allow to assign to the anyon like states also magnetic charge, fractional spin, and fractional electric charge.

Topological quantum computation [81, 26], [52], [17] is one of the most fascinating applications of FQHE. It relies on the notion of braids with strands representing the orbits of anyons. The unitary time evolution operator coding for topological computation is a representation of the element of the braid group represented by the time evolution of the braid. It is essential that the group involved is non-Abelian so that the system remembers the order of elementary braiding operations (exchange of neighboring strands). There is experimental evidence that  $\nu = 5/2$  anyons possessing fractional charge  $Q = e/4$  are non-Abelian [16, 14].

During last year I have been developing a model for DNA as topological quantum computer [26]. Therefore it is of considerable interest to find whether TGD could provide a first principle description of anyons and related phenomena. The introduction of a hierarchy of Planck constants realized in terms of generalized imbedding space with a book like structure is an excellent candidate in this respect [27]. As a rule the encounters between real world and quantum TGD have led to a more precise quantitative articulation of basic notions of quantum TGD and the same might happen also now.

### 13.6.2 A simple model for fractional quantum Hall effect

The generalization of the imbedding space suggests that it could be possible to understand fractional quantum Hall effect [2] at the level of basic quantum TGD as integer QHE for non-standard value of Planck constant.

The formula for the quantized Hall conductance is given by

$$\begin{aligned}\sigma &= \nu \times \frac{e^2}{h}, \\ \nu &= \frac{n}{m}.\end{aligned}\tag{13.6.1}$$

Series of fractions in  $\nu = 1/3, 2/5, 3/7, 4/9, 5/11, 6/13, 7/15, \dots, 2/3, 3/5, 4/7, 5/9, 6/11, 7/13, \dots, 5/3, 8/5, 11/7, 14/9, \dots, 4/3, 7/5, 10/7, 13/9, \dots, 1/5, 2/9, 3/13, \dots, 2/7, 3/11, \dots, 1/7, \dots$  with odd denominator have been observed as are also  $\nu = 1/2$  and  $\nu = 5/2$  states with even denominator [2].

The model of Laughlin [13] cannot explain all aspects of FQHE. The best existing model proposed originally by Jain is based on composite fermions resulting as bound states of electron and even number of magnetic flux quanta [11]. Electrons remain integer charged but due to the effective magnetic field electrons appear to have fractional charges. Composite fermion picture predicts all the observed fractions and also their relative intensities and the order in which they appear as the quality of sample improves.

Before proposing the TGD based model of FQHE as IQHE with non-standard value of Planck constant, it is good to represent a simple explanation of IQHE effect. Choose the coordinates of the current carrying slab so that  $x$  varies in the direction of Hall current and  $y$  in the direction of the main current. For IQHE the value of Hall conductivity is given by  $\sigma = j_y/E_x = n_e e v / v B = n_e e / B = N e^2 / h B S = N e^2 / m h$ , where  $m$  characterizes the value of magnetized flux and  $N$  is the total number of electrons in the current. In the Landau gauge  $A_y = x B$  one can assume that energy eigenstates are momentum eigenstates in the direction of current and harmonic oscillator Gaussians in  $x$ -direction in which Hall current runs. This gives

$$\Psi \propto \exp(i k y) H_n(x + k l^2) \exp\left(-\frac{(x + k l^2)^2}{2 l^2}\right), \quad l^2 = \frac{\hbar}{e B}.\tag{13.6.2}$$

Only the states for which the oscillator Gaussian differs considerably from zero inside slab are important so that the momentum eigenvalues are in good approximation in the range  $0 \leq k \leq k_{max} = L_x / l^2$ . Using  $N = (L_y / 2\pi) \int_0^{k_{max}} dk$  one obtains that the total number of momentum eigenstates associated with the given value of  $n$  is  $N = e B d L_x L_y / h = n$ . If  $\nu$  Landau states are filled, the value of  $\sigma$  is  $\sigma = \nu e^2 / h$ .

The interpretation of FQHE as IQHE with non standard value of Planck constant could explain also the fractionization of charge, spin, and electron number. There are  $2 \times 2 = 4$  combinations of

covering and factor spaces of  $CP_2$  and three of them can lead to the increase or at least fractionization of the Planck constant required by FQHE.

1. The prediction for the filling fraction in FQHE would be

$$\nu = \nu_0 \frac{\hbar_0}{\hbar} \quad , \quad \nu_0 = 1, 2, \dots \quad . \quad (13.6.3)$$

$\nu_0$  denotes the number of filled Landau levels.

2. Let us denote the options as C-C, C-F, F-C, F-F, where the first (second) letter tells whether a singular covering or factor space of  $CD$  ( $CP_2$ ) is in question. The observed filling fractions are consistent with options C-C, C-F, and F-C for which  $CD$  or  $CP_2$  or both correspond to a singular covering space. The values of  $\nu$  in various cases are given by the following table.

<i>Option</i>	<i>C – C</i>	<i>C – F</i>	<i>F – C</i>
$\nu$	$\frac{\nu_0}{n_a n_b}$	$\frac{\nu_0 n_b}{n_a}$	$\frac{\nu_0 n_a}{n_b}$

(13.6.4)

There is a complete symmetry under the exchange of  $CD$  and  $CP_2$  as far as values of  $\nu$  are considered.

3. All three options are consistent with observations. Charge fractionization allows only the options  $C – C$  and  $F – C$ . If one believes the general arguments stating that also spin is fractionized in FQHE then only the option  $C – C$ , for which charge and spin units are equal to  $1/n_b$  and  $1/n_a$  respectively, remains. For  $C – C$  option one must allow  $\nu_0 > 1$ .
4. Both  $\nu = 1/2$  and  $\nu = 5/2$  state has been observed [2, 8] . The fractionized charge is believed to be  $e/4$  in the latter case [16, 14] . This requires  $n_b = 4$  allowing only  $(C, C)$  and  $(F, C)$  options.  $n_i \geq 3$  holds true if coverings and factor spaces are correlates for Jones inclusions and this gives additional constraint. The minimal values of  $(\nu_0, n_a, n_b)$  are  $(2, 1, 4)$  for  $\nu = 1/2$  and  $(10, 1, 4)$  for  $\nu = 5/2$  for both  $C – C$  and  $F – C$  option. Filling fraction  $1/2$  corresponds in the composite fermion model and also experimentally to the limit of zero magnetic field [11] .  $n_b = 2$  would be inconsistent with the observed fractionization of electric charge for  $\nu = 5/2$  and with the vision inspired by Jones inclusions implying  $n_i \geq 3$ .
5. A possible problematic aspect of the TGD based model is the experimental absence of even values of  $m$  except  $m = 2$  (Laughlin’s model predicts only odd values of  $m$ ). A possible explanation is that by some symmetry condition possibly related to fermionic statistics (as in Laughlin model) both  $n_a$  and  $n_b$  must be odd. This would require that  $m = 2$  case differs in some manner from the remaining cases.
6. Large values of  $m$  in  $\nu = n/m$  emerge as  $B$  increases. This can be understood from flux quantization. One has  $e \int B dS = n\hbar$ . By using actual fractional charge  $e_F = e/n_b$  in the flux factor would give for  $(C, C)$  option  $e_F \int B dS = n n_a \hbar_0$ . The interpretation is that each of the  $n_b$  sheets contributes one unit to the flux for  $e$ . Note that the value of magnetic field at given sheet is not affected so that the build-up of multiple covering seems to keep magnetic field strength below critical value.
7. The understanding of the thermal stability is not trivial. The original FQHE was observed in 80 mK temperature corresponding roughly to a thermal energy of  $T \sim 10^{-5}$  eV. For graphene the effect is observed at room temperature. Cyclotron energy for electron is (from  $f_e = 6 \times 10^5$  Hz at  $B = .2$  Gauss) of order thermal energy at room temperature in a magnetic field varying in the range 1-10 Tesla. This raises the question why the original FQHE requires such

a low temperature. A possible explanation is that since FQHE involves several values of Planck constant, it is quantum critical phenomenon and is characterized by a critical temperature. The differences of single particle energies associated with the phase with ordinary Planck constant and phases with different Planck constant would characterize the transition temperature.

### 13.6.3 Description of QHE in terms of hierarchy of Planck constants

The proportionality  $\sigma_{xy} \propto \alpha_{em} \propto 1/\hbar$  suggests an explanation of FQHE [15, 2, 13] in terms of the hierarchy of Planck constants. Perhaps filling factors and magnetic fluxes are actually integer valued but the value of Planck constant defining the unit of magnetic flux is changed from its standard value - to its rational multiple in the most general case. The killer test for the hypothesis is to find whether higher order perturbative QED corrections in powers of  $\alpha_{em}$  are reduced from those predicted by QED in QHE phase. The proposed general principle governing the transition to large  $\hbar$  phase is states that Nature loves lazy theoreticians: if perturbation theory fails to converge, a phase transition increasing Planck constant occurs and guarantees the convergence. Geometrically the phase transition corresponds to the leakage of 3-surface from a given 8-D page to another one in the Big Book having singular coverings and factor spaces of  $CD \times CP_2$  as pages. Only cover

The hierarchy of Planck constants strongly suggests the emergence of quantum groups and fractionalization of quantum numbers [7]. The challenge is to figure out the details and see whether this framework is consistent with what is known about FQHE. At least the following questions pop up immediately in the mind of physicist.

1. What the effective 2-dimensionality of the system exhibiting QHE corresponds in TGD framework?
2. What happens in the phase transition leading to the phase exhibiting QHE effect?
3. What are the counterparts anyons? How the fractional electric and magnetic charges emerge at classical and quantum level in the two descriptions?

The TGD inspired description of charge fractionization is based on the weak form of electric-magnetic duality and the reduction of the hierarchy of Planck constants to the basic quantum TGD. Also now one can raise a series of questions.

1. Electric magnetic duality provides a natural description of charge quantization and fractionization. The explanation for the hierarchy of Planck constants predicts that all charges- even Noether charges- are fractionized in the same manner and come as multiples of  $1/n_a$  and  $1/n_b$ . Does this prediction make sense physically?
2. Does the singular gauge part  $\Delta A = d\Phi$  of Kähler gauge potential whose exponent is  $n_a$ - ( $n_b$ -) valued function of appropriate angle coordinates of  $M^4$  and  $CP_2$  provide a description of charge fractionization for a given sheet of the covering associated with a given value of Planck constant? Does this description reduce to the measurement interaction term which is indeed effective gauge part added to the Kähler gauge potential of either space-time surface or of wormhole throats or ends of space-time surface.
3. The Chern-Simons action associated with the induced Kähler gauge potential is Abelian: is this consistent with the non-Abelian character of the braiding matrix?

In the following I try to summarize the basic ideas giving hopes about a coherent description of quantum Hall effect and charge and spin fractionization in TGD framework.

#### Hierarchy of Planck constants and book like structure of imbedding space

TGD leads to a description for the hierarchy of Planck constants in terms of the generalization of  $CD \times CP_2$  to book like structure. To be more precise, the generalization takes place for any region  $CD \times CP_2 \subset H$ , where  $CD$  corresponds to a causal diamond defined as an intersection of future and past directed light-cones of  $M^4$ .  $CD$ s play key role in the formulation of quantum TGD in zero energy ontology in which the light-like boundaries of  $CD$  connected by light-like 3-surfaces can be said to be

carriers of positive and negative energy parts of zero energy states. They are also crucial for TGD inspired theory of consciousness, in particular for understanding the relationship between experienced and geometric time [4].

1. *Should one postulate the hierarchy of Planck constants separately?*

In the most general case both  $CD$  and  $CP_2$  are replaced with a book like structure consisting of singular coverings and factor spaces associated with them. A simple geometric argument identifying the square of Planck constant as scaling factor of the covariant metric tensor of  $M^4$  (or actually  $CD$ ) leads in the most general case to the identification of Planck constant as the ratio  $\hbar/\hbar_0 = x_a x_b$ , where  $x = n$  holds true for a singular covering of  $X$  and  $x = 1/n$  holds true for a singular factor space.  $x$  is the order of the maximal cyclic subgroup of the covering/divisor group  $G \subset SO(3)$ . The order of  $G$  can be thus larger than  $n$ . As a consequence, the spectrum of Planck constants is in principle rational-valued.  $\hbar_0$  is unique since it corresponds to the unit of rational numbers.

2. *Does the hierarchy follow from the basic quantum TGD?*

The proposed option is too general if one believes on the argument reducing the hierarchy of Planck constants to the basic quantum TGD. Recall that the argument goes as follows.

1. By the extreme non-linearity of the Kähler action the correspondence between the time derivatives of the imbedding space coordinates and canonical momentum densities is many-to-one. This leads naturally to the introduction of covering spaces of  $CD \times CP_2$ , which are singular in the sense that the sheets of the covering co-incide at the ends of  $CD$  and at wormhole throats. One can say that quantum criticality means also the instability of the 3-surfaces defined by the throats and the ends against the decay to several space-time sheets and consequent charge fractionization. The interpretation is as an instability caused by too strong density of mass and making perturbative description possible since the matter density at various branches is reduced. The nearer the vacuum extremal the system is, the lower the mass density needed to induce the instability is and the larger is the number of sheets resulting in this manner is.
2. The singular regions of the covering are regions in which the integer characterizing the multiple-valuedness of the time derivatives of the imbedding space coordinates as functions of canonical momentum densities is reduced from the maximal value. The reduction to single sheeted covering could (but need not!) take place over any Lagrangian manifold of  $CP_2$  rather than only over a homologically trivial geodesic sphere and would thus directly correspond to the vacuum degeneracy of Kähler action. One can also imagine the reduction of the integer characterizing multivaluedness to a smaller value different from one in non-vacuum regions.
3. In  $M^4$  degrees of freedom branching to a single sheeted covering can occur over any partonic 2-surface which does not enclose the tip of  $CD$ . In this case the Kähler gauge potential would contain a singular gauge term having an archetypal form  $\Delta A = d\phi/n_a$  at say upper hemisphere so that the magnetic flux would receive a non-vanishing contribution from North pole and give rise to a fractionized Kähler magnetic and therefore also to Kähler electric charge. This term is pure gauge for all partonic 2-surface not containing the tip of  $CD$ . Thus one species of anyons would be associated with this kind of partonic 2-surfaces. Second species would correspond to singular gauge transforms about which example would be  $\Delta A = d\Psi/n_b$ , where  $\Psi$  is the angle coordinate associated with a homologically non-trivial geodesic sphere. The modification of the Kähler gauge potential could be interpreted in terms of a measurement interaction term added to the Dirac action and their sum at the ends would give rise to the non-fractional contribution to the measurement interaction term. This kind of term would be also associated with Noether charges such as 4-momentum. Depending on whether one considers the end of space-time sheet or at wormhole throat, the measurement interaction term would be given as  $1/n_b$  or  $1/n_a$  multiple of the measurement interaction term in absence of branching and would be more complex than the simple archetypal forms. The general form of the measurement interaction term is discussed in [28].
4. Classically the fractional Noether charges would emerge from Chern-Simons representation of Kähler function with the Lagrangian multiplier term realizing the weak form of electric-magnetic duality as a constraint. The latter term would be responsible for the non-vanishing values of

four-momentum and angular momentum. The isometry charges in  $CP_2$  degrees of freedom would receive a contribution also from the Chern-Simons term.

5. The situation can be described mathematically either by using effectively only single sheet but an integer multiple of Planck constant or many-sheeted covering and ordinary value of Planck constant. In [27] the argument that this indeed leads to hierarchy of Planck constants including charge fractionization is developed in detail. The restriction to singular coverings is consistent with the experimental constraints and means that only integer valued Planck constants are possible. A given value of Planck constant corresponds only to a finite number of the pages of the Big Book and that the evolution by quantum jumps is analogous to a diffusion at half-line and tends to increase the value of Planck constant.
6. The following argument would suggest a direct connection between vacuum degeneracy, coverings, and the hierarchy of infinite primes. For vacuum extremal the number of sheets is formally infinite but the sheets are in a well-define sense "passive". On the other hand, by the arguments of [28] the numbers  $n_a$  and  $n_b$  for sheets correspond to powers  $p^{n_a}$  and  $p^{n_b}$  for a prime appearing in infinite prime characterizing the partonic 3-surface and having interpretation as particle numbers. The unit infinite primes  $X \pm 1$  correspond to the two basic infinite primes having interpretation as fermionic vacua are interpreted as Dirac sea: the numbers of bosons and fermions are vanishing for them. This suggests that the fermions of Dirac sea correspond to the "passive" sheets. This raises the question whether one could characterize the infinite degeneracy associated with vacuum extremals by these two infinite primes and non-vacuum extremals by infinite primes for which boson and fermion numbers are non-vanishing. The two infinite primes would correspond to  $CD$  and  $CP_2$  degrees of freedom. They could also correspond to the space-time sheets of Euclidian and Minkowskian signature of the induced metric meeting at the wormhole throat at which the induced 4-metric is degenerate. Bose-Einstein condensate of  $n_i$  bosons ( $i = a, b$ ) or fermion plus  $n_i - 1$  bosons would correspond to  $n_i$  sheets of covering.

Arithmetic quantum field theory allows infinite number of conservation laws corresponding to the conservation of the number theoretic momentum  $p = \sum_i n_i \log(p_i)$  which forces separate conservation of each number theoretic momentum  $n_i \log(p_i)$  since the logarithms of primes are linearly independent in the realm of rationals. This conservation law could correlate the partonic lines arriving in the interaction vertices and state that the total number of sheets of the covering is conserved although it can be shared by several partonic space-time sheets in the final state.

The reduction of the hierarchy of Planck constants to basic quantum TGD is of course only an interesting idea and the best strategy to proceed is to develop objections against it.

1. The branching of partonic 2-surfaces at the ends of space-time sheets and wormhole throats is analogous to the branching of the line of Feynman graph. The 3-D lines of generalized Feynman graphs indeed branch at the vertices and this leads to the basic objection against the proposed interpretation of the fractionization. Could one consider the possibility that branching corresponds to what happens in the vertices of Feynman diagrams? This cannot not seem to be the case. The point is that canonical momentum densities are identical so that also the conserved classical Noether and Kähler charges associated with various branches should be the same.
2. The value of gravitational Planck constant is enormous and one would mean enormously many-fold branching of partonic 2-surfaces of astrophysical size. Does this really make sense? Is this simply due the fact that the basic parameter  $GM_1M_2$  characterizing the strength of gravitational interaction is much larger than unity so that perturbation theory in terms of it fails to converge and the splitting to  $\hbar_{gr}/\hbar_0$  sheets guarantees that the perturbation theory at each sheet converges.
3. One can also ask whether the fractional charges can be observed directly since it seems that only the partonic 2-surfaces at the ends of the space-time sheet are observable.
4. Perhaps the most serious objection relates to the basic intuition about scaling of quantum lengths by  $\hbar$  since this scaling is fundamental for all predictions in the model of quantum biology. It is not obvious why the basic quantum lengths in  $M^4$  degrees of freedom - in particular the size

scale of  $CD$  - should be scaled up by  $n_a n_b$ . Could this scaling up result dynamically or can one find some simple kinematic argument forcing the size scale spectrum of  $CD$ s? Kinematic argument is more plausible and indeed exists. Suppose that one can speak about plane waves  $exp(inEt/\hbar_0)$ , where  $t$  is proper time coordinate associated with the line connecting the tips of  $CD$ . Periodic boundary conditions at  $t = T$  imply  $E = n\hbar_0/2\pi T$  where  $T$  is the proper time distance between the tips of  $CD$ . Suppose that  $\hbar_0$  is replaced with its  $n_a n_b$  multiple in the plane wave. As a consequence, the plane waves for sheets and for same value of  $E$  do not anymore satisfy periodic boundary conditions at  $t = T$  anymore. These conditions are however satisfied for  $t = n_a n_b T$ .

3. *Connection with quantum measurement theory*

The hierarchy of Planck constants relates closely to quantum measurement theory. The selection of quantization axis implied by the gauge terms  $\Delta A$  proportional to appropriate angle coordinates has a direct correlate at the level of imbedding space geometry. This means breaking of isometries of  $H$  for a given  $CD$  with preferred choice time axis (rest frame) and quantization axis of spin. For  $CP_2$  the choice of the quantization axes of color hyper charge and isospin imply symmetry breaking  $SU(3) \rightarrow U(2) \rightarrow U(1) \times U(1)$ . The "world of classical worlds" (WCW) is union over all Poincare and color translates of given  $CD \times CP_2$  so that these symmetries are not lost at the level of WCW although the loss can happen at the level of quantum states.

4. *How the different sectors of the generalized imbedding space are glued together?*

Intuitively the scaling of Planck constant scales up quantum lengths, in particular the size of  $CD$ . This looks trivial but one must describe precisely what is involved to check internal consistency and also to understand how to model the quantum phase transitions changing Planck constant. The first manner to understand the situation is to consider  $CD$  with a fixed range of  $M^4$  coordinates. The scaling up of the covariant Kähler metric of  $CD$  by  $r^2 = (\hbar/\hbar_0)^2$  scales up the size of  $CD$  by  $r$ . Another manner to see the situation is by scaling up the linear  $M^4$  coordinates by  $r$  for the larger  $CD$  so that  $M^4$  metric becomes same for both  $CD$ s. The smaller  $CD$  is glued to the larger one isometrically together along  $(M^2 \cap CD) \subset CD$  anywhere in the interior of the larger  $CD$ . What happens is non-trivial for the following reasons.

1. The singular coverings (and possibly also factor spaces) are different and  $M^4$  scaling is not a symmetry of the Kähler action so that the preferred extrema in the two cases do not relate by a simple scaling. The interpretation is in terms of the coding of the radiative corrections in powers of  $\hbar$  to the shape of the preferred extremals. This becomes clear from the representation of Kähler action in which  $M^4$  coordinates have the same range for two  $CD$ s but  $M^4$  metric differs by  $r^2$  factor.
2. In common  $M^4$  coordinates the  $M^4$  gauge part  $A_a$  of  $CP_2$  Kähler potential for the larger  $CD$  differs by a factor  $1/r$  from that for the smaller  $CD$ . This guarantees the invariance of four-momentum assignable to Chern-Simons action in the phase transition changing  $\hbar$ . The resulting discontinuity of  $A_a$  at  $M^2$  is analogous to a static voltage difference between the two  $CD$ s and  $M^2$  could be seen as an analog of Josephson junction. In absence of dissipation (expected in quantum criticality) the Kähler voltage could generate oscillatory fermion, em, and  $Z^0$  Josephson currents between the two  $CD$ s. Fermion current would flow in opposite directions for fermions and antifermions and also for quarks and leptons since Kähler gauge potential couples to quarks and leptons with opposite signs. In presence of dissipation fermionic currents would be ohmic and could force quarks and leptons and matter and antimatter to different pages of the Big Book. Quarks inside hadrons could have nonstandard value of Planck constant.

**Measurement interaction term as gauge transform of Kähler gauge potential and description of charge fractionization in terms of singular gauge transforms**

The introduction of a gauge part to the Kähler gauge potential of the imbedding space looks somewhat tricky idea. Can one really assign non-trivial physics to a mere gauge transformation? This is certainly the case if the gauge transformation is singular and induces a fractional Kähler magnetic charge and by electric-magnetic duality also a fractional Kähler electric charge. The introduction of a measurement

interaction term as a formal gauge transform of the Kähler gauge potential only in Dirac Kähler action or Kähler Chern-Simons Dirac action but not both provides a second manner to achieve a non-trivial physical effect. It is good to summarize the background in more detail before continuing.

The idea about description of quantum Hall effect in terms of a gauge part of Kähler gauge potential emerged from the idea that Chern-Simons action for Kähler gauge potential (equivalently the for induced classical color gauge field proportional to the Kähler form) could define TGD as an almost topological QFT. It turned out however that Kähler action and the corresponding modified Dirac action containing also Chern-Simons boundary term with the constraint term coming from electric-magnetic duality are the fundamental actions. The general ansatz for the classical field equations based on the proportionality of Kähler current to instanton current reduces TGD to almost topological QFT with action reducing to Chern-Simons term with a Lagrangian multiplier term guaranteeing the weak form of electric-magnetic duality. This term is of extreme importance since the extremals of mere Chern-Simons action would give rise to identically vanishing Kähler function and Kähler metric and WCW metric would not have any  $M^4$  part even if one gives up the extremality condition.

The measurement interaction term which corresponds to a gauge part of the Kähler gauge potential and can be added either to the interior part of Kähler Dirac action (and Kähler action) or to the Chern-Simons Dirac action. The measurement interaction term therefore modifies the physics and is visible also in the classical dynamics by the proportionality of Kähler current to instanton current. Note that the modification of Chern-Simons term assigned to the ends of the space-time sheet and to wormhole throats affects the space-time sheet since the Kähler action changes.

For Noether charges the Lagrangian multiplier term guaranteeing the weak form of electric magnetic duality in Chern-Simons action gives rise to non-vanishing Noether charges also in  $M^4$  degrees of freedom. The proposed view about the basic process behind the charge fractionization implies that all charges are fractionized in basically the same manner although it seems that  $M^4$  charges are  $n_b$  multiples and  $CP_2$  charges  $n_a$  multiples of  $1/n_a n_b$ . Also in this case the additional of a formal gauge term would realize the fractionization at the level of couplings and total anomalous coupling would correspond to a non-singular gauge transformation of  $A$ .

One can imagine several kinds of pseudo gauge transformations appearing in the measurement interaction term.

1. The first kind of gauge transformation corresponds to a gauge change for  $A_\mu$  with no reference to the fact that it is a projection of  $CP_2$  Kähler gauge potential. It is not clear whether measurement interaction could be induced also by this kind of gauge transform. In any case, the proposed form of measurement interaction can be interpreted in terms of a gauge transform at the level of imbedding space [28]
2. Second kind of gauge transformations are induced by the symplectic transformations of  $\delta M_\pm^4 \times CP_2$  and in general affect the induced metric and thus the gravitational properties of the system in the case of non-vacuum extremals. Furthermore, there exist no symplectic transformation allowing to eliminate the "gauge part" of  $A$  in  $M^2 \subset M^4$  or gauge part in  $CD \setminus M^2$  or  $CP_2 \setminus S^2$  if it corresponds to a scalar function which is discontinuous.  $\Delta A_\phi = k\phi$ ,  $k \neq n$ , where  $\phi$  is an angle variable in  $M^4$  or  $CP_2$  would represent a canonical example of this.
3. Third kind of gauge transform would characterize the pages of the Big Book and give rise to fractional Kähler magnetic charge and by definition would not be reducible to a gauge transform induced by a symplectic transformation. This raises the idea that the gauge parts of  $A$  in  $CD$  and  $CP_2$  could characterize the pages of the Big Book and thus the charge fractionization. In particular in the case of coverings one might argue that  $\Delta A$  must be pure gauge in the covering implying  $k = m/n_a$  or  $k = m/n_b$ .

The simplest hypothesis is that the ordinary measurement interaction term for trivial covering is simply scaled down by  $1/n_a n_b$  in the interior of the space-time sheet and by  $1/n_b$  or  $1/n_a$  at its ends and at throats where  $n_b$  or  $n_a$  sheets co-incide. With this interpretation  $\Delta A$  would provide a description of physics at a particular sheet of covering and there would be no need to introduce anything new at the level of imbedding space geometry since the coverings of the imbedding space would provide only a formal tool to describe the situation caused by the extreme non-linearity of the Kähler action.

### 13.6.4 In what kind of situations do anyons emerge?

Charge fractionization is a fundamental piece of quantum TGD and should be extremely general phenomenon and the basic characteristic of dark matter known to contribute 95 per cent to the matter of Universe.

1. In TGD framework scaling  $\hbar = m\hbar_0$  implies the scaling of the unit of angular momentum for  $m$ -fold covering of  $CD$  only if the many particle state is  $Z_m$  singlet.  $Z_m$  singletness for many particle states allows of course non-singletness for single particle states. For factor spaces of  $CD$  -if present- the scaling  $\hbar \rightarrow \hbar/m$  is compensated by the scaling  $l \rightarrow ml$  for  $L_z = l\hbar$  guaranteeing invariance under rotations by multiples of  $2\pi/m$ . Again one can pose the invariance condition on many-particle states but not to individual particles so that genuine physical effect is in question.
2. There is analogy with  $Z_3$ -singletness holding true for many quark states and one cannot completely exclude the possibility that quarks are actually fractionally charged leptons with  $m = 3$ -covering of  $CP_2$  reducing the value of Planck constant [83, 27] so that quarks would be anyonic dark matter with smaller Planck constant and the impossibility to observe quarks directly would reduce to the impossibility for them to exist at our space-time sheet. Confinement would in this picture relate to the fractionization requiring that the 2-surface associated with quark must surround the tip of  $CD$ . Whether this option really works remains an open question. In any case, TGD anyons are quite generally confined around the tip of  $CD$ .
3. The model of DNA as topological quantum computer [26] assumes that DNA nucleotides are connected by magnetic flux tubes to the lipids of the cell membrane. In this case, p-adically scaled down  $u$  and  $d$  quarks and their antiquarks are assumed to be associated with the ends of the flux tubes and provide a representation of DNA nucleotides. Quantum Hall states would be associated with partonic 2-surfaces assignable to the lipid layers of the cell and nuclear membranes and also endoplasmic reticulum filling the cell interior and making it macroscopic quantum system and explaining also its stability. The entire system formed in this manner would be single extremely complex anyonic surface and the coherent behavior of living system would result from the fusion of anyonic 2-surfaces associated with cells to larger anyonic surfaces giving rise to organs and organisms and maybe even larger macroscopically quantum coherent connected systems. An interesting possibility is that the ends of the flux tubes assumed to connect DNA nucleotides to lipids of various membranes carry instead of  $u$ ,  $d$  and their antiquarks fractionally charged electrons and neutrinos and their anti-particles having  $n_b = 3$  and large value of  $n_a$ .

In astrophysical scales gigantic values of Planck constants would be realized meaning coverings with huge number of sheets. This conforms with the fact that for vacuum extremals the coverings would be formally infinitely many sheeted.

1. Quite generally, one would expect that dark matter and its anyonic forms emerge in situations where the density of plasma like state of matter is very high so that  $N$ -fold cover of  $CD$  reduces the density of matter by  $1/N$  factor at given sheet of covering and thus also the repulsive Coulomb energy. Plasma state resulting in QHE is one example of this. The interiors of neutron stars and black hole like structures are extreme examples of this, and I have proposed that black holes are dark matter with a gigantic value of gravitational Planck constant implying that black hole entropy -which is proportional to  $1/\hbar$  - is of the same order of magnitude and even smaller as the entropy assignable to the spin of elementary particle. If the covering results from the basic quantum TGD this entropy would characterize single sheet of the covering only. The fact that there are  $n_a n_b$  sheets would mean that the total entropy has just the standard value! Could this mean that entropy is the critical contrple parameter which splits the 3-surface into parallel sheets?
2. The confinement of matter inside black hole could have interpretation in terms of macroscopic anyonic 2-surfaces containing the topologically condensed elementary particles. This conforms with the TGD inspired model for the final state of star [77] inspiring the conjecture that even ordinary stars could possess onion like structure with thin layers with radii given by p-adic length scale hypothesis.

3. The idea about hierarchy of Planck constants was inspired by the finding that planetary orbits can be regarded as Bohr orbits [27], [10]: the explanation was that visible matter has condensed around dark matter at spherical cells or tubular structures around planetary orbits. This led to the proposal that planetary system has formed through this kind of condensation process around spherical shells or flux tubes surrounding planetary orbits and containing dark matter.

The question why dark matter would concentrate around flux tubes surrounding planetary orbits was not answered. The answer could be that dark matter is anyonic matter at partonic 2-surfaces whose light-like orbits define the basic geometric objects of quantum TGD. These partonic 2-surfaces could contain a central spherical anyonic 2-surface connected by radial flux tubes to flux tubes surrounding the orbits of planets and other massive objects of solar system to form connected anyonic surfaces analogous to elementary particles.

4. If factor spaces appear in  $M^4$  degrees of freedom, they give rise to  $Z_n \subset G_a$  symmetries. In astrophysical systems the large value of  $\hbar$  necessarily requires a large value of  $n_a$  for  $CD$  coverings as the considerations of [55] - in particular the model for graviton dark graviton emission and detection - forces to conclude. The same conclusion follows also from the absence of evidence for exact orbifold type symmetries in  $M^4$  degrees of freedom for dark matter in astrophysical scales.

Coverings alone are enough to produce rational number valued spectrum for  $\hbar$  consistent with the observed spectrum of  $\nu$ , and one must keep in mind that the applications of theory do not allow to decide whether singular factor spaces are really needed and that the reduction of the hierarchy of Planck constants to basic quantum TGD for coverings disfavors the factor spaces. The possibility to interpret evolution in terms of the increase of Planck constant also favors coverings-only option.

### 13.6.5 What happens in FQHE?

This picture suggest following description for what would happen in QHE in TGD Universe accepting the C-C option implied by the basic quantum TGD.

1. Light-like 3-surfaces - locally random light-like orbits of partonic 2-surfaces- are identifiable as very tiny wormhole throats in the case of elementary particles. This is the case for electrons in particular. Partonic surfaces can be also large, even macroscopic, and the size scales up in the scaling of Planck constant. To avoid confusion, it must be emphasized that light-likeness is with respect to the induced metric and does not imply expansion with light velocity in Minkowski space since the contribution to the induced metric implying light-likeness typically comes from  $CP_2$  degrees of freedom. Strong classical gravitational fields are present near the wormhole throats. Second important point is that regions of space-time surface with Euclidian signature of the induced metric are implied:  $CP_2$  type extremals representing elementary particles and having light-like random curve as  $CP_2$  projection represents basic example of this. Hence rather exotic gravitational physics is predicted to manifest itself in everyday length scales.
2. The simplest identification for what happens in the phase transition to quantum Hall phase is that the end of wire carrying the Hall current corresponds to a partonic 2-surface having a macroscopic size. The electrons in the current correspond to similar 2-surfaces but with size of elementary particle for the ordinary value of Planck constant. As the electrons meet the end of the wire, the tiny wormhole throats of electrons suffer topological condensation to the boundary. One can say that one very large elementary particle having very high electron number is formed.
3. Fractionization occurs for charges in  $CP_2$  degrees of freedom with unit  $1/n_a$ . If the end of the wire forms part of a spherical surface surrounding the tip of the  $CD$  involved fractionization occurs also in  $CD$  degrees of freedom so that electrons can become carriers of anomalous electric and magnetic charges. If not then the total spin is  $n_a$  multiple of fundamental spin unit.

One of the basic question was whether it is possible to describe non-Abelian FQHE in TGD framework.

1. Chern- Simons action for Kähler gauge potential is Abelian. This raises the question whether the representations of the number theoretical braid group are also Abelian. Since there is evidence

for non-Abelian anyons, one might argue that this means a failure of the proposed approach. There are however many reasons to expect that braid group representations are non-Abelian. The action is for induced Kähler form rather than primary Maxwell field,  $U(1)$  gauge symmetry is transformed to a dynamical symmetry (symplectic transformations of  $CP_2$  representing isometries of WCW and definitely non-Abelian), and the particles of the theory belong to the representations of electro-weak and color gauge groups naturally defining the representations of braid group.

2. The finite subgroups of  $SU(2)$  defining covering and factor groups are in the general case non-commutative subgroups of  $SU(2)$  since the hierarchies of coverings and factors spaces are assumed to correspond to the two hierarchy of Jones inclusions to which one can assign ADE Lie algebras by McKay correspondence. The ADE Lie algebras define effective gauge symmetries having interpretation in terms of finite measurement resolution described in terms of Jones inclusion so that extremely rich structures are expected. The question arises whether the covering option implied by the basic quantum TGD allows coverings defined by finite groups. There seems to be no obvious reason why this could not be the case.

An interesting challenge is to relate concrete models of FQHE to the proposed description. Here only some comments about Laughlin's wave function are made.

1. In the description provided by Laughlin wave function FQHE results from a minimization of Coulomb energy. In TGD framework the tunneling to the page of  $H$  with  $m$  sheets of covering has the same effect since the density of electrons is reduced by  $1/m$  factor.
2. The formula  $\nu \propto e^2 N_e / e \int B dS$  with scaling up of magnetic flux by  $\hbar/\hbar_0 = m$  implies effective fractional filling factor. The scaling up of magnetic flux results from the presence of  $m$  sheets carrying magnetic field with same strength. Since the  $N_e$  electrons are shared between  $m$  sheets, the filling factor is fractional when one restricts the consideration to single sheet as one indeed does.
3. Laughlin wave function makes sense for  $\nu = 1/m$ ,  $m$  odd, and is  $m$ :th power of the many electron wave function for IQHE and expressible as the product  $\prod_{i < j} (z_i - z_j)^m$ , where  $z$  represents complex coordinate for the anyonic plane. The relative orbital angular momenta of electrons satisfy  $L_z \geq m$  if the value of Planck constant is standard. If Laughlin wave function makes sense also in TGD framework, then  $m$ :th power implies that many-electron wave function is singlet with respect to  $Z_m$  acting in covering and the value of relative angular momentum indeed satisfies  $L_z \geq m\hbar_0$  just as in Laughlin's theory.

# Chapter 1

## Appendix

### A-1 Introduction

In its original form this chapter contained brave speculations about the equivalence of loop diagrams with tree diagrams proposed to generalize the duality of hadronic string models. It however turned out that this picture has no obvious connection with the generalized Feynman diagrams- a notion which emerged years later. Since the physical interpretation and mathematical framework of quantum TGD has now reached relatively mature and stable state, I decided that it is time to drop out these speculations and leave only the hard mathematical facts as appendix possibly useful also for the reader.

### A-2 Hopf algebras and ribbon categories as basic structures

In this section the basic notions related to Hopf algebras and categories are discussed from TGD point of view. Examples are left to appendix. The new element is the graphical representation of the axioms leading to the idea about the equivalent of loop diagrams and tree diagrams based on general algebraic axioms.

#### A-2.1 Hopf algebras and ribbon categories very briefly

An algebraic formulation generalizing braided Hopf algebras and related structures to what might be called quantum category would involve the replacement of the co-product of Hopf algebras with morphism of quantum category having as its objects the Clifford algebras associated with configuration space spinor structure for various 3-topologies. The corresponding Fock spaces would define algebra modules and the objects of the category would consist of pairs of algebras and corresponding modules. The underlying primary structure would be second quantized free induced spinor fields associated with 3-surfaces with various 3-topologies and generalized conformal structures.

##### 1. Bi-algebras

Bi-algebras have two algebraic operations. Besides ordinary multiplication  $\mu : H \otimes H \rightarrow H$  there is also co-multiplication  $\Delta : H \rightarrow H \otimes H$ . Algebra satisfies the associativity axiom (Ass):  $a(bc) = (ab)c$ , or more formally,  $\mu(id \otimes \mu) = \mu(\mu \otimes id)$ , and the unit axiom (Un) stating that there is morphism  $\eta : k \rightarrow A$  mapping the unit of  $A$  to the unit of field  $k$ . Commutativity axiom (Co)  $ab = ba$  translates to  $\mu \otimes \tau \equiv \mu^{op} = \mu$ , where  $\tau$  permutes factors in tensor product  $A \otimes A$ .

$\Delta$  satisfies mirror images of these axioms. Co-associativity axiom (Coass) reads as  $(\Delta \otimes id)\Delta = (id \otimes \Delta)\Delta$ , co-unit axiom (Coun) states existence of morphism  $\epsilon : k \rightarrow C$  mapping the unit of  $A$  to that of  $k$ , and co-commutativity (Coco) reads as  $\tau \circ \Delta \equiv \Delta^{op} = \Delta$ . For a bi-algebra  $H$  also additional axioms are satisfied: in particular,  $\Delta(\mu)$  acts as algebra (bi-algebra) morphism. When represented graphically, this constraint states that a box diagram is equivalent to a tree diagram as will be found and served as the stimulus for the idea that loop diagrams might be equivalent with tree diagrams.

Left and right algebra modules and algebra representations are defined in an obvious manner and satisfy associativity and unit axioms. A left co-module corresponds a pair  $(V, \Delta_V)$  where the co-

action  $\Delta_N : V \rightarrow A \otimes V$  satisfies co-associativity and co-unit axioms. Right co-module is defined in an analogous manner.

Particle fusion  $A \otimes B \rightarrow C$  corresponds to  $\mu : A \otimes B \rightarrow C = AB$ . Co-multiplication  $\Delta$  corresponds time reversal  $C \rightarrow A \otimes B$  of this process, which is kind of a time-reversal for multiplication. The generalization would mean that  $\mu$  and  $\Delta$  become morphisms  $\mu : B \otimes C \rightarrow A$  and  $\Delta : A \rightarrow B \otimes C$ , where  $A, B, C$  are objects of the quantum category. They could be either representations of same algebra or even different algebras.

### 2. Drinfeld's quantum double

Drinfeld's quantum double [94] is a braided Hopf algebra obtained by combining Hopf algebra  $(H, \mu, \Delta, \eta, \epsilon, S, R)$  and its dual  $H^*$  to a larger Hopf algebra known as quasi-triangular Hopf algebra satisfying  $\Delta = R\Delta^{op}R^{-1}$ , where  $\Delta^{op}(a)$  is obtained by permuting the two tensor factors. Duality means existence of a scalar product and the two algebras correspond to Hermitian conjugates of each other.

In TGD framework the physical states associated with these algebras have opposite energies since in TGD framework antimatter (or matter depending on the phase of matter) corresponds to negative energy states. The states of the Universe would correspond to states with vanishing conserved quantum numbers, and in concordance with crossing symmetry, particle reactions could be interpreted as transitions generating zero energy states from vacuum.

The notion of duality [94] is needed to define an inner product and S-matrix. Essentially Dirac's bra-ket formalism is in question. The so called evaluation map  $ev : V \otimes V^* \rightarrow k$  defined as  $ev(v^i \otimes v_j) = \langle v^i, v_j \rangle = \delta_{ij}$  defines an inner product in any Hopf algebra module. The inverse of this map is the linear map  $k \rightarrow V$  defined by  $\delta_v(1) = v_i \otimes v^i$ . For a tensor category with unit  $I$ , field  $k$  is replaced with unit  $I$ , and left duality these maps are replaced with maps  $b_V : I \rightarrow V \otimes V^*$  and  $d_V = V \otimes V^* \rightarrow I$ . Right duality is defined in an analogous manner. The map  $d_V$  assigns to a given zero energy state S-matrix element. Algebra morphism property  $b_V(ab) = b_V(a)b_V(b)$  would mean that the outcome is essentially the counterpart of free field theory Feynman diagram. This diagram is convoluted with the S-matrix element coded to the entanglement coefficients between positive and negative energy particles of zero energy state.

### 3. Ribbon algebras and ribbon categories

The so called ribbon algebra [94] is obtained by replacing one-dimensional strands with ribbons and adding to the algebra the so called twist operation  $\theta$  acting as a morphism in algebra and in any algebra module. Twist allows to introduce the notion of trace, in particular quantum trace.

The thickening of one-dimensional strands to 2-dimensional ribbons is especially natural in TGD framework, and corresponds to a replacement of points of time=constant section of 4-surface with one-dimensional curves along which the S-matrix defined by R-matrix is constant. Ribbon category is defined in an obvious manner. There is also a more general definition of ribbon category with objects identified as representations of a given algebra and allowing morphisms with arbitrary number of incoming and outgoing strands having interpretation as many-particle vertices in TGD framework. The notion of quantum category defined as a generalization of a ribbon category involving the generalization of algebra product and co-product as morphisms between different objects of the category and allowing objects to correspond different algebras might catch the essentials of the physics of TGD Universe.

## A-2.2 Algebras, co-algebras, bi-algebras, and related structures

It is useful to formulate the notions of algebra, co-algebra, bi-algebra, and Hopf algebra in order to understand how they might help in attempt to formulate more precisely the view about what generalized Feynman diagrams could mean. Since I am a novice in the field of quantum groups, the definitions to be represented are more or less as such from the book "Quantum Groups" of Christian Kassel [94] with some material (such as the construction of Drinfeld double) taken from [55]. What is new is a graphical representation of algebra axioms and the proposal that algebra and co-algebra operations have interpretation in terms of generalized Feynman diagrams.

In the following considerations the notation  $id_k$  for the isomorphism  $k \rightarrow k \otimes k$  defined by  $x \rightarrow x \otimes x$  and its inverse will be used.

**Algebras**

Algebra can be defined as a triple  $(A, \mu, \eta)$ , where  $A$  is a vector space over field  $k$  and  $\mu : A \otimes A \rightarrow A$  and  $\eta : k \rightarrow A$  are linear maps satisfying the following axioms (Ass) and (Un).

(Ass): The square

$$\begin{array}{ccc}
 A \otimes A \otimes A & \xrightarrow{\mu \otimes id} & A \otimes A \\
 \downarrow id \otimes \mu & & \downarrow \mu \\
 A \otimes A & \xrightarrow{\mu} & A
 \end{array} \tag{A-2.1}$$

commutes.

(Un): The diagram

$$\begin{array}{ccccc}
 k \otimes A & \xrightarrow{\eta \otimes id} & A \otimes A & \xleftarrow{id \otimes \eta} & A \otimes k \\
 & \searrow \cong & \downarrow \mu & & \swarrow \cong \\
 & & A & & 
 \end{array} \tag{A-2.2}$$

commutes. Note that  $\eta$  imbeds field  $k$  to  $A$ .

(Comm) If algebra is commutative, the triangle

$$\begin{array}{ccc}
 A \otimes A & \xrightarrow{\tau_{A,A}} & A \otimes A \\
 \searrow \mu & & \swarrow \mu \\
 & & A
 \end{array} \tag{A-2.3}$$

commutes. Here  $\tau_{A,A}$  is the flip switching the factors:  $\tau_{A,A}(a \otimes a') = a' \otimes a$ .

A morphism of algebras  $f : (A, \mu, \eta) \rightarrow (A', \mu', \eta')$  is a linear map  $A \rightarrow A'$  such that

$$\mu' \circ (f \otimes f) = f \circ \mu, \text{ and } f \circ \eta = \eta' .$$

A graphical representation of the algebra axioms is obtained by assigning to the field  $k$  a dashed line to be referred as a vacuum line in the sequel and to  $A$  a full line, to  $\eta$  a vertex  $\times$  at which  $k$ -line changes to  $A$ -line. The product  $\mu$  can be represented as 3-particle vertex in which algebra lines fuse together. The three axioms (Ass), (Un) and (Comm) can be expressed graphically in figure A-2.2.

Note that associativity axiom implies that two tree diagrams not equivalent as Feynman diagrams are equivalent in the algebraic sense.

**Co-algebras**

The definition of co-algebra is obtained by systematically reversing the directions of arrows in the previous diagrams.

A co-algebra is a triple  $(C, \Delta, \epsilon)$ , where  $C$  is a vector space over field  $k$  and  $\Delta : C \rightarrow C \otimes C$  and  $\epsilon : C \rightarrow k$  are linear maps satisfying the following axioms (Coass) and (Coun).

(Coass): The square

$$\begin{array}{ccc}
 C & \xrightarrow{\Delta} & C \otimes C \\
 \downarrow \Delta & & \downarrow id \otimes \Delta \\
 C \otimes C & \xrightarrow{\Delta \otimes id} & C \otimes C \otimes C
 \end{array} \tag{A-2.4}$$

commutes.

Figure 1: Graphical representation for the axioms of algebra. a)  $a(bc) = (ab)c$ , b)  $ab = ba$ , c)  $ka = \mu(\eta(k), a)$  and  $ak = \mu(a, \eta(k))$ .

(Coun): The diagram

$$\begin{array}{ccccc}
 k \otimes C & \xleftarrow{\epsilon \otimes id} & C \otimes C & \xrightarrow{id \otimes \epsilon} & C \otimes k \\
 & \searrow \cong & \Delta \uparrow & \nearrow \cong & \\
 & & C & & 
 \end{array}
 \tag{A-2.5}$$

commutes. The map  $\Delta$  is called co-product or co-multiplication whereas  $\epsilon$  is called the counit. The commutative diagram state that the co-product is co-associative and that co-unit commutes with co-product.

(Cocomm) If co-algebra is commutative, the triangle

$$\begin{array}{ccc}
 & C & \\
 \Delta \swarrow & & \searrow \Delta \\
 C \otimes C & \xrightarrow{\tau_{C,C}} & C \otimes C
 \end{array}
 \tag{A-2.6}$$

commutes. Here  $\tau_{C,C}$  is the flip switching the factors:  $\tau_{C,C}(c \otimes c') = c' \otimes c$ .

A morphism of co-algebras  $f : (C, \Delta, \epsilon) \rightarrow (C', \Delta', \epsilon')$  is a linear map  $C \rightarrow C'$  such that

$$(f \otimes f) \circ \Delta = \Delta' \circ f \quad , \quad \text{and} \quad \epsilon = \epsilon' \circ f \quad .$$

It is straightforward to define notions like co-ideal and co-factor algebra by starting from the notions of ideal and factor algebra. A very useful notation is Sweedler's sigma notation for  $\Delta(x)$ ,  $x \in C$  as element of  $C \otimes C$  :

$$\Delta(x) = \sum_i x'_i \otimes x''_i \equiv \sum_{\{x\}} x' \otimes x'' \quad .$$

Also co-algebra axioms allow graphical representation. One assigns to  $\epsilon$  a vertex  $\times$  at which  $C$ -line changes to  $k$ -line: the interpretation is as an absorption of a particle by vacuum. The co-product  $\Delta$  can be represented as 3-particle vertex in which  $C$ -line decays to two  $C$ -lines. The graphical representation of the three axioms (Coass), (Coun), and (Cocomm) is related to the representation of algebra axioms by "time reversal", that is turning the diagrams for the algebra axioms upside down (see figure A-2.2).

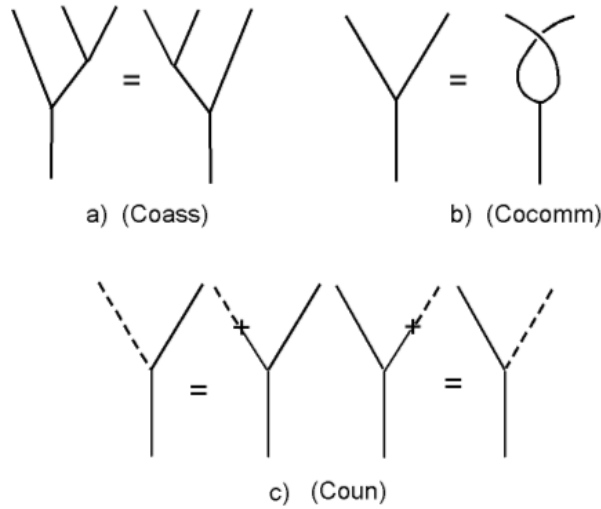

Figure 2: Graphical representation for the axioms of co-algebra is obtained by turning the representation for algebra axioms upside down. a)  $(id \otimes \Delta)\Delta = (\Delta \otimes id)\Delta$ , b)  $\Delta = \Delta^{op}$ , c)  $(\epsilon \otimes id) \circ \Delta = (id \otimes \epsilon) \circ \Delta = id$ .

**Bi-algebras**

Consider next a vector space  $H$  equipped simultaneously with an algebra structure  $(H, \mu, \eta)$  and a co-algebra structure  $(H, \Delta, \epsilon)$ . There are some compatibility conditions between these two structures.  $H \otimes H$  can be given the induced structures of a tensor product of algebras and of co-algebras.

The following two statements are equivalent.

1. The maps  $\mu$  and  $\eta$  are morphisms of co-algebras. For  $\mu$  this means that the diagrams

$$\begin{array}{ccc}
 H \otimes H & \xrightarrow{\mu} & H \\
 \downarrow (id \otimes \tau \otimes id) \otimes (\Delta \otimes \Delta) & & \downarrow \Delta \\
 (H \otimes H) \otimes (H \otimes H) & \xrightarrow{\mu \otimes \mu} & H \otimes H
 \end{array} \tag{A-2.7}$$

and

$$\begin{array}{ccc}
 H \otimes H & \xrightarrow{\epsilon \otimes \epsilon} & k \otimes k \\
 \downarrow \mu & & \downarrow id \\
 H & \xrightarrow{\epsilon} & k
 \end{array} \tag{A-2.8}$$

commute. For  $\eta$  this means that the diagrams

$$\begin{array}{ccc}
 k & \xrightarrow{\eta} & H \\
 \downarrow id & & \downarrow \Delta \\
 k \otimes k & \xrightarrow{\eta \otimes \eta} & H \otimes H
 \end{array}
 \qquad
 \begin{array}{ccc}
 k & \xrightarrow{\eta} & H \\
 \searrow id & & \swarrow \epsilon \\
 & k &
 \end{array} \tag{A-2.9}$$

commute.

- The maps  $\Delta$  and  $\epsilon$  are morphisms of algebras.  
For  $\Delta$  this means that diagrams

$$\begin{array}{ccc}
 H \otimes H & \xrightarrow{\Delta \otimes \Delta} & (H \otimes H) \otimes (H \otimes H) \\
 \downarrow \mu & & \downarrow (\mu \otimes \mu)(id \otimes \tau \otimes id) \\
 H & \xrightarrow{\Delta} & H \otimes H
 \end{array} \tag{A-2.10}$$

and

$$\begin{array}{ccc}
 k & \xrightarrow{\eta} & H \\
 \downarrow id & & \downarrow \Delta \\
 k \otimes k & \xrightarrow{\eta \otimes \eta} & H \otimes H
 \end{array} \tag{A-2.11}$$

commute.

For  $\epsilon$  this means that the diagrams

$$\begin{array}{ccc}
 H \otimes H & \xrightarrow{\epsilon \otimes \epsilon} & k \otimes k & k & \xrightarrow{\eta} & H \\
 \downarrow \mu & & \downarrow id & \swarrow id & & \searrow \epsilon \\
 H & \xrightarrow{\epsilon} & k & & k &
 \end{array} \tag{A-2.12}$$

commute. The proof of the theorem involves the comparison of the commutative diagrams expressing both statements to see that they are equivalent.

The theorem inspires the following definition.

**Definition:** A bi-algebra is a quintuple  $(H, \mu, \eta, \Delta, \epsilon)$ , where  $(H, \mu, \eta)$  is an algebra and  $(H, \Delta, \epsilon)$  is co-algebra satisfying the mutually equivalent conditions of the previous theorem. A morphisms of bi-algebras is a morphism for the underlying algebra and bi-algebra structures.

An element  $x \in H$  is known as primitive if one has  $\Delta(x) = 1 \otimes x + x \otimes 1$  and have  $\epsilon(x) = 0$ . The subspace of primitive elements is closed with respect to the commutator  $[x, y] = xy - yx$ . Note that for primitive elements  $\mu \circ \Delta = 2id_H$  holds true so that  $\mu/2$  acts as the left inverse of  $\Delta$ .

Given a vector space  $V$ , there exists a unique bi-algebra structure on the tensor algebra  $T(V)$  such that  $\Delta(v) = 1 \otimes v + v \otimes 1$  and  $\epsilon(v) = 0$  for any element  $v$  of  $V$ . By the symmetry of  $\Delta$  this bi-algebra structure is co-commutative and corresponds to the "classical limit". Also the Grassmann algebra associated with  $V$  allows bi-algebra structure defined in the same manner.

Figure A-2.2 provides a representation for the axioms of bi-algebra stating that  $\Delta$  and  $\epsilon$  act as algebra morphisms of algebra and or equivalent that  $\mu$  and  $\eta$  act as co-algebra morphisms. The axiom stating that  $\Delta$  ( $\mu$  is algebra (co-algebra) morphism implies that scattering diagrams differing by a box loop are equivalent. The statement that  $\mu$  is co-algebra morphism reads  $(id \otimes \mu \otimes id)(\Delta \otimes \Delta) = \Delta \circ \mu$  whereas the mirror statement  $\Delta(ab) = \Delta(a)\Delta(b)$  for  $\Delta$  reads as  $\Delta \circ \mu = \mu(\Delta \otimes \Delta)$  and gives rise to the same graph.

Figure 3: Graphical representation for the conditions guaranteeing that  $\mu$  and  $\eta$  ( $\Delta$  and  $\epsilon$ ) act as homomorphisms of co-algebra (algebra). a)  $(id \otimes \mu \otimes id)(\Delta \otimes \Delta) = \Delta \circ \mu$ , b)  $\epsilon \circ \mu = id \circ (\epsilon \otimes \epsilon)$ , c)  $\Delta \circ \eta = \mu \otimes id_k$ , d)  $\epsilon \circ \eta = id_k$ .

**Hopf algebras**

Given an algebra  $(A, \mu, \eta)$  and co-algebra  $(C, \Delta, \epsilon)$ , one can define a bilinear map, the convolution on the vector space  $Hom(C, A)$  of linear maps from  $C$  to  $A$ . By definition, if  $f$  and  $g$  are such linear maps, then the convolution  $f \star g$  is the composition of the maps

$$C \xrightarrow{\Delta} C \otimes C \xrightarrow{f \otimes g} A \otimes A \xrightarrow{\mu} A \tag{A-2.13}$$

Using Sweedler’s sigma notation one has

$$f \star g(x) = \sum_{\{x\}} f(x')g(x'') \tag{A-2.14}$$

It can be shown that the triple  $(Hom(C, A), \star, \Delta, \eta \circ \epsilon)$  is an algebra and that the map  $\Lambda_{C,A} : A \otimes C^* \rightarrow Hom(C, A)$  defined as

$$\Lambda_{C,A}(a \otimes \gamma)(c) = \gamma(c)a$$

is a morphism of algebras, where  $C^*$  is the dual of the finite-dimensional co-algebra  $C$ .

For  $A = C$  the result gives a mathematical justification for the crossing symmetry inspired re-interpretation of the unitary S-matrix interpreted usually as an element of  $Hom(A, A)$  as a state generated by element of  $A \otimes A^*$  from the vacuum  $|vac\rangle = |vac_A\rangle \otimes |vac_{A^*}\rangle$ . This corresponds to the interpretation of the reaction  $a_i|vac_A\rangle \rightarrow a_f|vac_A\rangle$  as a transition creating state  $a_i \otimes a_f^*|vac\rangle$  with vanishing conserved quantum numbers from vacuum.

With these prerequisites one can introduce the notion of Hopf algebra. Let  $(H, \mu, \eta, \Delta, \epsilon)$  be a bi-algebra. An endomorphism  $S$  of  $H$  is called an antipode for the bi-algebra  $H$  if

$$S \star id_H = id_H \star S = \eta \circ \epsilon \tag{A-2.15}$$

A Hopf algebra is a bi-algebra with an antipode. A morphism of a Hopf algebra is a morphism between the underlying bi-algebras commuting with the antipodes.

The graphical representation of the antipode axiom is given in the figure below.

The notion of scalar product central for physical applications boils down to the notion of duality. Duality between Hopf algebras  $U$  and  $H$  means the existence of a morphism  $x \rightarrow \Psi(x): H \rightarrow U^*$

Figure 4: Graphical representation of antipode axiom  $S \star id_H = id_H \star S = \eta \circ \epsilon$ .

defined by a bilinear form  $\langle u, x \rangle = \Psi(x)(u)$  on  $U \times H$ , which is a bi-algebra morphism. This means that the conditions

$$\begin{aligned}
 \langle uv, x \rangle &= \langle u \otimes v, \Delta(x) \rangle, & \langle u, xy \rangle &= \langle \Delta(u), x \otimes y \rangle, \\
 \langle 1, x \rangle &= \epsilon(x), & \langle u, 1 \rangle &= \epsilon(u), \\
 \langle S(u), x \rangle &= \langle u, S(x) \rangle
 \end{aligned}
 \tag{A-2.15}$$

are satisfied. The first condition on multiplication and co-multiplication, when expressed graphically, states that the decay  $x \rightarrow u \otimes v$  can be regarded as time reversal for the fusion of  $u \otimes v \rightarrow x$ . Second condition has analogous interpretation.

Figure 5: Graphical representation of the duality condition  $\langle uv, x \rangle = \langle u \otimes v, \Delta(x) \rangle$ .

### Modules and comodules

Left and right algebra modules and algebra representations are defined in an obvious manner and satisfy associativity and unit axioms having diagrammatic representation similar to that for corresponding algebra axioms.

A left co-module corresponds a pair  $(V, \Delta_V)$ , where the co-action  $\Delta_N: V \rightarrow C \otimes V$  satisfies co-associativity axiom  $(id_C \otimes \Delta_N) \circ \Delta_N = (\Delta \otimes id_N) \circ \Delta_N$  and co-unit axiom  $(\epsilon \otimes id) \circ \Delta_N = id_N$ . A right co-module is defined in an analogous manner. It is convenient to introduce Sweedlers's notation for  $\Delta_N$  as  $\Delta_N = \sum_{\{c\}} x_C \otimes x_N$ .

One can define module and comodule morphisms and tensor product of modules and co-modules in a rather obvious manner. The module  $N$  could be also algebra, call it  $A$ , in which case  $\mu_A$  and  $\eta_A$  are assumed to act as H-comodule morphisms.

The standard example is quantum plane  $A = M(2)_q$  is the free algebra generated variables  $x, y$  subject to relations  $yx = qxy$  and having coefficients in  $k$ . The action of  $\Delta_A$  reads as

$$\Delta_A \begin{pmatrix} x \\ y \end{pmatrix} = \begin{pmatrix} a & b \\ c & d \end{pmatrix} \otimes \begin{pmatrix} x \\ y \end{pmatrix} .$$

$\Delta_A$  defines algebra morphism from  $A$  to  $SL(2)_q \otimes A$ :  $\Delta_a(yx) = \Delta_A(y)\Delta_A(x) = q\Delta_A(x)\Delta_A(y) = \Delta(qxy)$ .

**Braided bi-algebras**

$\Delta^{op} = \tau_{H,H} \circ \Delta$  defines the opposite co-algebra  $H^{op}$  of  $H$ . A braided bi-algebra  $(H, \mu, \eta, \Delta, \epsilon)$  is called quasi-co-commutative (or quasi-triangular) if there exists an element  $R$  of algebra  $H \otimes H$  such that for all  $x \in H$  one has

$$\Delta^{op} = R\Delta R^{-1} .$$

One can express  $R$  in the form

$$R = \sum_i s_i \otimes t_i .$$

It is convenient to denote by  $R_{ij}$  the  $R$  matrix acting in  $i^{th}$  and  $j^{th}$  tensor factors of  $n^{th}$  tensor power of  $H$ . More precisely,  $R_{ij}$  can be defined as an operator acting in an  $n$ -fold tensor power of  $H$  by the formula  $R_{ij} = y^{(1)} \otimes y^{(2)} \otimes \dots \otimes y^{(p)}$ ,  $p \leq n$ ,  $y^{(k_i)} = s_i$  and  $y^{(k_j)} = t_j$ ,  $y^{(k)} = 1$  otherwise. For instance, one has  $R_{13} = \sum_i s_i \otimes 1 \otimes t_i$ .

With these prerequisites one can define a braided bi-algebra as a quasi-commutative bi-algebra  $(H, \mu, \eta, \Delta, \epsilon, S, S^{-1}, R)$  as an algebra with a preferred element  $R \in H \otimes H$  satisfying the two relations

$$\begin{aligned} (\Delta \otimes id_H)(R) &= R_{13}R_{23} , \\ (id_H \otimes \Delta)(R) &= R_{13}R_{12} . \end{aligned} \tag{A-2.16}$$

Braided bi-algebras, known also as quasi-triangular bi-algebras, are central in the theory of quantum groups, R-matrices, and braid groups. By a direct calculations one can verify the following relations.

1. Yang-Baxter equations

$$R_{12}R_{13}R_{23} = R_{23}R_{13}R_{12} , \tag{A-2.17}$$

and the relation

$$(\epsilon \otimes id_H)(R) = 1 \tag{A-2.18}$$

hold true.

2. Since  $H$  has an invertible antipode  $S$ , one has

$$\begin{aligned} (S \otimes id_H)(R) &= R^{-1} = (id_H \otimes S^{-1})(R) , \\ (S \otimes S)(R) &= R . \end{aligned} \tag{A-2.19}$$

The graphical representation of the Yang-Baxter equation in terms of the relations of braid group generators is given in the figure A-2.2.

Figure 6: Graphical representation of Yang-Baxter equation  $R_{12}R_{13}R_{23} = R_{23}R_{13}R_{12}$ .

**Ribbon algebras**

Let  $H$  be a braided Hopf algebra with a universal matrix  $R = \sum_i s_i \otimes t_i$  and set  $u = \sum_i S(t_i)s_i$ . It can be shown that  $u$  is invertible with the inverse  $u^{-1} = \sum_i s_i S^2(t_i)$  and that  $uS(u) = S(u)u$  is central element in  $H$ . Furthermore, one has  $\epsilon(u) = 1$  and  $\Delta(u) = (R_{21}R)^{-1}(u \otimes u)$ , and the antipode is given for any  $x \in H$  by  $S^2(x) = u x u^{-1}$ .

Ribbon algebra has besides  $R \in H \otimes H$  also a second preferred element called  $\theta$ . A braided Hopf algebra is called ribbon algebra if there exists a central element  $\theta$  of  $H$  satisfying the relations

$$\Delta(\theta) = (R_{21}R)^{-1}(\theta \otimes \theta) , \quad \epsilon(\theta) = 1 , \quad S(\theta) = \theta . \tag{A-2.20}$$

It can be shown that  $\theta^2$  acts like  $S(u)u$  on any finite-dimensional module [94] .

**Drinfeld’s quantum double**

Drinfeld’s quantum double construction allows to build a quasi-triangular Hopf algebra by starting from any Hopf algebra  $H$  and its dual  $H^*$ , which exists in a finite-dimensional case always, and as a vector space is isomorphic with  $H$ . Besides duality normal ordering is second ingredient of the construction. Physically the generators of the algebra and its dual correspond to creation and annihilation operator type operators. Drinfeld’s quantum double construction is represented in a very general manner in [94] . A construction easier to understand by a physicist is discussed in [55]. For this reason this representation is summarized here although the style differs from the representation of [94] followed in the other parts of appendices.

Consider first what is known.

1. Duality means the existence of basis  $\{e_a\}$  for  $H$  and  $\{e^a\}$  for  $H^*$  and inner product (or evaluation as it is called in [94] )  $ev : H^* \otimes H \rightarrow k$  defined as  $ev(e^a e_b) \equiv \langle e^a, e_b \rangle = \delta_b^a$  and its inverse  $\delta : k \rightarrow H^* \otimes H$  defined by  $\delta(1) = e^a e_a$ . One can extend the inner product to an inner product in the tensor product  $(H^* \otimes H^*) \otimes (H \otimes H)$  in an obvious manner.
2. The product (co-product) in  $H$  ( $H^*$ ) coincides with the co-product (product) in  $H^*$  ( $H$ ) in the sense that one has

$$\begin{aligned} \langle e^c, e_a e_b \rangle &= m_{ab}^c = \langle \Delta(e^c), e_b \otimes e_a \rangle , \\ \langle e^a e^b, e_c \rangle &= \mu_c^{ab} = \langle e^a \otimes e^b, \Delta(e_c) \rangle , \end{aligned} \tag{A-2.21}$$

These equations are quite general expressions for the duality expressed graphically in figure A-2.2.

3. The antipodes  $S$  for  $H$  and  $H^*$  can be represented as matrices

$$S_H(e_a) = S_a^b e_b \quad , \quad S_{H^*}(e^a) = (S^{-1})^a_b e^b \quad . \tag{A-2.22}$$

The task is to construct algebra product  $\mu$  and co-algebra product  $\Delta$ , unit  $\eta$  and co-unit  $\epsilon$ , antipode, and R-matrix  $R$  for  $H \otimes H^*$ . The natural basis for  $H \otimes H^*$  consists of  $e_a \otimes e^b$ .

1. Co-product  $\Delta$  is simply the product of co-products

$$\Delta(e_a e^b) = \Delta(e_a) \Delta(e^b) = m_{vu}^b \mu_a^{cd} e_c e^u \otimes e_d e^v \quad . \tag{A-2.23}$$

2. Product  $\mu$  involves normal ordering prescription allowing to transform products  $e^a e_b$  (elements of  $H^* \otimes H$ ) to combinations of basis elements  $e_a e^b$  (elements of  $H \otimes H^*$ ). This map must be consistent with the requirement that co-product acts as an algebra morphism. Drinfeld's normal ordering prescription, or rather a map  $c_{H^*,H}: H^* \otimes H \rightarrow H \otimes H^*$  is given by

$$c_{H^*,H}(e^a e_b) = R_{bd}^{ac} e_c e^d \quad , \quad R_{bd}^{ac} = m_{kd}^x m_{xu}^a \mu_b^{vy} \mu_y^{ck} (S^{-1})^u_v e_c e^d \quad . \tag{A-2.24}$$

The details of the formula are far from being obvious: the axioms of tensor category with duality to be discussed later might allow to relate  $R_{H^*,H}$  to  $R_{H,H}$  and this might help to understand the origin of the expression. Normal ordering map can be interpreted as braid operation exchanging  $H$  and  $H^*$  and the matrix defining the map could be regarded as R-matrix  $R_{H \otimes H^*}$ .

3. The universal R-matrix is given by

$$R = (e_a \otimes id_{H^*}) \otimes (id_H \otimes e^a) \quad , \tag{A-2.25}$$

where the summation convention is applied. One can show that  $R\Delta = \Delta^{op}R$  by a direct calculation.

4. The antipode  $S_{H \otimes H^*}$  follows from the product of antipodes for  $H$  and  $H^*$  using the fact that antipode is antihomomorphism using the normal ordering prescription

$$S_{H \otimes H^*}(e_a e^b) = c_{H^*,H}(S(e^b)S(e_a)) \quad . \tag{A-2.26}$$

**Quasi-Hopf algebras and Drinfeld associator**

Braided Hopf algebras are quasi-commutative in the sense that one has  $\Delta^{op} = R\Delta R^{-1}$ . Also the strict co-associativity can be given up and this means that one has

$$(\Delta \otimes id)\Delta = \Phi(id \otimes \Delta)\Phi^{-1} \quad , \tag{A-2.27}$$

where  $\Phi \in H \otimes H \otimes H$  is known as Drinfeld's associator and appears in the of conformal fields theories. If the resulting structure satisfies also the so called Pentagon Axiom (to be discussed later, see Eq. A-2.36 and figure A-2.3), it is called quasi-Hopf algebra. Pentagon Axiom boils down to the condition

$$(id \otimes id \otimes \Delta)(\Phi)(\Delta \otimes id \otimes id)(\Phi) = (id \otimes \Phi)(id \otimes id \otimes \Delta)(\Phi)(\Phi \otimes id) \quad . \tag{A-2.28}$$

The Yang-Baxter equation for quasi-Hopf algebra reads as

$$R_{12}\Phi_{312}R_{13}\Phi_{132}^{-1}R_{23}\Phi_{123} = \Phi_{321}R_{23}\Phi_{231}^{-1}R_{13}\Phi_{213}R_{12}\Phi_{123} . \quad (\text{A-2.29})$$

The left-hand side arises from a sequence of transformations

$$(12)3 \xrightarrow{\Phi_{123}} 1(23) \xrightarrow{R_{23}} 1(32) \xrightarrow{\Phi_{132}^{-1}} (31)2 \xrightarrow{R_{13}} 3(12) \xrightarrow{\Phi_{312}} 3(12) \xrightarrow{R_{12}} 3(21) .$$

The right-hand side arises from the sequence

$$(12)3 \xrightarrow{R_{12}} (21)3 \xrightarrow{\Phi_{213}} 2(13) \xrightarrow{R_{13}} 2(31) \xrightarrow{\Phi_{231}^{-1}} (23)1 \xrightarrow{R_{23}} (32)1 \xrightarrow{\Phi_{321}} 3(21) .$$

One can produce new quasi-Hopf algebras by gauge (or twist) transformations using invertible element  $\Omega \in H \otimes H$  called twist operator

$$\begin{aligned} \Delta(a) &\rightarrow \Omega\Delta(a)\Omega^{-1} , \\ \Phi &\rightarrow \Omega_{23}(id \otimes \Delta)(\Omega)\Phi(\Delta \otimes id)(\Omega^{-1})\Omega_{12}^{-1} , \\ R &\rightarrow \Omega R\Omega^{-1} . \end{aligned} \quad (\text{A-2.30})$$

Quasi-Hopf algebras appear in conformal field theories and correspond quantum universal enveloping algebras divided by their centralizer. Consider as an example the R-matrix  $R^{j_1, j_2}$  relating  $j_1 \otimes j_2$  and  $j_2 \otimes j_1$  representations  $\Delta^{j_1, j_2}(a)$  and  $\Delta^{j_2, j_1}(a)$  of the co-product  $\Delta$  of  $U(sl(2))_q$ .  $\Delta^{j, j}(a)$  commutes with  $R^{jj}$  for all elements of the quantum group. The action of  $g_i = qR^{jj}$  acting in  $i^{th}$  and  $(i+1)^{th}$  tensor factors extends to the representation  $(V_j)^{\otimes n}$  in an obvious manner. From the Yang-Baxter equation it follows that the operators  $g_i$  define a representation of braid group  $B_n$ :

$$\begin{aligned} g_i g_{i+1} g_i &= g_{i+1} g_i g_{i+1} , \\ g_i g_j &= g_j g_i , \text{ for } |j - k| \geq 2 . \end{aligned} \quad (\text{A-2.31})$$

Under certain conditions the braid group generators generate the whole centralizer  $C_q^n$  for the representation of quantum group. For instance, this occurs for  $j = 1/2$ . In this case the additional condition

$$g_i^2 = (q^2 - 1)g_i + q^2 \times 1 , \quad (\text{A-2.32})$$

so that the centralizer is isomorphic with the Hecke algebra  $H_n(q)$ , which can be regarded as a  $q$ -deformation of permutation group  $S_n$ .

The result generalizes. In Wess-Zumino-Witten model based on group  $G$  the relevant algebraic structure is  $U(G_q)/C^n(q)$ . This is quasi-Hopf algebra and the so called Drinfeld associator characterizes the quasi-associativity.

### A-2.3 Tensor categories

Hopf algebras and related structures do not seem to be quite enough in order to formulate elegantly the construction of S-matrix in TGD framework. A more general structure known as a braided tensor category with left duality and twist operation making the category to a ribbon category is needed. The algebra product  $\mu$  and co-product  $\Delta$  must be generalized so that they appear as morphisms  $\mu_{A \otimes B \rightarrow C}$  and  $\Delta_{A \rightarrow B \otimes C}$ : this gives hopes of describing 3-vertices algebraically. It is not clear whether one can assume single underlying algebra so that objects would correspond to different representations of this algebra or whether one allow even non-isomorphic algebras.

In the tensor category the tensor products of objects and corresponding morphisms belong to the category. In a braided category the objects  $U \otimes V$  and  $V \otimes U$  are related by a braiding morphism.

The notion of braided tensor category appears naturally in topological and conformal quantum field theories and seems to be an appropriate tool also in TGD context. The basic category theoretical notions are discussed in [94] and I have already earlier considered category theory as a possible tool in the construction of quantum TGD and TGD inspired theory of consciousness [14].

In braided tensor categories one introduces the braiding morphism  $c_{V,W} : V \otimes W \rightarrow W \otimes V$ , which is closely related to R-matrix. In categories allowing duality arrows with both directions are allowed ad diagrams analogous to pair creation from vacuum are possible. In ribbon categories one introduces also the twist operation  $\theta_V$  as a morphism of object and the  $\Theta_W$  satisfies the axiom:  $\theta_{V \otimes W} = (\theta_V \otimes \theta_W)c_{W,V}c_{V,W}$ . One can also introduce morphisms with arbitrary number of incoming lines and outgoing lines and visualize them as boxes, coupons. Isotopy principle, originally related to link and knot diagrams provides a powerful tool allowing to interpret the basic axioms of ribbon categories in terms of isotopy invariance of the diagrams and to invent theorems by just isotoping.

**Categories, functors, natural transformations**

Categories [94, 100, 113, 88] are roughly collections of objects A, B, C... and morphisms  $f(A \rightarrow B)$  between objects A and B such that decomposition of two morphisms is always defined. Identity morphisms map objects to objects. Examples of categories are open sets of some topological spaces with continuous maps between them acting as morphisms, linear spaces with linear maps between them acting as morphisms, groups with group homomorphisms taking the role of morphisms. Practically any collection of mathematical structures can be regarded as a category. Morphisms can be very general: for instance, partial ordering  $a \leq b$  can define a morphism  $f(A \rightarrow B)$ .

Functors between categories map objects to objects and morphisms to morphisms so that a product of morphisms is mapped to the product of the images and identity morphism is mapped to identity morphism. Functor  $F : \mathcal{C} \rightarrow \mathcal{D}$  commutes also with the maps  $s$  and  $b$  assigning to a morphism  $f : V \rightarrow W$  its source  $s(f) = V$  and target  $b(f) = W$ .

A natural transformation between functors  $F$  and  $G$  from  $\mathcal{C} \rightarrow \mathcal{C}'$  is a family of morphisms  $\eta(V) : F(V) \rightarrow G(V)$  in  $\mathcal{C}'$  indexed by objects  $V$  of  $\mathcal{C}$  such that for any morphisms  $f : V \rightarrow W$  in  $\mathcal{C}$ , the square

$$\begin{array}{ccc}
 F(V) & \xrightarrow{\eta(V)} & G(V) \\
 \downarrow F(f) & & \downarrow G(f) \\
 F(W) & \xrightarrow{\eta(W)} & G(W)
 \end{array} \tag{A-2.33}$$

commutes.

The functor  $F : \mathcal{C} \rightarrow \mathcal{D}$  is said to be equivalence of categories if there exists a functor  $G : \mathcal{D} \rightarrow \mathcal{C}$  such and natural isomorphisms

$$\eta : id_{\mathcal{D}} \rightarrow FG \text{ and } \theta : GF \rightarrow id_{\mathcal{C}}$$

The notion of adjoint functor is a more general notion than equivalence of categories. In this case  $\eta$  and  $\theta$  are natural transformations but not necessary natural isomorphisms in such a manner that the composite maps

$$\begin{array}{ccccc}
 F(V) & \xrightarrow{\eta(F(V))} & (FGF)(V) & \xrightarrow{F(\theta(V))} & F(V) \\
 \\
 G(W) & \xrightarrow{G(\eta(W))} & (GFG)(W) & \xrightarrow{\theta(G(W))} & G(W)
 \end{array} \tag{A-2.34}$$

are identify morphisms for all objects V in  $\mathcal{C}$  and W in  $\mathcal{D}$ .

The product  $C = AB$  for objects of categories is defined by the requirement that there exist projection morphisms  $\pi_A$  and  $\pi_B$  from C to A and B and that for any object D and pair of morphisms  $f(D \rightarrow A)$  and  $g(D \rightarrow B)$  there exist morphism  $h(D \rightarrow C)$  such that one has  $f = \pi_A h$  and  $g = \pi_B h$ . Graphically this corresponds to a square diagram in which pairs A,B and C,D correspond to the pairs formed by opposite vertices of the square and arrows DA and DB correspond to morphisms f and g,

arrows CA and CB to the morphisms  $\pi_A$  and  $\pi_B$  and the arrow  $h$  to the diagonal DC. Examples of product categories are Cartesian products of topological spaces, linear spaces, differentiable manifolds, groups, etc. The tensor products of linear spaces and algebras provides an especially interesting example of product in the recent case. One can define also more advanced concepts such as limits and inverse limits. Also the notions of sheafs, presheafs, and topos are important.

**Tensor categories**

Let  $\mathcal{C}$  be a category. Tensor product  $\otimes$  is a functor from  $\mathcal{C} \times \mathcal{C}$  to  $\mathcal{C}$  if

1. there is an object  $V \otimes W$  associated with any pair  $(V, W)$  of objects of  $\mathcal{C}$
2. there is an morphism  $f \otimes g$  associated with any pair  $(f, g)$  of morphisms of  $\mathcal{C}$  such that  $s(f \otimes g) = s(f) \otimes s(g)$  and  $b(f \otimes g) = b(f) \otimes b(g)$ ,
3. if  $f'$  and  $g'$  are morphisms such that  $s(f') = b(f)$  and  $s(g') = b(g)$  then  $(f' \otimes g') \circ (f \otimes g) = (f' \circ f) \otimes (g' \circ g)$  ,
4.  $id_{V \otimes W} = id_{W \otimes V}$  .

Any functor with these properties is called tensor product. The tensor product of vector spaces provides the most familiar example of a tensor product functor.

In figure 4 the general rules for graphical representations of morphisms are given.

Figure 7: The graphical representation of morphisms. a)  $g \circ f: V \rightarrow W$ , b)  $f \otimes g$ , c)  $f : U_1 \otimes \dots \otimes U_m \rightarrow V_1 \otimes \dots \otimes V_n$ .

An associativity constraint for the tensor product is a natural isomorphism

$$a : \otimes(\otimes \times id) \rightarrow \otimes(id \times \otimes) .$$

On basis of general definition of natural isomorphisms (see Eq. A-2.33) one can conclude that for any triple  $(U, V, W)$  of objects of  $\mathcal{C}$  there exists an isomorphism

$$\begin{array}{ccc}
 (U \otimes V) \otimes W & \xrightarrow{a_{U,V,W}} & U \otimes (V \otimes W) \\
 \downarrow (f \otimes g) \otimes h & & \downarrow f \otimes (g \otimes h) \\
 (U' \otimes V') \otimes W' & \xrightarrow{a_{U',V',W'}} & U' \otimes (V' \otimes W')
 \end{array} \tag{A-2.35}$$

Associativity constraints satisfies Pentagon Axiom [94] if the following diagrams commutes.

$$\begin{array}{ccc}
 U \otimes (V \otimes W) \otimes X & \xleftarrow{a_{U,V,W} \otimes id_X} & ((U \otimes V) \otimes W) \otimes X \\
 \downarrow a_{U,V \otimes W, X} & & \downarrow a_{U \otimes V, W, X} \\
 & & (U \otimes V) \otimes (W \otimes X) \\
 & & \downarrow a_{U, V, W \otimes X} \\
 U \otimes ((V \otimes W) \otimes X) & \xrightarrow{id_U \otimes a_{V, W, X}} & U \otimes (V \otimes (W \otimes X))
 \end{array} \tag{A-2.36}$$

Pentagon axiom has been already mentioned while discussing the definition of quasi-Hopf algebras. In figure A-2.3 are graphical illustrations of associativity morphism  $a(U, V, W)$ , Triangle Axiom, and Pentagon Axiom are given.

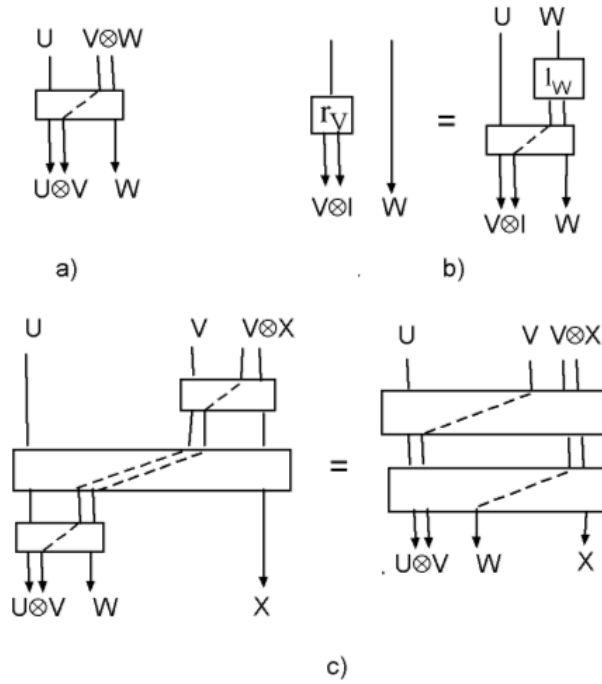

Figure 8: Graphical representations of a) the associativity isomorphism  $a_{U,V,W}$ , b) Triangle Axiom, c) Pentagon Axiom.

Assume that an object  $I$  is fixed in the category. A left unit constraint with respect to  $I$  is a natural isomorphism

$$l : \otimes(I \times id) \rightarrow id$$

By Eq. A-2.33 this means that for any object  $V$  of  $C$  there exists an isomorphism

$$l_V : I \otimes V \rightarrow V \tag{A-2.37}$$

such that

$$\begin{array}{ccc}
 I \otimes V & \xrightarrow{l_V} & V \\
 \downarrow id_I \otimes f & & \downarrow f \\
 I \otimes V' & \xrightarrow{l_{V'}} & V'
 \end{array} \tag{A-2.38}$$

The right unit constraint  $r : \otimes(id \times I) \rightarrow id$  can be defined in a completely analogous manner.

Given an associativity constraint  $a$ , and left and right unit constraints  $l, r$  with respect to an object  $I$ , one can say that the Triangle Axiom is satisfied if the triangle

$$\begin{array}{ccc}
 (V \otimes I) \otimes W & \xrightarrow{a_{V,I,W}} & V \otimes (I \otimes W) \\
 \searrow r_V \otimes id_W & & \swarrow id_W \otimes l_W \\
 & V \otimes W &
 \end{array} \tag{A-2.39}$$

commutes (see figure A-2.3).

These ingredients lead allow to define tensor category  $(\mathcal{C}, I, a, l, r)$  as a category  $\mathcal{C}$  which is equipped with a tensor product  $\otimes : \mathcal{C} \times \mathcal{C} \rightarrow \mathcal{C}$  satisfying associativity constraint  $a$ , left unit constraint  $l$  and right unit constraint  $r$  with respect to  $I$ , such that Pentagon Axiom and Triangle Axiom are satisfied.

The definition of a tensor functor  $F : \mathcal{C} \rightarrow \mathcal{D}$  involves also additional isomorphisms.  $\phi_0 : I \rightarrow F(I)$  satisfies commutative diagrams involving right and left unit constraints  $l$  and  $r$ . The family of isomorphisms

$$\phi_2(U, V) : F(U) \otimes F(V) \rightarrow F(U \otimes V)$$

satisfies a commutative diagram stating that  $\phi_2$  commutes with associativity constraints. The interested reader can consult [94] for details. One can also define the notions of natural tensor transformation, natural tensor isomorphism, and tensor equivalence between tensor categories by applying the general category theoretical tools.

Keeping track of associativity isomorphisms is obviously a rather heavy burden. Fortunately, it can be shown that one can assign to a tensor category  $\mathcal{C}$  a strictly associative (or briefly, strict) tensor category which is tensor equivalent of  $\mathcal{C}$ .

### Braided tensor categories

Braided tensor categories satisfy also commutativity constraint  $c$  besides associativity constraint  $a$ . Denote by  $\tau : \mathcal{C} \times \mathcal{C} \rightarrow \mathcal{C} \times \mathcal{C}$  the flip functor defined by  $\tau(V, W) = (W, V)$ . Commutativity constraint is a natural isomorphism

$$c : \otimes \rightarrow \otimes \tau .$$

This means that for any pair  $(V, W)$  of objects there exists isomorphism

$$c_{V,W} : V \otimes W \rightarrow W \otimes V$$

such that the square

$$\begin{array}{ccc}
 V \otimes W & \xrightarrow{c_{V,W}} & W \otimes V \\
 \downarrow f \otimes g & & \downarrow g \otimes f \\
 V' \otimes W' & \xrightarrow{c_{V',W'}} & W' \otimes V'
 \end{array} \tag{A-2.40}$$

commutes.

The commutativity constraint satisfies Hexagon Axiom if the two hexagonal diagrams

(H1)

$$\begin{array}{ccc}
 U \otimes (V \otimes W) & \xrightarrow{c_{U,V \otimes W}} & (V \otimes W) \otimes U \\
 \uparrow a_{U,V,W} & & \downarrow a_{V,W,U} \\
 (U \otimes V) \otimes W & & V \otimes (W \otimes U) \\
 \downarrow c_{U,V} \otimes id_W & \xrightarrow{id_V \otimes c_{U,W}} & \uparrow \\
 (V \otimes U) \otimes W & \xrightarrow{a_{V,U,W}} & V \otimes (U \otimes W)
 \end{array} \tag{A-2.41}$$

and (H2)

$$\begin{array}{ccc}
 (U \otimes V) \otimes W & \xrightarrow{c_{U \otimes V,W}} & W \otimes (U \otimes V) \\
 \uparrow a_{U,V,W}^{-1} & & \downarrow a_{W,U,V}^{-1} \\
 U \otimes (V \otimes W) & & (W \otimes U) \otimes V \\
 \downarrow id_U \otimes c_{V,W} & \xrightarrow{c_{U,W} \otimes id_V} & \uparrow \\
 U \otimes (W \otimes V) & \xrightarrow{a_{U,W,V}^{-1}} & (U \otimes W) \otimes V
 \end{array} \tag{A-2.42}$$

commute.

The braiding operation  $c_{V,W}$  and the association operation  $a(U, V, W)$ , and pentagon and hexagon axioms are illustrated in the figure A-2.3 below.

### Duality and tensor categories

The notion of a dual of the finite-dimensional vector space as a space of linear maps from  $V$  to field  $k$  can be lifted to a concept applying for tensor category. A strict (strictly associative) tensor category  $(\mathcal{C}, \otimes, I)$  with unit object  $I$  is said to possess left duality if for each object  $V$  of  $\mathcal{C}$  there exists an object  $V^*$  and morphisms

$$b_V : I \rightarrow V \otimes V^* \text{ and } d_V : V^* \otimes V \rightarrow I$$

such that

$$(id \otimes d_V)(b_V \otimes id_V) = id_V \text{ and } (d_V \otimes id_{V^*})(id_{V^*} \otimes b_V) = id_{V^*} . \tag{A-2.43}$$

One can define the transpose of  $f$  in terms of  $b_V$  and  $d_V$ . The idea how this is achieved is obvious from figure A-2.3.

$$f^* = (d_V \otimes id_{U^*})(id_{V^*} \otimes f \otimes id_{U^*})(id_{V^*} \otimes b_U) . \tag{A-2.44}$$

Also the braiding operation  $c_{V^*,W}$  can be expressed in terms of  $c_{V,W}^{-1}$ ,  $b_V$  and  $d_V$  by using the isotopy of Fig. A-2.3:

$$c_{V^*,W} = (d_V \otimes id_{W \otimes V^*})(id_{V^*} \otimes c_{V,W}^{-1} \otimes id_{V^*})(id_{V^*} \otimes W \otimes b_V) . \tag{A-2.45}$$

Figure 9: Graphical representations a) of the braiding morphism  $c_{V,W}$  and its inverse  $c_{V,W}^{-1}$ , b) of naturality of  $c_{V,W}$ , c) of First Hexagon Axiom.

Drinfeld quantum double can be regarded as a tensor product of Hopf algebra and its dual and in this case one can introduce morphisms  $ev_H : H \otimes H^* \rightarrow k$  defined as  $e^i \otimes e_j \rightarrow \delta_j^i$  defining inner product and its inverse  $\delta : k \rightarrow H \otimes H$  defined as  $1 \rightarrow e^i e_i$ , where summation over  $i$  is understood. For categories these morphisms are generalized to morphism  $d_V$  from objects  $V$  of category to unit object  $I$  and  $b_V$  from  $I$  to object of category. The elements of  $H$  and  $H^*$  are described as strands with opposite directions, whereas  $d_V$  and  $b_V$  correspond to annihilation and creation of strand–anti-strand pair as show in figure A-2.3.

Figure 10: Graphical representations a) of the morphisms  $b_V$  and  $d_V$ , b) of the transpose  $f^*$ , c) of braiding operation  $c_{V^*,W}$  expressed in terms of  $c_{V,W}$ .

**Ribbon categories**

According to the definition of [94] ribbon category is a strict braided tensor category  $(\mathcal{C}, \otimes, I)$  with a left duality with a family of natural morphisms  $\theta_V : V \rightarrow V$  indexed by the objects  $V$  of  $\mathcal{C}$  satisfying the conditions

$$\begin{aligned} \theta_{V \otimes W} &= \theta_V \otimes \theta_W c_{W,V} c_{V,W} \text{ ,} \\ \theta_{V^*} &= (\theta_V)^* \end{aligned} \tag{A-2.46}$$

for all objects  $V, W$  of  $\mathcal{C}$ . The naturality of twist means for for any morphisms  $f : V \rightarrow W$  one has  $\theta_W f = f \theta_V$ . The graphical representation for the axioms and is in Fig. A-2.3.

Figure 11: Graphical representations a) of  $\theta_{V \otimes W} = \theta_V \otimes \theta_W c_{W,V} c_{V,W}$ , b) of  $\theta_{V^*} = (\theta_V)^*$ , c) of  $\theta_W f = f \theta_V$ , d) of right duality for a ribbon category.

The existence of the twist operation provides  $\mathcal{C}$  with right duality necessary in order to define trace (see Fig. A-2.3).

$$\begin{aligned} d'_V &= (id_{V^*} \otimes \theta_V) c_{V,V^*} b_V, \\ b'_V &= d_V c_{V,V^*} (\theta_V \otimes id_{V^*}). \end{aligned} \tag{A-2.47}$$

One can define quantum trace for any endomorphisms  $f$  of ribbon category:

$$tr_q(f) = d'_V (f \otimes id_{V^*}) b_V = d_V c_{V,V^*} (\theta_V f \otimes id_{V^*}) b_V. \tag{A-2.48}$$

Again the graphical representation is the best manner to understand the definition, see figure A-2.3. Quantum trace has the basic properties of trace:  $tr_q(fg) = tr_q(gf)$ ,  $tr_q(f \otimes g) = tr_q(f)tr_q(g)$ ,  $tr_q(f) = tr_q(f^*)$ . The proof of these properties is easiest using isotropy principle.

Figure 12: Graphical representations of a)  $tr_q(f)$ , b) of  $tr_q(fg) = tr_q(gf)$ , c) of  $tr(f \otimes g) = tr(f)tr(g)$ .

The quantum dimension of an object  $V$  of ribbon category can be defined as the quantum trace for the identity morphism of  $V$ :  $dim_q(V) = tr_q(id_V) = d'_V b_V$ . Quantum dimension is represented as a vacuum bubble. Quantum dimension satisfies the conditions  $dim_q(V \otimes W) = dim_q(V)dim_q(W)$  and  $dim_q(V) = dim_q(V^*)$ .

A more general definition of ribbon category inspired by the considerations of [55] is obtained by allowing the generalization of morphisms  $\mu$  and  $\Delta$  so that they become morphisms  $\mu_{A \otimes B \rightarrow C}$  and  $\Delta_{C \rightarrow A \otimes B}$  of ribbon category. Graphically the general morphism with arbitrary number of incoming outgoing strands can be represented as a box or "coupon". An important special case of ribbon categories consists of modules over braided Hopf algebras allowing ribbon algebra structure.

### A-3 Axiomatic approach to S-matrix based on the notion of quantum category

This section can be regarded as an attempt of a physicists with some good intuitions and intentions but rather poor algebraic skills to formulate basic axioms about S-matrix in terms of what might be

called quantum category. The basic result is an interpretation for the equivalence of loop diagrams with tree diagrams as a consequence of basic algebra and co-algebra axioms generalized to the level of tensor category. The notion of quantum category emerges naturally as a generalization of ribbon category, when algebra product and co-algebra product are interpreted as morphisms between different objects of the ribbon category.

The general picture suggest that the operations  $\Delta$  and  $\mu$  generalized to algebra homomorphisms  $A \rightarrow B \otimes C$  and  $A \otimes B \rightarrow C$  in a tensor category whose objects are either representations of an algebra or even algebras might provide an appropriate mathematical tool for saying something interesting about S-matrix in TGD Universe. These algebras need not necessarily be bi-algebras. In the following it is demonstrated that the equivalence of loop diagrams to tree diagrams follows from suitably generalized bi-algebra axioms. Also the interpretation of various morphisms involved with Hopf algebra structure is discussed.

### A-3.1 $\Delta$ and $\mu$ and the axioms eliminating loops

The first task is to find a physical interpretation for the basic algebraic operations and how the basic algebra axioms might allow to eliminate loops. The physical interpretation of morphisms  $\Delta$  and  $\mu$  as algebra or category morphisms has been already discussed. As already found, the condition that  $\Delta$  ( $\mu$ ) acts as an algebra (co-algebra) morphism leads to a condition stating that a box graph for 2-particle scattering is equivalent with tree graph. It is interesting to identify the corresponding conditions in the case of self energy loops and vertex corrections.

The condition

$$\mu_{B \otimes C \rightarrow A} \circ \Delta_{A \rightarrow B \otimes C} = K \times id_A , \tag{A-3.1}$$

where  $K$  is a numerical factor, is a natural additional condition stating that a line with a self energy loop is equivalent with a line without the loop. The condition is illustrate in figure A-3.1. For the co-commutative tensor algebra  $T(V)$  of vector space with  $\Delta(x) = 1 \otimes x + x \otimes 1$  one would have  $K = 2$  for the generators of  $T(V)$ . For a product of  $n$  generators one has  $K = 2^n$ .

Figure 13: Graphical representations for the conditions a)  $(id \otimes \mu \otimes id)(\Delta \otimes \Delta) = \Delta \circ \mu$ , b)  $\mu_{B \otimes C \rightarrow A} \circ \Delta_{A \rightarrow B \otimes C} = K \times id_A$ , and c)  $(\mu \otimes id) \circ (\Delta \otimes id) \circ \Delta = K \times \Delta$ .

The condition  $\Delta_{A \rightarrow B \otimes C} \circ \mu_{B \otimes C \rightarrow A} = K \times id_A$  cannot hold true since multiplication is not an irreversible process. If this were the case one could reduce tree diagrams to collections of free propagator lines.

In quantum field theories also vertex corrections are a source of divergences. The requirement that the graph representing a vertex correction is equivalent with a simple tree graph representing a decay gives an additional algebraic condition. For bi-algebras the condition would read

$$(\mu \otimes id) \circ (\Delta \otimes id) \circ \Delta = K \Delta , \tag{A-3.2}$$

where  $K$  is a simple multiplicative factor. In fact, for the co-commutative tensor algebra  $T(V)$  of vector space the left hand side would be  $3 \times \Delta(x)$  giving  $K = 3$  for generators  $T(V)$ . The condition is illustrated in figure A-3.1.

Using the standard formulas of appendix for quantum groups one finds that in the case of  $U_q(sl(2))$  the condition  $\mu \circ \Delta(X) = K_X X$ ,  $K_X$  constant, is not true in general. Rather, one has  $\mu \circ \Delta(X) = X K_X (q^{H/2} + q^{-H/2}, q^{1/2}, q^{-1/2})$ . The action on the vacuum state is however proportional to that of  $X$ , being given by  $K_X(2, 1, 1)X$ . The function  $K_X$  for a given  $X$  can be deduced from  $\mu \circ \Delta(X_{\pm}) = q^{H/2} X_{\pm} + X_{\pm} q^{-H/2} = X_{\pm} (q^{\pm 1/2} + q^{H/2} + q^{-H/2})$ . The eigen states of Cartan algebra generators are expected to be eigen states of  $\mu \circ \Delta$  also in the case of a general quantum group.  $\mu \circ \Delta$  is analogous to a single particle operator like kinetic energy and its action on multi-particle state is a sum over all tensor factors with  $\mu \circ \Delta$  applied to each of them. For eigen states of  $\mu \circ \Delta$  the projective equivalence of loop diagrams with tree diagrams would make sense.

Since self energy loops, vertex corrections, and box diagrams represent the basic divergences of renormalizable quantum field theories, these axioms raise the hope that the basic infinities of quantum field theories could be eliminated by the basic axioms for the morphisms of quantum category.

There are also morphisms related to the topology changes in which the 3-surface remains connected. For instance, processes in which the number of boundary components can change could be of special relevance if the family replication phenomenon reduces to the boundary topology. Also 3-topology can change. The experience with topological quantum field theories [128], stimulates the hope that the braid group representations of the topological invariants of 3-topology might be of help in the construction of S-matrix.

The equivalence of loop diagrams with tree diagrams must have algebraic formulation using the language of standard quantum field theory. In the third section it was indeed found that thanks to the presence of the emission of vacuons, the equivalence of loop diagrams with tree diagrams corresponds to the vanishing of loop corrections in the standard quantum field theory framework. Furthermore, the non-cocommutative Hopf algebra of Feynman diagrams discussed in [66] becomes co-commutative when the loop corrections vanish so that TGD program indeed has an elegant algebraic formulation also in the standard framework.

### **A-3.2 The physical interpretation of non-trivial braiding and quasi-associativity**

The exchange of the tensor factors by braiding could also correspond to a physically non-trivial but unitary operation as it indeed does in anyon physics [9, 15]. What would differentiate between elementary particles and anyons would be the non-triviality of the super-canonical and Super Kac-Moody conformal central extensions which have the same origin (addition of a multiplication by a multiple of the Hamiltonian of a canonical transformation to the action of isometry generator). The proposed interpretation of braiding acting in the complex plane in which the conformal weights of the elements of the super-canonical algebra represent punctures justifies the non-triviality. Hexagon Axioms would state that two generalized Feynman diagrams involving exchanges, dissociations and re-associations are equivalent.

An interesting question is whether the association  $(A, B) \rightarrow (A \otimes B)$  could be interpreted as a formation of bound state entanglement between  $A$  and  $B$ . A possible space-time correlate for association is topological condensation of  $A$  and  $B$  to the same space-time sheet. Association would be trivial if all particles are at same space-time sheet  $X^4$  but non-trivial if some subset of particles condense at an intermediate space-time sheet  $Y^4$  condensing in turn at  $X^4$ .

Be as it may, association isomorphisms  $a_{A,B,C}$  would state that the state space obtained by binding  $A$  with bound bound states  $(B \otimes C)$  is unitarily related with the state space obtained by binding  $(A \otimes B)$  bound states with  $C$ . With this interpretation Pentagon axiom would state that two generalized Feynman diagrams depicted in figure A-2.3 leading from initial to final to final state by dissociation and reassociation are equivalent.

### **A-3.3 Generalizing the notion of bi-algebra structures at the level of configuration space**

Configuration space of 3-surfaces decomposes into sectors corresponding to different 3-topologies. Also other signatures might be involved and I have proposed that the sectors are characterized by the collection of p-adic primes labelling space-time sheets of the 3-surface and that a given space-time surface could be characterized by an infinite prime or integer. The general problem is to continue various geometric structures from a given sector  $A$  of configuration space to other sector  $B$ .

An especially interesting special case corresponds to a continuation from 1-particle sector to two-particle sector or vice versa and corresponds to TGD variant of 3-vertex. All these continuations involve the imbedding of a structure associated with the sector  $A$  to a structure associated with sector  $B$ . For the continuation from 1-particle sector to 2-particle sector the map is analogous to co-algebra homomorphism  $\Delta$ . For the reverse continuation it is analogous to the algebra product  $\mu$ . Now however one does not have maps  $\Delta : A \rightarrow A \otimes A$  and  $\mu : A \otimes A \rightarrow A$  but  $\Delta : A \rightarrow B \otimes C$  and  $\mu : B \otimes C \rightarrow A$  unless the algebras are isomorphic.  $\mu \circ \Delta = id$  should hold true as an additional condition but  $\Delta \circ \mu = id$  cannot hold true since product maps many pairs to the same element.

### Continuation of the configuration space spinor structure

The basic example of a structure to be continued is configuration space spinor structure. Configuration space spinor fields in different sectors should be related to each other. The isometry generators and gamma matrices of configuration space span a super-canonical algebra. The continuation requires that the super algebra basis of different sectors are related. Also vacua must be related. Isometry generators correspond to bosonic generators of the super-canonical algebra. There is also a natural extension of the super-canonical algebra defined by the Poisson structure of the configuration space.

This view suggests that in the first approximation one could see the construction of S-matrix as following process.

1. Incoming/outgoing states correspond to positive/negative energy states localized to the sectors of configuration space with fixed 3-topologies.
2. In order to construct an S-matrix matrix element between two states localized in sectors A and B, one must continue the state localized in A to B or vice versa and calculate overlap. The continuation involves a sequence of morphisms mapping various structures between sectors. In particular, topological transformations describing particle decay and fusion are possible so that the analogs of product  $\mu$  and co-product  $\Delta$  are involved. The construction of three-manifold topological invariants [128] in topological quantum field theories provides concrete ideas about how to proceed.
3. The S-matrix element describing a particular transition can be expressed as any path leading from the sector A to B or vice versa. There is a huge symmetry very much analogous to the independence of the final result of the analytic continuation on the path chosen since generalized Feynman graphs allow all moves changing intermediate topologies so that initial and final 3-topologies are same. Generalized conformal invariance probably also poses restrictions on possible paths of continuation. In the path integral approach one would have simply sum over all these equivalent paths and thus encounter the fundamental difficulties related to the infinite-dimensional integration.
4. Quantum classical correspondence suggests that the continuation operation has a space-time correlate. That is, the absolute minimum of Kähler action going through the initial and final 3-sheets defines a sequence of transitions changing the topology of 3-sheet. The localization to a particular sector of course selects particular absolute minimum. There are two possible interpretations. Either the continuation from A is not possible to all possible sectors but only to those with 3-topologies appearing in  $X^4$ , or the absolute minimum represents some kind of minimal continuation involving minimum amount of calculational labor.
5. Quantum classical correspondence and the possibility to represent the rows of S-matrix as zero energy quantum states suggests that the paths for continuation can be also represented at the space-time level, perhaps in terms of braided join along boundaries bonds connecting two light like 3-surfaces representing the initial and final states of particle reaction. Since light like 3-surfaces are metrically two-dimensional and allow conformal invariance, this suggests a connection with braid diagrams in the sense that it should be possible to regard the paths connecting sectors of configuration space consisting of unions of disjoint 3-surfaces (corresponding interacting 4-surfaces are connected) as generalized braids for which also decay and fusion for the strands of braid are possible. Quantum algebra structure and effective metric 2-dimensionality of the light like 3-surfaces suggests different braidings for join along boundaries bonds connecting boundaries of 3-surfaces define non-equivalent 3-surfaces.

**Co-multiplication and second quantized induced spinor fields**

At the microscopic level the construction of S-matrix reduces to understanding what happens for the classical spinor fields in a vertex, which corresponds to an incoming 3-surface A decaying to two outgoing 3-surfaces B and C. At the classical level incoming spinor field A develops into a spinor fields B and C expressible as linear combinations of appropriate spinor basis. At quantum level one must understand how the Fock space defined by the incoming spinor fields of A is mapped to the tensor product of Fock spaces of B and C. The idea about the possible importance of co-algebras came with the realization that this mapping is obviously is very much like a co-product. Co-algebras and bi-algebras possessing both algebra and co-algebra structure indeed suggest a general approach giving hopes of understanding how Feynman diagrammatics generalizes to TGD framework.

The first guess is that fermionic oscillator operators are mapped by the imbedding  $\Delta$  to a superposition of operators  $a_{Bn}^\dagger \otimes Id_C$  and  $Id_B \otimes a_{Cn}^\dagger$  with obvious formulas for Hermitian conjugates.  $\Delta$  induces the mapping of higher Fock states and the construction of S-matrix should reduce to the construction of this map.

$\Delta$  is analogous to the definition for co-product operation although there is also an obvious difference due to the fact that  $\Delta$  imbeds algebra  $A$  to  $B \otimes C$  rather than to  $A \otimes A$ . Only in the case that the algebras are isomorphic, the situation reduces to that for Hopf algebras. Category theoretical approach however allows to consider a more general situation in which  $\Delta$  is a morphism in the category of Fock algebras associated with 3-surfaces.

$\Delta$  preserves fermion number and should respect Fock algebra structure, in particular commute with the anti-commutation relations of fermionic oscillator operators. The basis of fermionic oscillator operators would naturally correspond to fermionic super-canonical generators in turn defining configuration space gamma matrices.

Since any leg can be regarded as incoming leg, strong consistency conditions result on the coefficients in the expression

$$\Delta(a_{An}^\dagger) = C(A, B)_n^m a_{Bm}^\dagger \otimes Id_C + C(A, C)_n^m Id_B \otimes a_{Cm}^\dagger \tag{A-3.3}$$

by forming the cyclic permutations in  $A, B, C$ . This option corresponds to the co-commutative situation and quantum group structure. If identity matrices are replaced with something more general, co-product becomes non-cocommutative.

**A-3.4 Ribbon category as a fundamental structure?**

There exists a generalization of the braided tensor category inspired by the axiomatic approach to topological quantum field theories which seems to almost catch the proposed mathematical requirements. This category is also called ribbon [7] [112] but in more general sense than it is defined in [94].

One adds to the tangle diagrams (braid diagrams with both directions of strands and possibility of strand–anti-strand annihilation) also "coupons", which are boxes representing morphisms with arbitrary numbers of incoming and outgoing strands. As a special case 3-particle vertices are obtained. The strands correspond to representations of a fixed Hopf algebra  $H$ .

In the recent case it would seem safest to postulate that strands correspond to algebras, which can be different because of the potential dependence of the details of Fock algebra on 3-topology and other properties of 3-surface. For instance, configuration space metric defined by anti-commutators of the gamma matrices is degenerate for vacuum extremals so that the infinite Clifford algebra is definitely "smaller" than for surfaces with  $D \geq 3$ -dimensional  $CP_2$  projection.

One might feel that the full ribbon algebra is an un-necessary luxury since only 3-particle vertices are needed since higher vertices describing decays of 3-surfaces can be decomposed to 3-vertices in the generic case. On the other hand, many-sheeted space-time and p-adic fractality suggest that coupons with arbitrary number of incoming and outgoing strands are needed in order to obtain the p-adic hierarchy of length scale dependent theories.

The situation would be the same as in the effective quantum field theories involving arbitrarily high vertices and would require what might be called universal algebra allowing n-ary multiplications and co-multiplications rather than only binary ones. Also strands within strands hierarchy is strongly suggestive and would require a fractal generalization of the ribbon algebra. Note that associativity and

commutativity conditions for morphisms which more than three incoming and outgoing lines would force to generalize the notion of R-matrix and would bring in conditions stating that more complex loop diagrams are equivalent with tree diagrams.

### A-3.5 Minimal models and TGD

Quaternion conformal invariance with non-vanishing  $c$  and  $k$  for anyons is highly attractive option and minimal super-conformal field theories attractive candidate since they describe critical systems and TGD Universe is indeed a quantum critical system.

#### Rational conformal field theories and TGD

The highest weight representations of Virasoro algebra are known as Verma modules containing besides the ground state with conformal weight  $\Delta$  the states generated by Virasoro generators  $L_n$ ,  $n \geq 0$ . For some values of  $\Delta$  Verma module contains states with conformal weight  $\Delta + l$  annihilated by Virasoro generators  $L_n$ ,  $n \geq 1$ . In this case the number of primary fields is reduced since Virasoro algebra acts as a gauge algebra. The conformal weights  $\Delta$  of the Verma modules allowing null states are given by the Kac formula

$$\Delta_{mm'} = \Delta_0 + \frac{1}{4}(\alpha_+ m + \alpha_- m')^2, \quad m, m' \in \{1, 2, \dots\}, \quad (\text{A-3.4})$$

$$\begin{aligned} \Delta_0 &= \frac{1}{24}(c-1), \\ \alpha_{\pm} &= \frac{\sqrt{1-c} \pm \sqrt{25-c}}{\sqrt{24}}. \end{aligned} \quad (\text{A-3.5})$$

The descendants  $\prod_{n \geq 1} L_n^{k_n} |\Delta\rangle$  annihilated by  $L_n$ ,  $n > 0$ , have conformal weights at level  $l = \sum_n n k_n = mm'$ .

In the general case the operator products of primary fields satisfying these conditions form an algebra spanned by infinitely many primary fields. The situation changes if the central charge  $c$  satisfies the condition

$$c = 1 - \frac{6(p'-p)^2}{pp'}, \quad (\text{A-3.6})$$

where  $p$  and  $p'$  are mutually prime positive integers satisfying  $p < p'$ . In this case the Kac weights are rational

$$\Delta_{m,m'} = \frac{(mp' - m'p)^2 - (p' - p)^2}{4pp'}, \quad 0 < m < p, \quad 0 < m' < p'. \quad (\text{A-3.7})$$

Obviously, the number of primary fields is finite. This option does not seem to be realistic in TGD framework were super-conformal invariance is realized.

For  $N = 1$  super-conformal invariance the unitary representations have central extension and conformal weights given by

$$\begin{aligned} c &= \frac{3}{2} \left(1 - \frac{8}{m(m+2)}\right), \\ \Delta_{p,q}(NS) &= \frac{[(m+2)p - mq]^2 - 4}{8m(m+2)}, \quad 0 \leq p \leq m, \quad 1 \leq q \leq m+2. \end{aligned} \quad (\text{A-3.8})$$

For Ramond representations the conformal weights are

$$\Delta_{p,q}(R) = \Delta(NS) + \frac{1}{16} . \tag{A-3.9}$$

The states with vanishing conformal weights correspond to light elementary particles and the states with  $p = q$  have vanishing conformal weight in NS sector. Also this option is non-realistic since in TGD framework super-generators carry fermion number so that  $G$  cannot be a Hermitian operator.

$N = 2$  super-conformal algebra is the most interesting one from TGD point of view since it involves also a bosonic  $U(1)$  charge identifiable as fermion number and  $G^\pm(z)$  indeed carry  $U(1)$  charge<sup>1</sup>. Hence one has  $N = 2$  super-conformal algebra is generated by the energy momentum tensor  $T(z)$ ,  $U(1)$  current  $J(z)$ , and super generators  $G^\pm(z)$ .  $U(1)$  current would correspond to fermion number and super generators would involve contraction of covariantly constant neutrino spinor with second quantized induced spinor field. The further facts that  $N = 2$  algebra is associated naturally with Kähler geometry, that the partition functions associated with  $N = 2$  super-conformal representations are modular invariant, and that  $N = 2$  algebra defines so called chiral ring defining a topological quantum field theory [55], lend further support for the belief that  $N = 2$  super-conformal algebra acts in super-canonical degrees of freedom.

The values of  $c$  and conformal weights for  $N = 2$  super-conformal field theories are given by

$$\begin{aligned} c &= \frac{3k}{k+2} , \\ \Delta_{l,m}(NS) &= \frac{l(l+2) - m^2}{4(k+2)} , \quad l = 0, 1, \dots, k , \\ q_m &= \frac{m}{k+2} , \quad m = -l, -l+2, \dots, l-2, l . \end{aligned} \tag{A-3.10}$$

$q_m$  is the fractional value of the  $U(1)$  charge, which would now correspond to a fractional fermion number. For  $k = 1$  one would have  $q = 0, 1/3, -1/3$ , which brings in mind anyons.  $\Delta_{l=0,m=0} = 0$  state would correspond to a massless state with a vanishing fermion number. Note that  $SU(2)_k$  Wess-Zumino model has the same value of  $c$  but different conformal weights. More information about conformal algebras can be found from the appendix of [55].

For Ramond representation  $L_0 - c/24$  or equivalently  $G_0$  must annihilate the massless states. This occurs for  $\Delta = c/24$  giving the condition  $k = 2 [l(l+2) - m^2]$  (note that  $k$  must be even and that  $(k, l, m) = (4, 1, 1)$  is the simplest non-trivial solution to the condition). Note the appearance of a fractional vacuum fermion number  $q_{vac} = \pm c/12 = \pm k/4(k+2)$ . I have proposed that NS and Ramond algebras could combine to a larger algebra containing also lepto-quark type generators.

Quaternion conformal invariance [15] encourages to consider the possibility of super-symmetrizing also spin and electro-weak spin of fermions. In this case the conformal algebra would extend to a direct sum of Ramond and NS  $N = 8$  algebras associated with quarks and leptons. This algebra in turn extends to a larger algebra if lepto-quark generators acting as half odd-integer Virasoro generators are allowed. The algebra would contain spin and electro-weak spin as fermionic indices. Poincare and color Kac-Moody generators would act as symplectically extended isometry generators on configuration space Hamiltonians expressible in terms of Hamiltonians of  $X_l^3 \times CP_2$ . Electro-weak and color Kac-Moody currents have conformal weight  $h = 1$  whereas  $T$  and  $G$  have conformal weights  $h = 2$  and  $h = 3/2$ .

The experience with  $N = 4$  super-conformal invariance suggests that the extended algebra requires the inclusion of also second quantized induced spinor fields with  $h = 1/2$  and their super-partners with  $h = 0$  and realized as fermion-antifermion bilinears. Since  $G$  and  $\Psi$  are labelled by  $2 \times 4$  spinor indices, super-partners would correspond to  $2 \times (3 + 1) = 8$  massless electro-weak gauge boson states with polarization included. Their inclusion would make the theory highly predictive since induced spinor and electro-weak fields are the fundamental fields in TGD.

In TGD framework both quark and lepton numbers correspond to NS and Ramond type representations, which in conformal field theories can be assigned to the topologies of complex plane and cylinder. This would suggest that a given three-surface allows either NS or Ramond representation

---

<sup>1</sup>I realized that TGD super-conformal algebra corresponds to  $N = 2$  algebra while writing this and proposed it earlier as a generalization of super-conformal algebra!

and is either leptonic or quark like but one must be very cautious with this kind of conclusion. Interestingly, NS and Ramond type representations allow a symmetry acting as a spectral flow in the indices of the generators and transforming NS and Ramond type representations continuously to each other [55]. The flow acts as

$$\begin{aligned}
 L_n &\rightarrow L_n + \alpha J_n + \frac{c}{6} \alpha^2 \delta_{n,0} \\
 J_n &\rightarrow J_n + \frac{c}{3} \alpha \delta_{n,0} \ , \\
 G_n^\pm &\rightarrow G_{n \pm \alpha}^\pm \ .
 \end{aligned}
 \tag{A-3.11}$$

The choice  $\alpha = \pm 1/2$  transforms NS representation to Ramond representation. The idea that leptons could be transformed to quarks in a continuous manner does not sound attractive in TGD framework. Note that the action of Super Kac-Moody Virasoro algebra in the space of super-canonical conformal weights can be interpreted as a spectral flow.

### Co-product for Super Kac-Moody and Super Virasoro algebras

By the previous considerations the quantized conformal weights  $z_1, z_2, z_3$  of super-canonical generators defining punctures of 2-surface should correspond to line punctures of 3-surface. One cannot avoid the thought that these line punctures should meet at single point so that three-vertex would have also quantum field theoretical interpretation.

Each point  $z_k$  corresponds to its own Virasoro algebra  $V_k = \{L_n^{z_k}\}$  and Kac-Moody algebra  $J_k = \{J_n^{z_k}\}$  defined by Laurent series of  $T(z)$  and  $J(z)$  at  $z_k$ . Also super-generators are involved. To minimize notational labor denote by  $X_n^{z_k}$ ,  $k = 1, 2, 3$  the generators in question.

The co-algebra product for Super-Virasoro and Super-Kac-Moody involves in the case of fusion  $A_1 \otimes A_2 \rightarrow A_3$  a co-algebra product assigning to the generators  $X_n^{z_3}$  direct sum of generators of  $X_k^{z_1}$  and  $X_l^{z_2}$ . The most straightforward approach is to express the generators  $X_n^{z_3}$  in terms of generators  $X_k^{z_1}$  and  $X_l^{z_2}$ . This is achieved by using the expressions for generators as residy integrals of energy momentum tensor and Kac Moody currents. For Virasoro generators this is carried out explicitly in [55]. The resulting co-product conserves the value of central extension whereas for the naive co-product this would not be the case. Obviously, the geometric co-product does not conserve conformal weight.

## A-4 Some examples of bi-algebras and quantum groups

The appendix summarizes briefly the simplest bi- and Hopf algebras and some basic constructions related to quantum groups.

### A-4.1 Hecke algebra and Temperley-Lieb algebra

Braid group is accompanied by several algebras. For Hecke algebra, which is particular case of braid algebra, one has

$$\begin{aligned}
 e_{n+1}e_n e_{n+1} &= e_n e_{n+1} e_n \ , \\
 e_n^2 &= (t - 1)e_n + t \ .
 \end{aligned}
 \tag{A-4.1}$$

The algebra reduces to that for symmetric group for  $t = 1$ .

Hecke algebra can be regarded as a discrete analog of Kac Moody algebra or loop algebra with  $G$  replaced by  $S_n$ . This suggests a connection with Kac-Moody algebras and imbedding of Galois groups to Kac-Moody group.  $t = p^n$  corresponds to a finite field. Fractal dimension  $t = \mathcal{M} : \mathcal{N}$  relates naturally to braid group representations: fractal dimension of quantum quaternions might be appropriate interpretation.  $t=1$  gives symmetric group. Infinite braid group could be seen as a quantum variant of Galois group for algebraic closure of rationals.

Temperley-Lieb algebra assignable with Jones inclusions of hyper-finite factors of type  $II_1$  with  $\mathcal{M} : \mathcal{N} < 4$  is given by the relations

$$\begin{aligned} e_{n+1}e_nen + 1 &= e_{n+1} \\ e_nen_{n+1}e_n &= e_n, \\ e_n^2 &= te_n, \quad , t = -\sqrt{\mathcal{M} : \mathcal{N}} = -2\cos(\pi/n), \quad n = 3, 4, \dots \end{aligned} \tag{A-4.2}$$

The conditions involving three generators differ from those for braid group algebra since  $e_n$  are now proportional to projection operators. An alternative form of this algebra is given by

$$\begin{aligned} e_{n+1}e_nen + 1 &= te_{n+1} \\ e_nen_{n+1}e_n &= te_n, \\ e_n^2 &= e_n = e_n^*, \quad , t = -\sqrt{\mathcal{M} : \mathcal{N}} = -2\cos(\pi/n), \quad n = 3, 4, \dots \end{aligned} \tag{A-4.3}$$

This representation reduces to that for Temperley-Lieb algebra with obvious normalization of projection operators. These algebras are somewhat analogous to function fields but the value of coordinate is fixed to some particular values. An analogous discretization for function fields corresponds to a formation of number theoretical braids.

### A-4.2 Simplest bi-algebras

Let  $k(x_1, \dots, x_n)$  denote the free algebra of polynomials in variables  $x_i$  with coefficients in field  $k$ .  $x_i$  can be regarded as points of a set. The algebra  $Hom(k(x_1, \dots, x_n), A)$  of algebra homomorphisms  $k(x_1, \dots, x_n) \rightarrow A$  can be identified as  $A^n$  since by the homomorphism property the images  $f(x_i)$  of the generators  $x_1, \dots, x_n$  determined the homomorphism completely. Any commutative algebra  $A$  can be identified as the  $Hom(k[x], A)$  with a particular homomorphism corresponding to a line in  $A$  determined uniquely by an element of  $A$ .

The matrix algebra  $M(2)$  can be defined as the polynomial algebra  $k(a, b, c, d)$ . Matrix multiplication can be represented universally as an algebra morphism  $\Delta$  from from  $M_2 = k(a, b, c, d)$  to  $M_2^{\otimes 2} = k(a', a'', b', b'', c', c'', d', d'')$  to  $k(a, b, c, d)$  in matrix form as

$$\Delta \begin{pmatrix} a & b \\ c & d \end{pmatrix} = \begin{pmatrix} a' & b' \\ c' & d' \end{pmatrix} \begin{pmatrix} a'' & b'' \\ c'' & d'' \end{pmatrix} .$$

This morphism induces algebra multiplication in the matrix algebra  $M_2(A)$  for any commutative algebra  $A$ .

$M(2)$ ,  $GL(2)$  and  $SL(2)$  provide standard examples about bi-algebras.  $SL(2)$  can be defined as a commutative algebra by dividing free polynomial algebra  $k(a, b, c, d)$  spanned by the generators  $a, b, c, d$  by the ideal  $det - 1 = ad - bc - 1 = 0$  expressing that the determinant of the matrix is one. In the matrix representation  $\mu$  and  $\eta$  are defined in obvious manner and  $\mu$  gives powers of the matrix

$$A = \begin{pmatrix} a & b \\ c & d \end{pmatrix} .$$

$\Delta$ , counit  $\epsilon$ , and antipode  $S$  can be written in case of  $SL(2)$  as

$$\begin{pmatrix} \Delta(a) & \Delta(b) \\ \Delta(c) & \Delta(d) \end{pmatrix} = \begin{pmatrix} a & b \\ c & d \end{pmatrix} \otimes \begin{pmatrix} a & b \\ c & d \end{pmatrix} ,$$

$$\begin{pmatrix} \epsilon(a) & \epsilon(b) \\ \epsilon(c) & \epsilon(d) \end{pmatrix} = \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix} .$$

$$S \begin{pmatrix} a & b \\ c & d \end{pmatrix} = (ad - bc)^{-1} \begin{pmatrix} d & -b \\ -c & a \end{pmatrix} .$$

Note that matrix representation is only an economical manner to summarize the action of  $\Delta$  on the generators  $a, b, c, d$  of the algebra. For instance, one has  $\Delta(a) = a \rightarrow a \otimes a + b \otimes c$ . The resulting algebra is both commutative and co-commutative.

$SL(2)_q$  can be defined as a Hopf algebra by dividing the free algebra generated by elements  $a, b, c, d$  by the relations

$$\begin{aligned} ba &= qab \ , & db &= qbd \ , \\ ca &= qac \ , & dc &= qcd \ , \\ bc &= cb \ , & ad - da &= (q^{-1} - 1)bc \ , \end{aligned}$$

and the relation

$$\det_q = ad - q^{-1}bc = 1$$

stating that the quantum determinant of  $SL(2)_q$  matrix is one.

$\mu, \eta, \Delta, \epsilon$  are defined as in the case of  $SL(2)$ . Antipode  $S$  is defined by

$$S \begin{pmatrix} a & b \\ c & d \end{pmatrix} = \det_q^{-1} \begin{pmatrix} d & -qb \\ -q^{-1}c & a \end{pmatrix} .$$

The relations above guarantee that it defines quantum inverse of  $A$ . For  $q$  an  $n^{\text{th}}$  root of unity,  $S^{2n} = id$  holds true which signals that these parameter values are somehow exceptional. This result is completely general.

Given an algebra, the  $R$  point of  $SL_q(2)$  is defined as a four-tuple  $(A, B, C, D)$  in  $R^4$  satisfying the relations defining the point of  $SL_q(2)$ . One can say that  $R$ -points provide representations of the universal quantum algebra  $SL_q(2)$ .

### A-4.3 Quantum group $U_q(sl(2))$

Quantum group  $U_q(sl(2))$  or rather, quantum enveloping algebra of  $sl(2)$ , can be constructed by applying Drinfeld's quantum double construction (to avoid confusion note that the quantum Hopf algebra associated with  $SL(2)$  is the quantum analog of a commutative algebra generated by powers of a  $2 \times 2$  matrix of unit determinant).

The commutation relations of  $sl(2)$  read as

$$[X_+, X_-] = H \ , \quad [H, X_{\pm}] = \pm 2X_{\pm} \ . \quad (\text{A-4.4})$$

$U_q(sl(2))$  allows co-algebra structure given by

$$\begin{aligned} \Delta(J) &= J \otimes 1 + 1 \otimes J \ , & S(J) &= -J \ , & \epsilon(J) &= 0 \ , & J &= X_{\pm}, H \ , \\ S(1) &= 1 \ , & \epsilon(1) &= 1 \ . \end{aligned} \quad (\text{A-4.5})$$

The enveloping algebras of Borel algebras  $U(B_{\pm})$  generated by  $\{1, X_+, H\}$   $\{1, X_-, hH\}$  define the Hopf algebra  $H$  and its dual  $H^*$  in Drinfeld's construction.  $h$  could be called Planck's constant vanishes at the classical limit. Note that  $H^*$  reduces to  $\{1, X_-\}$  at this limit. Quantum deformation parameter  $q$  is given by  $\exp(2h)$ . The duality map  $\star : H \rightarrow H^*$  reads as

$$\begin{aligned} a &\rightarrow a^* \ , & ab &= (ab)^* = b^*a^* \ , \\ 1 &\rightarrow 1 \ , & H &\rightarrow H^* = hH \ , & X_+ &\rightarrow (X_+)^* = hX_- \ . \end{aligned} \quad (\text{A-4.6})$$

The commutation relations of  $U_q(sl(2))$  read as

$$[X_+, X_-] = \frac{q^H - q^{-H}}{q - q^{-1}} \ , \quad [H, X_{\pm}] = \pm 2X_{\pm} \ . \quad (\text{A-4.7})$$

Co-product  $\Delta$ , antipode  $S$ , and co-unit  $\epsilon$  differ from those  $U(sl(2))$  only in the case of  $X_{\pm}$ :

$$\begin{aligned} \Delta(X_{\pm}) &= X_{\pm} \otimes q^{H/2} + q^{-H/2} \otimes X_{\pm} \ , \\ S(X_{\pm}) &= -q^{\pm 1} X_{\pm} \ . \end{aligned} \quad (\text{A-4.8})$$

When  $q$  is not a root of unity, the universal R-matrix is given by

$$R = q^{\frac{H \otimes H}{2}} \sum_{n=0}^{\infty} \frac{(1-q^{-2})^n}{[n]_q!} q^{\frac{n(1-n)}{2}} q^{\frac{nH}{2}} X_+^n \otimes q^{-\frac{nH}{2}} X_-^n . \tag{A-4.9}$$

When  $q$  is  $m$ :th root of unity the  $q$ -factorial  $[n]_q!$  vanishes for  $n \geq m$  and the expansion does not make sense.

For  $q$  not a root of unity the representation theory of quantum groups is essentially the same as of ordinary groups. When  $q$  is  $m^{th}$  root of unity, the situation changes. For  $l = m = 2n$   $n^{th}$  powers of generators span together with the Casimir operator a sub-algebra commuting with the whole algebra providing additional numbers characterizing the representations. For  $l = m = 2n + 1$  same happens for  $m^{th}$  powers of Lie-algebra generators. The generic representations are not fully reducible anymore. In the case of  $U_q(sl(2))$  irreducibility occurs for spins  $n < l$  only. Under certain conditions on  $q$  it is possible to decouple the higher representations from the theory. Physically the reduction of the number of representations to a finite number means a symmetry analogous to a gauge symmetry. The phenomenon resembles the occurrence of null vectors in the case of Virasoro and Kac Moody representations and there indeed is a deep connection between quantum groups and Kac-Moody algebras [55].

One can wonder what is the precise relationship between  $U_q(sl(2))$  and  $SL_q(2)$  which both are quantum groups using loose terminology. The relationship is duality. This means the existence of a morphism  $x \rightarrow \Psi(x) M_q(2) \rightarrow U_q^*$  defined by a bilinear form  $\langle u, x \rangle = \Psi(x)(u)$  on  $U_q \times M_q(2)$ , which is bi-algebra morphism. This means that the conditions

$$\begin{aligned} \langle uv, x \rangle &= \langle u \otimes v, \Delta(x) \rangle , & \langle u, xy \rangle &= \langle \Delta(u), x \otimes y \rangle , \\ \langle 1, x \rangle &= \epsilon(x) , & \langle u, 1 \rangle &= \epsilon(u) \end{aligned}$$

are satisfied. It is enough to find  $\Psi(x)$  for the generators  $x = A, B, C, D$  of  $M_q(2)$  and show that the duality conditions are satisfied. The representation

$$\rho(E) = \begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix} , \quad \rho(F) = \begin{pmatrix} 0 & 0 \\ 1 & 0 \end{pmatrix} , \quad \rho(K = q^H) = \begin{pmatrix} q & 0 \\ 0 & q^{-1} \end{pmatrix} ,$$

extended to a representation

$$\rho(u) = \begin{pmatrix} A(u) & B(u) \\ C(u) & D(u) \end{pmatrix}$$

of arbitrary element  $u$  of  $U_q(sl(2))$  defines for elements in  $U_q^*$ . It is easy to guess that  $A(u), B(u), C(u), D(u)$ , which can be regarded as elements of  $U_q^*$ , can be regarded also as R points that is images of the generators  $a, b, c, d$  of  $SL_q(2)$  under an algebra morphism  $SL_q(2) \rightarrow U_q^*$ .

### A-4.4 General semisimple quantum group

The Drinfeld's construction of quantum groups applies to arbitrary semi-simple Lie algebra and is discussed in detail in [55]. The construction relies on the use of Cartan matrix.

Quite generally, Cartan matrix  $A = \{a_{ij}\}$  is  $n \times n$  matrix satisfying the following conditions:

- i)  $A$  is indecomposable, that is does not reduce to a direct sum of matrices.
- ii)  $a_{ij} \leq 0$  holds true for  $i < j$ .
- iii)  $a_{ij} = 0$  is equivalent with  $a_{ji} = 0$ .

$A$  can be normalized so that the diagonal components satisfy  $a_{ii} = 2$ .

The generators  $e_i, f_i, k_i$  satisfying the commutations relations

$$\begin{aligned} k_i k_j &= k_j k_i , & k_i e_j &= q_i^{a_{ij}} e_j k_i , \\ k_i f_j &= q_i^{-a_{ij}} e_j k_i , & e_i f_j - f_j e_i &= \delta_{ij} \frac{k_i - k_i^{-1}}{q_i - q_i^{-1}} , \end{aligned} \tag{A-4.10}$$

and so called Serre relations

$$\begin{aligned} \sum_{l=0}^{1-a_{ij}} (-1)^l \begin{bmatrix} 1-a_{ij} \\ l \end{bmatrix}_{q_i} e_i^{1-a_{ij}-l} e_j e_i^l &= 0, \quad i \neq j, \\ \sum_{l=0}^{1-a_{ij}} (-1)^l \begin{bmatrix} 1-a_{ij} \\ l \end{bmatrix}_{q_i} f_i^{1-a_{ij}-l} f_j f_i^l &= 0, \quad i \neq j. \end{aligned} \quad (\text{A-4.11})$$

Here  $q_i = q^{D_i}$  where one has  $D_i a_{ij} = a_{ij} D_i$ .  $D_i = 1$  is the simplest choice in this case. Comultiplication is given by

$$\Delta(k_i) = k_i \otimes k_i, \quad (\text{A-4.12})$$

$$\Delta(e_i) = e_i \otimes k_i + 1 \otimes e_i, \quad (\text{A-4.13})$$

$$\Delta(f_i) = f_i \otimes 1 + k_i^{-1} \otimes 1. \quad (\text{A-4.14})$$

$$(\text{A-4.15})$$

The action of antipode  $S$  is defined as

$$S(e_i) = -e_i k_i^{-1}, \quad S(f_i) = -k_i f_i, \quad S(k_i) = -k_i^{-1}. \quad (\text{A-4.16})$$

### A-4.5 Quantum affine algebras

The construction of Drinfeld and Jimbo generalizes also to the case of untwisted affine Lie algebras, which are in one-one correspondence with semisimple Lie algebras. The representations of quantum deformed affine algebras define corresponding deformations of Kac-Moody algebras. In the following only the basic formulas are summarized and the reader not familiar with the formalism can consult a more detailed treatment can be found in [55].

#### 1. Affine algebras

The Cartan matrix  $A$  is said to be of affine type if the conditions  $\det(A) = 0$  and  $a_{ij} a_{ji} \geq 4$  (no summation) hold true. There always exists a diagonal matrix  $D$  such that  $B = DA$  is symmetric and defines symmetric bilinear degenerate metric on the affine Lie algebra.

The Dynkin diagrams of affine algebra of rank  $l$  have  $l+1$  vertices (so that Cartan matrix has one null eigenvector). The diagrams of semisimple Lie-algebras are sub-diagrams of affine algebras. From the  $(l+1) \times (l+1)$  Cartan matrix of an untwisted affine algebra  $\hat{A}$  one can recover the  $l \times l$  Cartan matrix of  $A$  by dropping away 0:th row and column.

For instance, the algebra  $A_1^1$ , which is affine counterpart of  $SL(2)$ , has Cartan matrix  $a_{ij}$

$$A = \begin{pmatrix} 2 & -2 \\ -2 & 2 \end{pmatrix}$$

with a vanishing determinant.

Quite generally, in untwisted case quantum algebra  $U_q(\hat{G}_l)$  as  $3(l+1)$  generators  $e_i, f_i, k_i$  ( $i = 0, 1, \dots, l$ ) satisfying the relations of Eq. A-4.11 for Cartan matrix of  $\mathcal{G}^{(1)}$ . Affine quantum group is obtained by adding to  $U_q(\hat{G}_l)$  a derivation  $d$  satisfying the relations

$$[d, e_i] = \delta_{i0} e_i, \quad [d, f_i] = \delta_{i0} f_i, \quad [d, k_i] = 0. \quad (\text{A-4.17})$$

with comultiplication  $\Delta(d) = d \otimes 1 + 1 \otimes d$ .

#### 2. Kac Moody algebras

The undeformed extension  $\hat{G}_l$  associated with the affine Cartan matrix  $\mathcal{G}_l^{(1)}$  is the Kac Moody algebra associated with the group  $G$  obtained as the central extension of the corresponding loop algebra. The loop algebra is defined as

$$L(\mathcal{G}) = \mathcal{G} \otimes C[t, t^{-1}], \quad (\text{A-4.18})$$

where  $C[t, t^{-1}]$  is the algebra of Laurent polynomials with complex coefficients. The Lie bracket is

$$[x \times P, y \otimes Q] = [x, y] \otimes PQ \quad . \quad (A-4.19)$$

The non-degenerate bilinear symmetric form  $(,)$  in  $\mathcal{G}_l$  induces corresponding form in  $L(\mathcal{G}_l)$  as  $(x \otimes P, y \otimes Q) = (x, y)PQ$ .

A two-cocycle on  $L(\mathcal{G}_l)$  is defined as

$$\Psi(a, b) = Res\left(\frac{da}{dt}, b\right) \quad , \quad (A-4.20)$$

where the residue of a Laurent is defined as  $Res(\sum_n a_n t^n) = a_{-1}$ . The two-cocycle satisfies the conditions

$$\begin{aligned} \Psi(a, b) &= -\Psi(b, a) \quad , \\ \Psi([a, b], c) + \Psi([b, c], a) + \Psi([c, a], b) &= 0 \quad . \end{aligned} \quad (A-4.21)$$

The two-cocycle defines the central extension of loop algebra  $L(\mathcal{G}_l)$  to Kac Moody algebra  $L(\mathcal{G}_l) \otimes Cc$ , where  $c$  is a new central element commuting with the loop algebra. The new bracket is defined as  $[,] + \Psi(, )c$ . The algebra  $\tilde{L}(\mathcal{G}_l)$  is defined by adding the derivation  $d$  which acts as  $td/dt$  measuring the conformal weight.

The standard basis for Kac Moody algebra and corresponding commutation relations are given by

$$\begin{aligned} J_n^x &= x \otimes t^n \quad , \\ [J_n^x, J_m^y] &= J_{n+m}^{[x,y]} + n\delta_{m+n,0}c \quad . \end{aligned} \quad (A-4.22)$$

The finite dimensional irreducible representations of  $G$  defined representations of Kac Moody algebra with a vanishing central extension  $c = 0$ . The highest weight representations are characterized by highest weight vector  $|v\rangle$  such that

$$\begin{aligned} J_n^x |v\rangle &= 0, \quad n > 0 \quad , \\ c |v\rangle &= k |v\rangle \quad . \end{aligned} \quad (A-4.23)$$

### 3. Quantum affine algebras

Drinfeld has constructed the quantum affine extension  $U_q(\mathcal{G}_l)$  using quantum double construction. The construction of generators uses almost the same basic formulas as the construction of semi-simple algebras. The construction involves the automorphism  $D_t : U_q(\tilde{\mathcal{G}}_l) \otimes C[t, t^{-1}] \rightarrow U_q(\tilde{\mathcal{G}}_l) \otimes C[t, t^{-1}]$  given by

$$\begin{aligned} D_t(e_i) &= t^{\delta_{i0}} e_i \quad , \quad D_t(f_i) = t^{\delta_{i0}} f_i \quad , \\ D_t(k_i) &= k_i \quad \quad \quad D_t(d) = d \quad , \end{aligned} \quad (A-4.24)$$

and the co-product

$$\Delta_t(a) = (D_t \otimes 1)\Delta(a) \quad , \quad \Delta_t^{op}(a) = (D_t \otimes 1)\Delta^{op}(a) \quad , \quad (A-4.25)$$

where the  $\Delta(a)$  is the co-product defined by the same general formula as applying in the case of semi-simple Lie algebras. The universal R-matrix is given by

$$\mathcal{R}(t) = (D_t \otimes 1)\mathcal{R} \quad , \quad (A-4.26)$$

and satisfies the equations

$$\begin{aligned}
 \mathcal{R}(t)\Delta_t(a) &= \Delta_t^{op}(a)\mathcal{R} \ , \\
 (\Delta_z \otimes id)\mathcal{R}(u) &= \mathcal{R}_{13}(zu)\mathcal{R}_{23}(u) \ , \\
 (id \otimes \Delta_u)\mathcal{R}(zu) &= \mathcal{R}_{13}(z)\mathcal{R}_{12}(zu) \ , \\
 \mathcal{R}_{12}(t)\mathcal{R}_{13}(tw)\mathcal{R}_{23}(w) &= \mathcal{R}_{23}(w)\mathcal{R}_{13}(tw)\mathcal{R}_{12}(t) \ .
 \end{aligned}
 \tag{A-4.27}$$

The infinite-dimensional representations of affine algebra give representations of Kac-Moody algebra when one restricts the consideration to generations  $e_i, f_i, k_i, i > 0$ .

## A-5 Basic properties of $CP_2$ and elementary facts about p-adic numbers

### A-5.1 $CP_2$ as a manifold

$CP_2$ , the complex projective space of two complex dimensions, is obtained by identifying the points of complex 3-space  $C^3$  under the projective equivalence

$$(z^1, z^2, z^3) \equiv \lambda(z^1, z^2, z^3) . \quad (\text{A-5.1})$$

Here  $\lambda$  is any non-zero complex number. Note that  $CP_2$  can be also regarded as the coset space  $SU(3)/U(2)$ . The pair  $z^i/z^j$  for fixed  $j$  and  $z^i \neq 0$  defines a complex coordinate chart for  $CP_2$ . As  $j$  runs from 1 to 3 one obtains an atlas of three coordinate charts covering  $CP_2$ , the charts being holomorphically related to each other (e.g.  $CP_2$  is a complex manifold). The points  $z^3 \neq 0$  form a subset of  $CP_2$  homeomorphic to  $R^4$  and the points with  $z^3 = 0$  a set homeomorphic to  $S^2$ . Therefore  $CP_2$  is obtained by "adding the 2-sphere at infinity to  $R^4$ ".

Besides the standard complex coordinates  $\xi^i = z^i/z^3$ ,  $i = 1, 2$  the coordinates of Eguchi and Freund [119] will be used and their relation to the complex coordinates is given by

$$\begin{aligned} \xi^1 &= z + it , \\ \xi^2 &= x + iy . \end{aligned} \quad (\text{A-5.2})$$

These are related to the "spherical coordinates" via the equations

$$\begin{aligned} \xi^1 &= r \exp(i \frac{(\Psi + \Phi)}{2}) \cos(\frac{\Theta}{2}) , \\ \xi^2 &= r \exp(i \frac{(\Psi - \Phi)}{2}) \sin(\frac{\Theta}{2}) . \end{aligned} \quad (\text{A-5.3})$$

The ranges of the variables  $r, \Theta, \Phi, \Psi$  are  $[0, \infty], [0, \pi], [0, 4\pi], [0, 2\pi]$  respectively.

Considered as a real four-manifold  $CP_2$  is compact and simply connected, with Euler number Euler number 3, Pontryagin number 3 and second  $b = 1$ .

### A-5.2 Metric and Kähler structure of $CP_2$

In order to obtain a natural metric for  $CP_2$ , observe that  $CP_2$  can be thought of as a set of the orbits of the isometries  $z^i \rightarrow \exp(i\alpha)z^i$  on the sphere  $S^5$ :  $\sum z^i \bar{z}^i = R^2$ . The metric of  $CP_2$  is obtained by projecting the metric of  $S^5$  orthogonally to the orbits of the isometries. Therefore the distance between the points of  $CP_2$  is that between the representative orbits on  $S^5$ .

The line element has the following form in the complex coordinates

$$ds^2 = g_{a\bar{b}} d\xi^a d\bar{\xi}^b , \quad (\text{A-5.4})$$

where the Hermitian, in fact Kähler metric  $g_{a\bar{b}}$  is defined by

$$g_{a\bar{b}} = R^2 \partial_a \partial_{\bar{b}} K , \quad (\text{A-5.5})$$

where the function  $K$ , Kähler function, is defined as

$$\begin{aligned} K &= \log(F) , \\ F &= 1 + r^2 . \end{aligned} \quad (\text{A-5.6})$$

The Kähler function for  $S^2$  has the same form. It gives the  $S^2$  metric  $dzd\bar{z}/(1+r^2)^2$  related to its standard form in spherical coordinates by the coordinate transformation  $(r, \phi) = (\tan(\theta/2), \phi)$ .

The representation of the  $CP_2$  metric is deducible from  $S^5$  metric is obtained by putting the angle coordinate of a geodesic sphere constant in it and is given

$$\frac{ds^2}{R^2} = \frac{(dr^2 + r^2\sigma_3^2)}{F^2} + \frac{r^2(\sigma_1^2 + \sigma_2^2)}{F}, \quad (\text{A-5.7})$$

where the quantities  $\sigma_i$  are defined as

$$\begin{aligned} r^2\sigma_1 &= \text{Im}(\xi^1 d\xi^2 - \xi^2 d\xi^1), \\ r^2\sigma_2 &= -\text{Re}(\xi^1 d\xi^2 - \xi^2 d\xi^1), \\ r^2\sigma_3 &= -\text{Im}(\xi^1 d\bar{\xi}^1 + \xi^2 d\bar{\xi}^2). \end{aligned} \quad (\text{A-5.8})$$

$R$  denotes the radius of the geodesic circle of  $CP_2$ . The vierbein forms, which satisfy the defining relation

$$s_{kl} = R^2 \sum_A e_k^A e_l^A, \quad (\text{A-5.9})$$

are given by

$$\begin{aligned} e^0 &= \frac{dr}{F}, & e^1 &= \frac{r\sigma_1}{\sqrt{F}}, \\ e^2 &= \frac{r\sigma_2}{\sqrt{F}}, & e^3 &= \frac{r\sigma_3}{F}. \end{aligned} \quad (\text{A-5.10})$$

The explicit representations of vierbein vectors are given by

$$\begin{aligned} e^0 &= \frac{dr}{F}, & e^1 &= \frac{r(\sin\Theta\cos\Psi d\Phi + \sin\Psi d\Theta)}{2\sqrt{F}}, \\ e^2 &= \frac{r(\sin\Theta\sin\Psi d\Phi - \cos\Psi d\Theta)}{2\sqrt{F}}, & e^3 &= \frac{r(d\Psi + \cos\Theta d\Phi)}{2F}. \end{aligned} \quad (\text{A-5.11})$$

The explicit representation of the line element is given by the expression

$$ds^2/R^2 = \frac{dr^2}{F^2} + \frac{r^2}{4F^2}(d\Psi + \cos\Theta d\Phi)^2 + \frac{r^2}{4F}(d\Theta^2 + \sin^2\Theta d\Phi^2). \quad (\text{A-5.12})$$

The vierbein connection satisfying the defining relation

$$de^A = -V_B^A \wedge e^B, \quad (\text{A-5.13})$$

is given by

$$\begin{aligned} V_{01} &= -\frac{e^1}{r}, & V_{23} &= \frac{e^1}{r}, \\ V_{02} &= -\frac{e^2}{r}, & V_{31} &= \frac{e^2}{r}, \\ V_{03} &= (r - \frac{1}{r})e^3, & V_{12} &= (2r + \frac{1}{r})e^3. \end{aligned} \quad (\text{A-5.14})$$

The representation of the covariantly constant curvature tensor is given by

$$\begin{aligned} R_{01} &= e^0 \wedge e^1 - e^2 \wedge e^3, & R_{23} &= e^0 \wedge e^1 - e^2 \wedge e^3, \\ R_{02} &= e^0 \wedge e^2 - e^3 \wedge e^1, & R_{31} &= -e^0 \wedge e^2 + e^3 \wedge e^1, \\ R_{03} &= 4e^0 \wedge e^3 + 2e^1 \wedge e^2, & R_{12} &= 2e^0 \wedge e^3 + 4e^1 \wedge e^2. \end{aligned} \quad (\text{A-5.15})$$

Metric defines a real, covariantly constant, and therefore closed 2-form  $J$

$$J = -ig_{a\bar{b}}d\xi^a d\bar{\xi}^b , \quad (\text{A-5.16})$$

the so called Kähler form. Kähler form  $J$  defines in  $CP_2$  a symplectic structure because it satisfies the condition

$$J^k_r J^{rl} = -\delta^{kl} . \quad (\text{A-5.17})$$

The form  $J$  is integer valued and by its covariant constancy satisfies free Maxwell equations. Hence it can be regarded as a curvature form of a  $U(1)$  gauge potential  $B$  carrying a magnetic charge of unit  $1/2g$  ( $g$  denotes the gauge coupling). Locally one has therefore

$$J = dB , \quad (\text{A-5.18})$$

where  $B$  is the so called Kähler potential, which is not defined globally since  $J$  describes homological magnetic monopole.

It should be noticed that the magnetic flux of  $J$  through a 2-surface in  $CP_2$  is proportional to its homology equivalence class, which is integer valued. The explicit representations of  $J$  and  $B$  are given by

$$\begin{aligned} B &= 2re^3 , \\ J &= 2(e^0 \wedge e^3 + e^1 \wedge e^2) = \frac{r}{F^2} dr \wedge (d\Psi + \cos\Theta d\Phi) + \frac{r^2}{2F} \sin\Theta d\Theta d\Phi . \end{aligned} \quad (\text{A-5.19})$$

The vierbein curvature form and Kähler form are covariantly constant and have in the complex coordinates only components of type (1,1).

Useful coordinates for  $CP_2$  are the so called canonical coordinates in which Kähler potential and Kähler form have very simple expressions

$$\begin{aligned} B &= \sum_{k=1,2} P_k dQ_k , \\ J &= \sum_{k=1,2} dP_k \wedge dQ_k . \end{aligned} \quad (\text{A-5.20})$$

The relationship of the canonical coordinates to the "spherical" coordinates is given by the equations

$$\begin{aligned} P_1 &= -\frac{1}{1+r^2} , \\ P_2 &= \frac{r^2 \cos\Theta}{2(1+r^2)} , \\ Q_1 &= \Psi , \\ Q_2 &= \Phi . \end{aligned} \quad (\text{A-5.21})$$

### A-5.3 Spinors in $CP_2$

$CP_2$  doesn't allow spinor structure in the conventional sense [103]. However, the coupling of the spinors to a half odd multiple of the Kähler potential leads to a respectable spinor structure. Because the delicacies associated with the spinor structure of  $CP_2$  play a fundamental role in TGD, the arguments of Hawking are repeated here.

To see how the space can fail to have an ordinary spinor structure consider the parallel transport of the vierbein in a simply connected space  $M$ . The parallel propagation around a closed curve with

a base point  $x$  leads to a rotated vierbein at  $x$ :  $e^A = R_B^A e^B$  and one can associate to each closed path an element of  $SO(4)$ .

Consider now a one-parameter family of closed curves  $\gamma(v) : v \in (0, 1)$  with the same base point  $x$  and  $\gamma(0)$  and  $\gamma(1)$  trivial paths. Clearly these paths define a sphere  $S^2$  in  $M$  and the element  $R_B^A(v)$  defines a closed path in  $SO(4)$ . When the sphere  $S^2$  is contractible to a point e.g., homologically trivial, the path in  $SO(4)$  is also contractible to a point and therefore represents a trivial element of the homotopy group  $\Pi_1(SO(4)) = Z_2$ .

For a homologically nontrivial 2-surface  $S^2$  the associated path in  $SO(4)$  can be homotopically nontrivial and therefore corresponds to a nonclosed path in the covering group  $Spin(4)$  (leading from the matrix 1 to -1 in the matrix representation). Assume this is the case.

Assume now that the space allows spinor structure. Then one can parallel propagate also spinors and by the above construction associate a closed path of  $Spin(4)$  to the surface  $S^2$ . Now, however this path corresponds to a lift of the corresponding  $SO(4)$  path and cannot be closed. Thus one ends up with a contradiction.

From the preceding argument it is clear that one could compensate the non-allowed  $-1$ - factor associated with the parallel transport of the spinor around the sphere  $S^2$  by coupling it to a gauge potential in such a way that in the parallel transport the gauge potential introduces a compensating  $-1$ -factor. For a  $U(1)$  gauge potential this factor is given by the exponential  $exp(i2\Phi)$ , where  $\Phi$  is the magnetic flux through the surface. This factor has the value  $-1$  provided the  $U(1)$  potential carries half odd multiple of Dirac charge  $1/2g$ . In case of  $CP_2$  the required gauge potential is half odd multiple of the Kähler potential  $B$  defined previously. In the case of  $M^4 \times CP_2$  one can in addition couple the spinor components with different chiralities independently to an odd multiple of  $B/2$ .

### A-5.4 Geodesic sub-manifolds of $CP_2$

Geodesic sub-manifolds are defined as sub-manifolds having common geodesic lines with the imbedding space. As a consequence the second fundamental form of the geodesic manifold vanishes, which means that the tangent vectors  $h_\alpha^k$  (understood as vectors of  $H$ ) are covariantly constant quantities with respect to the covariant derivative taking into account that the tangent vectors are vectors both with respect to  $H$  and  $X^4$ .

In [85] a general characterization of the geodesic sub-manifolds for an arbitrary symmetric space  $G/H$  is given. Geodesic sub-manifolds are in 1-1-correspondence with the so called Lie triple systems of the Lie-algebra  $g$  of the group  $G$ . The Lie triple system  $t$  is defined as a subspace of  $g$  characterized by the closedness property with respect to double commutation

$$[X, [Y, Z]] \in t \text{ for } X, Y, Z \in t . \tag{A-5.22}$$

$SU(3)$  allows, besides geodesic lines, two nonequivalent (not isometry related) geodesic spheres. This is understood by observing that  $SU(3)$  allows two nonequivalent  $SU(2)$  algebras corresponding to subgroups  $SO(3)$  (orthogonal  $3 \times 3$  matrices) and the usual isospin group  $SU(2)$ . By taking any subset of two generators from these algebras, one obtains a Lie triple system and by exponentiating this system, one obtains a 2-dimensional geodesic sub-manifold of  $CP_2$ .

Standard representatives for the geodesic spheres of  $CP_2$  are given by the equations

$$S_I^2 : \xi^1 = \bar{\xi}^2 \text{ or equivalently } (\Theta = \pi/2, \Psi = 0) ,$$

$$S_{II}^2 : \xi^1 = \xi^2 \text{ or equivalently } (\Theta = \pi/2, \Phi = 0) .$$

The non-equivalence of these sub-manifolds is clear from the fact that isometries act as holomorphic transformations in  $CP_2$ . The vanishing of the second fundamental form is also easy to verify. The first geodesic manifold is homologically trivial: in fact, the induced Kähler form vanishes identically for  $S_I^2$ .  $S_{II}^2$  is homologically nontrivial and the flux of the Kähler form gives its homology equivalence class.

## A-6 $CP_2$ geometry and standard model symmetries

### A-6.1 Identification of the electro-weak couplings

The delicacies of the spinor structure of  $CP_2$  make it a unique candidate for space  $S$ . First, the coupling of the spinors to the  $U(1)$  gauge potential defined by the Kähler structure provides the missing  $U(1)$  factor in the gauge group. Secondly, it is possible to couple different  $H$ -chiralities independently to a half odd multiple of the Kähler potential. Thus the hopes of obtaining a correct spectrum for the electromagnetic charge are considerable. In the following it will be demonstrated that the couplings of the induced spinor connection are indeed those of the GWS model [40] and in particular that the right handed neutrinos decouple completely from the electro-weak interactions.

To begin with, recall that the space  $H$  allows to define three different chiralities for spinors. Spinors with fixed  $H$ -chirality  $e = \pm 1$ ,  $CP_2$ -chirality  $l, r$  and  $M^4$ -chirality  $L, R$  are defined by the condition

$$\begin{aligned}\Gamma\Psi &= e\Psi, \\ e &= \pm 1,\end{aligned}\tag{A-6.1}$$

where  $\Gamma$  denotes the matrix  $\Gamma_9 = \gamma_5 \times \gamma_5$ ,  $1 \times \gamma_5$  and  $\gamma_5 \times 1$  respectively. Clearly, for a fixed  $H$ -chirality  $CP_2$ - and  $M^4$ -chiralities are correlated.

The spinors with  $H$ -chirality  $e = \pm 1$  can be identified as quark and lepton like spinors respectively. The separate conservation of baryon and lepton numbers can be understood as a consequence of generalized chiral invariance if this identification is accepted. For the spinors with a definite  $H$ -chirality one can identify the vielbein group of  $CP_2$  as the electro-weak group:  $SO(4) = SU(2)_L \times SU(2)_R$ .

The covariant derivatives are defined by the spinorial connection

$$A = V + \frac{B}{2}(n_+1_+ + n_-1_-) .\tag{A-6.2}$$

Here  $V$  and  $B$  denote the projections of the vielbein and Kähler gauge potentials respectively and  $1_+(-)$  projects to the spinor  $H$ -chirality  $+(-)$ . The integers  $n_{\pm}$  are odd from the requirement of a respectable spinor structure.

The explicit representation of the vielbein connection  $V$  and of  $B$  are given by the equations

$$\begin{aligned}V_{01} &= -\frac{e^1}{r}, & V_{23} &= \frac{e^1}{r}, \\ V_{02} &= -\frac{e^2}{r}, & V_{31} &= \frac{e^2}{r}, \\ V_{03} &= (r - \frac{1}{r})e^3, & V_{12} &= (2r + \frac{1}{r})e^3,\end{aligned}\tag{A-6.3}$$

and

$$B = 2re^3 ,\tag{A-6.4}$$

respectively. The explicit representation of the vielbein is not needed here.

Let us first show that the charged part of the spinor connection couples purely left handedly. Identifying  $\Sigma_3^0$  and  $\Sigma_2^1$  as the diagonal (neutral) Lie-algebra generators of  $SO(4)$ , one finds that the charged part of the spinor connection is given by

$$A_{ch} = 2V_{23}I_L^1 + 2V_{13}I_L^2 ,\tag{A-6.5}$$

where one have defined

$$\begin{aligned}I_L^1 &= \frac{(\Sigma_{01} - \Sigma_{23})}{2}, \\ I_L^2 &= \frac{(\Sigma_{02} - \Sigma_{13})}{2}.\end{aligned}\tag{A-6.6}$$

$A_{ch}$  is clearly left handed so that one can perform the identification

$$W^\pm = \frac{2(e^1 \pm ie^2)}{r} , \quad (\text{A-6.7})$$

where  $W^\pm$  denotes the charged intermediate vector boson.

Consider next the identification of the neutral gauge bosons  $\gamma$  and  $Z^0$  as appropriate linear combinations of the two functionally independent quantities

$$\begin{aligned} X &= re^3 , \\ Y &= \frac{e^3}{r} , \end{aligned} \quad (\text{A-6.8})$$

appearing in the neutral part of the spinor connection. We show first that the mere requirement that photon couples vectorially implies the basic coupling structure of the GWS model leaving only the value of Weinberg angle undetermined.

To begin with let us define

$$\begin{aligned} \bar{\gamma} &= aX + bY , \\ \bar{Z}^0 &= cX + dY , \end{aligned} \quad (\text{A-6.9})$$

where the normalization condition

$$ad - bc = 1 ,$$

is satisfied. The physical fields  $\gamma$  and  $Z^0$  are related to  $\bar{\gamma}$  and  $\bar{Z}^0$  by simple normalization factors.

Expressing the neutral part of the spinor connection in term of these fields one obtains

$$\begin{aligned} A_{nc} &= [(c+d)2\Sigma_{03} + (2d-c)2\Sigma_{12} + d(n_+1_+ + n_-1_-)]\bar{\gamma} \\ &+ [(a-b)2\Sigma_{03} + (a-2b)2\Sigma_{12} - b(n_+1_+ + n_-1_-)]\bar{Z}^0 . \end{aligned} \quad (\text{A-6.10})$$

Identifying  $\Sigma_{12}$  and  $\Sigma_{03} = 1 \times \gamma_5 \Sigma_{12}$  as vectorial and axial Lie-algebra generators, respectively, the requirement that  $\gamma$  couples vectorially leads to the condition

$$c = -d . \quad (\text{A-6.11})$$

Using this result plus previous equations, one obtains for the neutral part of the connection the expression

$$A_{nc} = \gamma Q_{em} + Z^0 (I_L^3 - \sin^2 \theta_W Q_{em}) . \quad (\text{A-6.12})$$

Here the electromagnetic charge  $Q_{em}$  and the weak isospin are defined by

$$\begin{aligned} Q_{em} &= \Sigma^{12} + \frac{(n_+1_+ + n_-1_-)}{6} , \\ I_L^3 &= \frac{(\Sigma^{12} - \Sigma^{03})}{2} . \end{aligned} \quad (\text{A-6.13})$$

The fields  $\gamma$  and  $Z^0$  are defined via the relations

$$\begin{aligned} \gamma &= 6d\bar{\gamma} = \frac{6}{(a+b)}(aX + bY) , \\ Z^0 &= 4(a+b)\bar{Z}^0 = 4(X - Y) . \end{aligned} \quad (\text{A-6.14})$$

The value of the Weinberg angle is given by

$$\sin^2\theta_W = \frac{3b}{2(a+b)} , \quad (\text{A-6.15})$$

and is not fixed completely. Observe that right handed neutrinos decouple completely from the electro-weak interactions.

The determination of the value of Weinberg angle is a dynamical problem. The angle is completely fixed once the YM action is fixed by requiring that action contains no cross term of type  $\gamma Z^0$ . Pure symmetry non-broken electro-weak YM action leads to a definite value for the Weinberg angle. One can however add a symmetry breaking term proportional to Kähler action and this changes the value of the Weinberg angle.

To evaluate the value of the Weinberg angle one can express the neutral part  $F_{nc}$  of the induced gauge field as

$$F_{nc} = 2R_{03}\Sigma^{03} + 2R_{12}\Sigma^{12} + J(n_+1_+ + n_-1_-) , \quad (\text{A-6.16})$$

where one has

$$\begin{aligned} R_{03} &= 2(2e^0 \wedge e^3 + e^1 \wedge e^2) , \\ R_{12} &= 2(e^0 \wedge e^3 + 2e^1 \wedge e^2) , \\ J &= 2(e^0 \wedge e^3 + e^1 \wedge e^2) , \end{aligned} \quad (\text{A-6.17})$$

in terms of the fields  $\gamma$  and  $Z^0$  (photon and  $Z$ - boson)

$$F_{nc} = \gamma Q_{em} + Z^0(I_L^3 - \sin^2\theta_W Q_{em}) . \quad (\text{A-6.18})$$

Evaluating the expressions above one obtains for  $\gamma$  and  $Z^0$  the expressions

$$\begin{aligned} \gamma &= 3J - \sin^2\theta_W R_{03} , \\ Z^0 &= 2R_{03} . \end{aligned} \quad (\text{A-6.19})$$

For the Kähler field one obtains

$$J = \frac{1}{3}(\gamma + \sin^2\theta_W Z^0) . \quad (\text{A-6.20})$$

Expressing the neutral part of the symmetry broken YM action

$$\begin{aligned} L_{ew} &= L_{sym} + f J^{\alpha\beta} J_{\alpha\beta} , \\ L_{sym} &= \frac{1}{4g^2} \text{Tr}(F^{\alpha\beta} F_{\alpha\beta}) , \end{aligned} \quad (\text{A-6.21})$$

where the trace is taken in spinor representation, in terms of  $\gamma$  and  $Z^0$  one obtains for the coefficient  $X$  of the  $\gamma Z^0$  cross term (this coefficient must vanish) the expression

$$\begin{aligned} X &= -\frac{K}{2g^2} + \frac{fp}{18} , \\ K &= \text{Tr} [Q_{em}(I_L^3 - \sin^2\theta_W Q_{em})] , \end{aligned} \quad (\text{A-6.22})$$

In the general case the value of the coefficient  $K$  is given by

$$K = \sum_i \left[ -\frac{(18 + 2n_i^2) \sin^2 \theta_W}{9} \right] , \quad (\text{A-6.23})$$

where the sum is over the spinor chiralities, which appear as elementary fermions and  $n_i$  is the integer describing the coupling of the spinor field to the Kähler potential. The cross term vanishes provided the value of the Weinberg angle is given by

$$\sin^2 \theta_W = \frac{9 \sum_i 1}{(fg^2 + 2 \sum_i (18 + n_i^2))} . \quad (\text{A-6.24})$$

In the scenario where both leptons and quarks are elementary fermions the value of the Weinberg angle is given by

$$\sin^2 \theta_W = \frac{9}{\left(\frac{fg^2}{2} + 28\right)} . \quad (\text{A-6.25})$$

The bare value of the Weinberg angle is  $9/28$  in this scenario, which is quite close to the typical value  $9/24$  of GUTs [71] .

## A-6.2 Discrete symmetries

The treatment of discrete symmetries C, P, and T is based on the following requirements:

- a) Symmetries must be realized as purely geometric transformations.
- b) Transformation properties of the field variables should be essentially the same as in the conventional quantum field theories [24] .

The action of the reflection  $P$  on spinors of is given by

$$\Psi \rightarrow P\Psi = \gamma^0 \otimes \gamma^0 \Psi . \quad (\text{A-6.26})$$

in the representation of the gamma matrices for which  $\gamma^0$  is diagonal. It should be noticed that  $W$  and  $Z^0$  bosons break parity symmetry as they should since their charge matrices do not commute with the matrix of  $P$ .

The guess that a complex conjugation in  $CP_2$  is associated with T transformation of the physicist turns out to be correct. One can verify by a direct calculation that pure Dirac action is invariant under T realized according to

$$\begin{aligned} m^k &\rightarrow T(M^k) , \\ \xi^k &\rightarrow \bar{\xi}^k , \\ \Psi &\rightarrow \gamma^1 \gamma^3 \otimes 1 \Psi . \end{aligned} \quad (\text{A-6.27})$$

The operation bearing closest resemblance to the ordinary charge conjugation corresponds geometrically to complex conjugation in  $CP_2$ :

$$\begin{aligned} \xi^k &\rightarrow \bar{\xi}^k , \\ \Psi &\rightarrow \Psi^\dagger \gamma^2 \gamma^0 \otimes 1 . \end{aligned} \quad (\text{A-6.28})$$

As one might have expected symmetries CP and T are exact symmetries of the pure Dirac action.

## A-7 Basic facts about induced gauge fields

Since the classical gauge fields are closely related in TGD framework, it is not possible to have space-time sheets carrying only single kind of gauge field. For instance, em fields are accompanied by  $Z^0$  fields for extremals of Kähler action. Weak forces is however absent unless the space-time sheets contains topologically condensed exotic weakly charged particles responding to this force. Same applies to classical color forces. The fact that these long range fields are present forces to assume that there exists a hierarchy of scaled up variants of standard model physics identifiable in terms of dark matter.

Classical em fields are always accompanied by  $Z^0$  field and some components of color gauge field. For extremals having homologically non-trivial sphere as a  $CP_2$  projection em and  $Z^0$  fields are the only non-vanishing electroweak gauge fields. For homologically trivial sphere only  $W$  fields are non-vanishing. Color rotations does not affect the situation.

For vacuum extremals all electro-weak gauge fields are in general non-vanishing although the net gauge field has  $U(1)$  holonomy by 2-dimensionality of the  $CP_2$  projection. Color gauge field has  $U(1)$  holonomy for all space-time surfaces and quantum classical correspondence suggest a weak form of color confinement meaning that physical states correspond to color neutral members of color multiplets.

### A-7.1 Induced gauge fields for space-times for which $CP_2$ projection is a geodesic sphere

If one requires that space-time surface is an extremal of Kähler action and has a 2-dimensional  $CP_2$  projection, only vacuum extremals and space-time surfaces for which  $CP_2$  projection is a geodesic sphere, are allowed. Homologically non-trivial geodesic sphere correspond to vanishing  $W$  fields and homologically non-trivial sphere to non-vanishing  $W$  fields but vanishing  $\gamma$  and  $Z^0$ . This can be verified by explicit examples.

$r = \infty$  surface gives rise to a homologically non-trivial geodesic sphere for which  $e_0$  and  $e_3$  vanish imply the vanishing of  $W$  field. For space-time sheets for which  $CP_2$  projection is  $r = \infty$  homologically non-trivial geodesic sphere of  $CP_2$  one has

$$\gamma = \left(\frac{3}{4} - \frac{\sin^2(\theta_W)}{2}\right)Z^0 \simeq \frac{5Z^0}{8} .$$

The induced  $W$  fields vanish in this case and they vanish also for all geodesic sphere obtained by  $SU(3)$  rotation.

$Im(\xi^1) = Im(\xi^2) = 0$  corresponds to homologically trivial geodesic sphere. A more general representative is obtained by using for the phase angles of standard complex  $CP_2$  coordinates constant values. In this case  $e^1$  and  $e^3$  vanish so that the induced em,  $Z^0$ , and Kähler fields vanish but induced  $W$  fields are non-vanishing. This holds also for surfaces obtained by color rotation. Hence one can say that for non-vacuum extremals with 2-D  $CP_2$  projection color rotations and weak symmetries commute.

### A-7.2 Space-time surfaces with vanishing em, $Z^0$ , or Kähler fields

In the following the induced gauge fields are studied for general space-time surface without assuming the extremal property. In fact, extremal property reduces the study to the study of vacuum extremals and surfaces having geodesic sphere as a  $CP_2$  projection and in this sense the following arguments are somewhat obsolete in their generality.

#### Space-times with vanishing em, $Z^0$ , or Kähler fields

The following considerations apply to a more general situation in which the homologically trivial geodesic sphere and extremal property are not assumed. It must be emphasized that this case is possible in TGD framework only for a vanishing Kähler field.

Using spherical coordinates  $(r, \Theta, \Psi, \Phi)$  for  $CP_2$ , the expression of Kähler form reads as

$$\begin{aligned} J &= \frac{r}{F^2} dr \wedge (d\Psi + \cos(\Theta)d\Phi) + \frac{r^2}{2F} \sin(\Theta)d\Theta \wedge d\Phi , \\ F &= 1 + r^2 . \end{aligned} \tag{A-7.1}$$

The general expression of electromagnetic field reads as

$$\begin{aligned} F_{em} &= (3+2p)\frac{r}{F^2}dr \wedge (d\Psi + \cos(\Theta)d\Phi) + (3+p)\frac{r^2}{2F}\sin(\Theta)d\Theta \wedge d\Phi , \\ p &= \sin^2(\Theta_W) , \end{aligned} \quad (\text{A-7.2})$$

where  $\Theta_W$  denotes Weinberg angle.

a) The vanishing of the electromagnetic fields is guaranteed, when the conditions

$$\begin{aligned} \Psi &= k\Phi , \\ (3+2p)\frac{1}{r^2F}(d(r^2)/d\Theta)(k + \cos(\Theta)) + (3+p)\sin(\Theta) &= 0 , \end{aligned} \quad (\text{A-7.3})$$

hold true. The conditions imply that  $CP_2$  projection of the electromagnetically neutral space-time is 2-dimensional. Solving the differential equation one obtains

$$\begin{aligned} r &= \sqrt{\frac{X}{1-X}} , \\ X &= D \left[ \frac{|k+u|}{C} \right]^\epsilon , \\ u &\equiv \cos(\Theta) , \quad C = k + \cos(\Theta_0) , \quad D = \frac{r_0^2}{1+r_0^2} , \quad \epsilon = \frac{3+p}{3+2p} , \end{aligned} \quad (\text{A-7.4})$$

where  $C$  and  $D$  are integration constants.  $0 \leq X \leq 1$  is required by the reality of  $r$ .  $r = 0$  would correspond to  $X = 0$  giving  $u = -k$  achieved only for  $|k| \leq 1$  and  $r = \infty$  to  $X = 1$  giving  $|u+k| = [(1+r_0^2)/r_0^2]^{(3+2p)/(3+p)}$  achieved only for

$$\text{sign}(u+k) \times \left[ \frac{1+r_0^2}{r_0^2} \right]^{\frac{3+2p}{3+p}} \leq k+1 ,$$

where  $\text{sign}(x)$  denotes the sign of  $x$ .

The expressions for Kähler form and  $Z^0$  field are given by

$$\begin{aligned} J &= -\frac{p}{3+2p}Xdu \wedge d\Phi , \\ Z^0 &= -\frac{6}{p}J . \end{aligned} \quad (\text{A-7.5})$$

The components of the electromagnetic field generated by varying vacuum parameters are proportional to the components of the Kähler field: in particular, the magnetic field is parallel to the Kähler magnetic field. The generation of a long range  $Z^0$  vacuum field is a purely TGD based feature not encountered in the standard gauge theories.

b) The vanishing of  $Z^0$  is achieved by the replacement of the parameter  $\epsilon$  with  $\epsilon = 1/2$  as becomes clear by considering the condition stating that  $Z^0$  field vanishes identically. Also the relationship  $F_{em} = 3J = -\frac{3}{4}\frac{r^2}{F}du \wedge d\Phi$  is useful.

c) The vanishing Kähler field corresponds to  $\epsilon = 1, p = 0$  in the formula for em neutral space-times. In this case classical em and  $Z^0$  fields are proportional to each other:

$$\begin{aligned} Z^0 &= 2e^0 \wedge e^3 = \frac{r}{F^2}(k+u)\frac{\partial r}{\partial u}du \wedge d\Phi = (k+u)du \wedge d\Phi , \\ r &= \sqrt{\frac{X}{1-X}} , \quad X = D|k+u| , \\ \gamma &= -\frac{p}{2}Z^0 . \end{aligned} \quad (\text{A-7.6})$$

For a vanishing value of Weinberg angle ( $p = 0$ ) em field vanishes and only  $Z^0$  field remains as a long range gauge field. Vacuum extremals for which long range  $Z^0$  field vanishes but em field is non-vanishing are not possible.

### The effective form of $CP_2$ metric for surfaces with 2-dimensional $CP_2$ projection

The effective form of the  $CP_2$  metric for a space-time having vanishing em,  $Z^0$ , or Kähler field is of practical value in the case of vacuum extremals and is given by

$$\begin{aligned} ds_{eff}^2 &= (s_{rr}(\frac{dr}{d\Theta})^2 + s_{\Theta\Theta})d\Theta^2 + (s_{\Phi\Phi} + 2ks_{\Phi\Psi})d\Phi^2 = \frac{R^2}{4}[s_{\Theta\Theta}^{eff}d\Theta^2 + s_{\Phi\Phi}^{eff}d\Phi^2] , \\ s_{\Theta\Theta}^{eff} &= X \times \left[ \frac{\epsilon^2(1-u^2)}{(k+u)^2} \times \frac{1}{1-X} + 1 - X \right] , \\ s_{\Phi\Phi}^{eff} &= X \times [(1-X)(k+u)^2 + 1 - u^2] , \end{aligned} \quad (A-7.7)$$

and is useful in the construction of vacuum imbedding of, say Schwartzchild metric.

### Topological quantum numbers

Space-times for which either em,  $Z^0$ , or Kähler field vanishes decompose into regions characterized by six vacuum parameters: two of these quantum numbers ( $\omega_1$  and  $\omega_2$ ) are frequency type parameters, two ( $k_1$  and  $k_2$ ) are wave vector like quantum numbers, two of the quantum numbers ( $n_1$  and  $n_2$ ) are integers. The parameters  $\omega_i$  and  $n_i$  will be referred as electric and magnetic quantum numbers. The existence of these quantum numbers is not a feature of these solutions alone but represents a much more general phenomenon differentiating in a clear cut manner between TGD and Maxwell's electrodynamics.

The simplest manner to avoid surface Kähler charges and discontinuities or infinities in the derivatives of  $CP_2$  coordinates on the common boundary of two neighboring regions with different vacuum quantum numbers is topological field quantization, 3-space decomposes into disjoint topological field quanta, 3-surfaces having outer boundaries with possibly macroscopic size.

Under rather general conditions the coordinates  $\Psi$  and  $\Phi$  can be written in the form

$$\begin{aligned} \Psi &= \omega_2 m^0 + k_2 m^3 + n_2 \phi + \text{Fourier expansion} , \\ \Phi &= \omega_1 m^0 + k_1 m^3 + n_1 \phi + \text{Fourier expansion} . \end{aligned} \quad (A-7.8)$$

$m^0, m^3$  and  $\phi$  denote the coordinate variables of the cylindrical  $M^4$  coordinates) so that one has  $k = \omega_2/\omega_1 = n_2/n_1 = k_2/k_1$ . The regions of the space-time surface with given values of the vacuum parameters  $\omega_i, k_i$  and  $n_i$  and  $m$  and  $C$  are bounded by the surfaces at which space-time surface becomes ill-defined, say by  $r > 0$  or  $r < \infty$  surfaces.

The space-time surface decomposes into regions characterized by different values of the vacuum parameters  $r_0$  and  $\Theta_0$ . At  $r = \infty$  surfaces  $n_2, \omega_2$  and  $m$  can change since all values of  $\Psi$  correspond to the same point of  $CP_2$ : at  $r = 0$  surfaces also  $n_1$  and  $\omega_1$  can change since all values of  $\Phi$  correspond to same point of  $CP_2$ , too. If  $r = 0$  or  $r = \infty$  is not in the allowed range space-time surface develops a boundary.

This implies what might be called topological quantization since in general it is not possible to find a smooth global imbedding for, say a constant magnetic field. Although global imbedding exists it decomposes into regions with different values of the vacuum parameters and the coordinate  $u$  in general possesses discontinuous derivative at  $r = 0$  and  $r = \infty$  surfaces. A possible manner to avoid edges of space-time is to allow field quantization so that 3-space (and field) decomposes into disjoint quanta, which can be regarded as structurally stable units a 3-space (and of the gauge field). This doesn't exclude partial join along boundaries for neighboring field quanta provided some additional conditions guaranteeing the absence of edges are satisfied.

For instance, the vanishing of the electromagnetic fields implies that the condition

$$\Omega \equiv \frac{\omega_2}{n_2} - \frac{\omega_1}{n_1} = 0 , \quad (A-7.9)$$

is satisfied. In particular, the ratio  $\omega_2/\omega_1$  is rational number for the electromagnetically neutral regions of space-time surface. The change of the parameter  $n_1$  and  $n_2$  ( $\omega_1$  and  $\omega_2$ ) in general generates magnetic field and therefore these integers will be referred to as magnetic (electric) quantum numbers.

## A-8 p-Adic numbers and TGD

### A-8.1 p-Adic number fields

p-Adic numbers ( $p$  is prime: 2,3,5,...) can be regarded as a completion of the rational numbers using a norm, which is different from the ordinary norm of real numbers [51] . p-Adic numbers are representable as power expansion of the prime number  $p$  of form:

$$x = \sum_{k \geq k_0} x(k)p^k, \quad x(k) = 0, \dots, p-1 . \quad (\text{A-8.1})$$

The norm of a p-adic number is given by

$$|x| = p^{-k_0(x)} . \quad (\text{A-8.2})$$

Here  $k_0(x)$  is the lowest power in the expansion of the p-adic number. The norm differs drastically from the norm of the ordinary real numbers since it depends on the lowest pinary digit of the p-adic number only. Arbitrarily high powers in the expansion are possible since the norm of the p-adic number is finite also for numbers, which are infinite with respect to the ordinary norm. A convenient representation for p-adic numbers is in the form

$$x = p^{k_0} \varepsilon(x) , \quad (\text{A-8.3})$$

where  $\varepsilon(x) = k + \dots$  with  $0 < k < p$ , is p-adic number with unit norm and analogous to the phase factor  $\exp(i\phi)$  of a complex number.

The distance function  $d(x, y) = |x - y|_p$  defined by the p-adic norm possesses a very general property called ultra-metricity:

$$d(x, z) \leq \max\{d(x, y), d(y, z)\} . \quad (\text{A-8.4})$$

The properties of the distance function make it possible to decompose  $R_p$  into a union of disjoint sets using the criterion that  $x$  and  $y$  belong to same class if the distance between  $x$  and  $y$  satisfies the condition

$$d(x, y) \leq D . \quad (\text{A-8.5})$$

This division of the metric space into classes has following properties:

- a) Distances between the members of two different classes  $X$  and  $Y$  do not depend on the choice of points  $x$  and  $y$  inside classes. One can therefore speak about distance function between classes.
- b) Distances of points  $x$  and  $y$  inside single class are smaller than distances between different classes.
- c) Classes form a hierarchical tree.

Notice that the concept of the ultra-metricity emerged in physics from the models for spin glasses and is believed to have also applications in biology [59] . The emergence of p-adic topology as the topology of the effective space-time would make ultra-metricity property basic feature of physics.

### A-8.2 Canonical correspondence between p-adic and real numbers

The basic challenge encountered by p-adic physicist is how to map the predictions of the p-adic physics to real numbers. p-Adic probabilities provide a basic example in this respect. Identification via common rationals and canonical identification and its variants have turned out to play a key role in this respect.

### Basic form of canonical identification

There exists a natural continuous map  $I : R_p \rightarrow R_+$  from p-adic numbers to non-negative real numbers given by the "pinary" expansion of the real number for  $x \in R$  and  $y \in R_p$  this correspondence reads

$$\begin{aligned} y &= \sum_{k>N} y_k p^k \rightarrow x = \sum_{k<N} y_k p^{-k} , \\ y_k &\in \{0, 1, \dots, p-1\} . \end{aligned} \quad (\text{A-8.6})$$

This map is continuous as one easily finds out. There is however a little difficulty associated with the definition of the inverse map since the pinary expansion like also decimal expansion is not unique ( $1 = 0.999\dots$ ) for the real numbers  $x$ , which allow pinary expansion with finite number of pinary digits

$$\begin{aligned} x &= \sum_{k=N_0}^N x_k p^{-k} , \\ x &= \sum_{k=N_0}^{N-1} x_k p^{-k} + (x_N - 1)p^{-N} + (p-1)p^{-N-1} \sum_{k=0,\dots} p^{-k} . \end{aligned} \quad (\text{A-8.7})$$

The p-adic images associated with these expansions are different

$$\begin{aligned} y_1 &= \sum_{k=N_0}^N x_k p^k , \\ y_2 &= \sum_{k=N_0}^{N-1} x_k p^k + (x_N - 1)p^N + (p-1)p^{N+1} \sum_{k=0,\dots} p^k \\ &= y_1 + (x_N - 1)p^N - p^{N+1} , \end{aligned} \quad (\text{A-8.8})$$

so that the inverse map is either two-valued for p-adic numbers having expansion with finite pinary digits or single valued and discontinuous and non-surjective if one makes pinary expansion unique by choosing the one with finite pinary digits. The finite pinary digit expansion is a natural choice since in the numerical work one always must use a pinary cutoff on the real axis.

### The topology induced by canonical identification

The topology induced by the canonical identification in the set of positive real numbers differs from the ordinary topology. The difference is easily understood by interpreting the p-adic norm as a norm in the set of the real numbers. The norm is constant in each interval  $[p^k, p^{k+1})$  (see Fig. A-8.2) and is equal to the usual real norm at the points  $x = p^k$ : the usual linear norm is replaced with a piecewise constant norm. This means that p-adic topology is coarser than the usual real topology and the higher the value of  $p$  is, the coarser the resulting topology is above a given length scale. This hierarchical ordering of the p-adic topologies will be a central feature as far as the proposed applications of the p-adic numbers are considered.

Ordinary continuity implies p-adic continuity since the norm induced from the p-adic topology is rougher than the ordinary norm. p-Adic continuity implies ordinary continuity from right as is clear already from the properties of the p-adic norm (the graph of the norm is indeed continuous from right). This feature is one clear signature of the p-adic topology.

The linear structure of the p-adic numbers induces a corresponding structure in the set of the non-negative real numbers and p-adic linearity in general differs from the ordinary concept of linearity. For example, p-adic sum is equal to real sum only provided the summands have no common pinary digits. Furthermore, the condition  $x +_p y < \max\{x, y\}$  holds in general for the p-adic sum of the real numbers. p-Adic multiplication is equivalent with the ordinary multiplication only provided that

Figure 14: The real norm induced by canonical identification from 2-adic norm.

either of the members of the product is power of  $p$ . Moreover one has  $x \times_p y < x \times y$  in general. The p-Adic negative  $-1_p$  associated with p-adic unit 1 is given by  $(-1)_p = \sum_k (p-1)p^k$  and defines p-adic negative for each real number  $x$ . An interesting possibility is that p-adic linearity might replace the ordinary linearity in some strongly nonlinear systems so these systems would look simple in the p-adic topology.

These results suggest that canonical identification is involved with some deeper mathematical structure. The following inequalities hold true:

$$\begin{aligned} (x + y)_R &\leq x_R + y_R \ , \\ |x|_p |y|_R \leq (xy)_R &\leq x_R y_R \ , \end{aligned} \tag{A-8.9}$$

where  $|x|_p$  denotes p-adic norm. These inequalities can be generalized to the case of  $(R_p)^n$  (a linear vector space over the p-adic numbers).

$$\begin{aligned} (x + y)_R &\leq x_R + y_R \ , \\ |\lambda|_p |y|_R \leq (\lambda y)_R &\leq \lambda_R y_R \ , \end{aligned} \tag{A-8.10}$$

where the norm of the vector  $x \in T_p^n$  is defined in some manner. The case of Euclidian space suggests the definition

$$(x_R)^2 = \left( \sum_n x_n^2 \right)_R \ . \tag{A-8.11}$$

These inequalities resemble those satisfied by the vector norm. The only difference is the failure of linearity in the sense that the norm of a scaled vector is not obtained by scaling the norm of the original vector. Ordinary situation prevails only if the scaling corresponds to a power of  $p$ .

These observations suggests that the concept of a normed space or Banach space might have a generalization and physically the generalization might apply to the description of some non-linear systems. The nonlinearity would be concentrated in the nonlinear behavior of the norm under scaling.

**Modified form of the canonical identification**

The original form of the canonical identification is continuous but does not respect symmetries even approximately. This led to a search of variants which would do better in this respect. The modification of the canonical identification applying to rationals only and given by

$$I_Q(q = p^k \times \frac{r}{s}) = p^k \times \frac{I(r)}{I(s)} \tag{A-8.12}$$

is uniquely defined for rationals, maps rationals to rationals, has also a symmetry under exchange of target and domain. This map reduces to a direct identification of rationals for  $0 \leq r < p$  and  $0 \leq s < p$ . It has turned out that it is this map which most naturally appears in the applications. The map is obviously continuous locally since p-adically small modifications of  $r$  and  $s$  mean small modifications of the real counterparts.

Canonical identification is in a key role in the successful predictions of the elementary particle masses. The predictions for the light elementary particle masses are within extreme accuracy same for  $I$  and  $I_Q$  but  $I_Q$  is theoretically preferred since the real probabilities obtained from p-adic ones by  $I_Q$  sum up to one in p-adic thermodynamics.

### Generalization of number concept and notion of imbedding space

TGD forces an extension of number concept: roughly a fusion of reals and various p-adic number fields along common rationals is in question. This induces a similar fusion of real and p-adic imbedding spaces. Since finite p-adic numbers correspond always to non-negative reals  $n$ -dimensional space  $R^n$  must be covered by  $2^n$  copies of the p-adic variant  $R_p^n$  of  $R^n$  each of which projects to a copy of  $R_+^n$  (four quadrants in the case of plane). The common points of p-adic and real imbedding spaces are rational points and most p-adic points are at real infinity.

For a given p-adic space-time sheet most points are literally infinite as real points and the projection to the real imbedding space consists of a discrete set of rational points: the interpretation in terms of the unavoidable discreteness of the physical representations of cognition is natural. Purely local p-adic physics implies real p-adic fractality and thus long range correlations for the real space-time surfaces having enough common points with this projection.

p-Adic fractality means that  $M^4$  projections for the rational points of space-time surface  $X^4$  are related by a direct identification whereas  $CP_2$  coordinates of  $X^4$  at these points are related by  $I$ ,  $I_Q$  or some of its variants implying long range correlates for  $CP_2$  coordinates. Since only a discrete set of points are related in this manner, both real and p-adic field equations can be satisfied and there are no problems with symmetries. p-Adic effective topology is expected to be a good approximation only within some length scale range which means infrared and UV cutoffs. Also multi-p-fractality is possible.
