### Abstract

In this paper, we propose a new test of uniformity on the circle based on the Gini mean difference of the sample arc-lengths. These sample arc-lengths, which are the gaps between successive observations on the circumference of the circle, are analogous to sample spacings on the real line. The Gini mean difference, which compares these arc-lengths between themselves, is analogous to Rao's spacings statistic, which has been used to test the uniformity of circular data.

We obtain both the exact and asymptotic distributions of the Gini mean difference arc-lengths test, under the null hypothesis of circular uniformity. We also provide a table of upper percentile values of the exact distribution for small to moderate sample sizes. Illustrative examples in circular data analysis are also given. It is shown that a generalized Gini mean difference test has better asymptotic efficiency than the corresponding generalized Rao's test in the sense of Pitman asymptotic relative efficiency.

#### 1. Introduction

Sample observations representing directions in two dimensions can be modeled as random variables taking values on the circumference of the circle. We take this circle to be the unit circle with unit radius and a circumference of length  $2\pi$ . A circular probability distribution is one whose support is this circumference.

The simple goodness-of-fit problem on the circle consists of testing fit to a single fixed circular distribution for a given data set. In particular, consider a random sample of angular measurements  $\theta_1, \theta_2, \ldots, \theta_n$  with circular distribution function F defined on the interval  $[0, 2\pi)$ . We are interested in testing the null hypothesis

$$H_0: F = F_0$$

where  $F_0$  is a completely specified distribution function.

Without loss of generality, if F is assumed to be continuous as we shall do, by way of the probability integral transform, the goodness-of-fit problem reduces to one of testing circular uniformity, i.e. testing the null hypothesis

$$H_0: F(\theta) = \frac{\theta}{2\pi} \cdot I(0 \le \theta < 2\pi).$$

Let  $0 \leq \theta_{(1)} \leq \theta_{(2)} \leq \ldots \leq \theta_{(n)} < 2\pi$  denote the sample order statistics. The sample arc-lengths are defined by the random variables

$$D_k = \theta_{(k)} - \theta_{(k-1)}, \text{ for } k = 1, 2, \dots, n$$
 (1.1)

where we take  $\theta_{(0)} = \theta_{(n)} - 2\pi$  to make  $D_1$  the natural gap between the first and last order statistics that straddle the origin. The sample arc-lengths  $\{D_k\}$  represent the differences between successive observations on the circumference of the circle, and thus are analogous to spacings on the real line. When data are directions in two dimensions and represented by angles, the sample arc-lengths  $\{D_k\}$  are said to form the "maximal invariant," i.e. they remain invariant under the choice of zero-direction and sense of rotation. This is a primary prerequisite for any test for circular data, and tests based on these sample arc-lengths satisfy this condition and are the focus here for testing the null hypothesis. Under the null hypothesis of circular uniformity, the joint distribution of  $(D_1, D_2, \ldots, D_n)$  is a Dirichlet $(1, 1, \ldots, 1; 1)$  distribution on the (n - 1)simplex with probability density function

$$f_{D_1,D_2,\dots,D_{n-1}}(d_1,d_2,\dots,d_{n-1}) = \frac{(n-1)!}{(2\pi)^{n-1}} \cdot I\left(\bigcap_{k=1}^{n-1} (d_k > 0), \sum_{k=1}^{n-1} d_k \le 2\pi\right).$$
(1.2)

Moreover, under the null hypothesis, these sample arc-lengths are exchangeable random variables and have the same distribution as the spacings from a random sample of (n-1) random variables from the Uniform distribution on the line segment  $[0, 2\pi)$ . This suggests that spacings tests on the real line, with some minor modifications, can be used for circular statistical inference. In fact, spacings tests are the only general class of goodness-of-fit tests that are directly applicable to both circular and linear data. The spacings or arclengths  $\{D_k\}$  form the maximal invariant statistic under changes in origin so that every rotationally invariant statistic that is useful for the circular case can be expressed in terms of  $\{D_k\}$  (cf. Jammalamadaka and SenGupta (2001)).

Most common among spacings tests are symmetric spacings tests, i.e. general test statistics of the form

$$V_n(g) = \frac{1}{n} \sum_{k=1}^n g(nD_k)$$
(1.3)

where  $g(\cdot)$  is a real-valued function satisfying some regularity conditions, and

$$W_n(h) = \frac{1}{n(n-1)} \sum_{i=1}^n \sum_{j=1}^n h(nD_i, nD_j)$$
(1.4)

where  $h : [0, \infty) \times [0, \infty) \to \mathbb{R}$  is a symmetric function satisfying some regularity conditions. Test statistics of the form  $V_n(g)$  are symmetric sumfunctions of the sample spacings (e.g. cf. with Pyke (1965), Sethuraman and Rao (1970), and Rao and Sethuraman (1975)), and those of the form  $W_n(h)$ are U-statistics of the sample spacings (cf. with Tung and Jammalamadaka (2010)). Moreover, as these papers show, these symmetric spacings tests are known to have asymptotic Normal distributions under mild conditions. Among spacings tests of the form  $V_n(g)$ , Rao's spacings test (cf. with Rao (1969), Rao (1976))

$$J_n = \frac{1}{n} \sum_{k=1}^n \frac{|nD_k - 2\pi|}{2} = \frac{1}{2} \sum_{k=1}^n \left| D_k - \frac{2\pi}{n} \right| = \sum_{k=1}^n \left( D_k - \frac{2\pi}{n} \right)_+$$
(1.5)

which corresponds to taking  $g(t) = |t - 2\pi|/2$ , has the following nice geometric interpretation for the circle: Being adapted to the circular case, we will refer to it as Rao's arc-lengths test. Suppose *n* arcs, each of fixed length  $(2\pi)/n$ , are placed starting with each of the sample observations on the circumference. The uncovered part of the circumference contributed by observation  $\theta_k$  is given by  $\left(D_k - \frac{2\pi}{n}\right)_+$  whereas  $J_n$  gives the total uncovered portion of the circumference. The circumference is completely covered by these fixed arcs, resulting in  $J_n = 0$ , whenever the sample observations are uniformly distributed on the circumference, which happens with zero probability under the null hypothesis. Large values of  $J_n$  indicate clustering of sample observations or evidence for directionality, and rejection of the null hypothesis of circular uniformity. Rao's test is a powerful statistic that can discriminate between uniform (isotropic) and concentrated (anisotropic) circular distributions, regardless of whether the distributions are unimodal or multimodal.

Under the null hypothesis of circular uniformity, the probability density function of  $J_n$  is

$$f_{J_n}(u) = \sum_{k=1}^{n-1} \binom{n}{k} \left(\frac{u}{2\pi}\right)^{n-k-1} \frac{\psi_k(nu) \cdot (n-1)! \cdot I[0 \le u \le 2\pi(1-1/n)]}{n^{k-1}(n-k-1)!}$$
(1.6)

where

$$\psi_k(x) = \frac{1}{2\pi(k-1)!} \sum_{j=0}^{\infty} (-1)^j \binom{k}{j} \left(\frac{x}{2\pi} - j\right)_+^{k-1}.$$
 (1.7)

Rao's test is one of the few spacings-type statistics for which both the exact and asymptotic distributions are known. A table of upper percentiles of the exact distribution for  $J_n$  was first given in Rao (1976), and extended tables of these critical values can be found in Russell and Levitin (1995).

Under the null hypothesis,  $J_n$  has an asymptotic Normal distribution, i.e.

in the limit as  $n \to \infty$ ,

$$\sqrt{n} \left( J_n - e^{-1} \right) = \sqrt{n} \left( \frac{1}{2} \sum_{k=1}^n \left| D_k - \frac{2\pi}{n} \right| - e^{-1} \right)$$
  
$$\xrightarrow{D} N_1 \left( 0, 2e^{-1} - 5e^{-2} \right).$$
(1.8)

We introduce the Gini mean difference arc-lengths test in the next section and obtain both its exact and asymptotic distributions under the null hypothesis. We also furnish a table of upper percentile values of the exact distribution. Section 3 contains examples of circular data analysis featuring Rao's test and the Gini mean difference test. Section 4 discusses the Pitman asymptotic relative efficiencies of a generalized Rao's test, and a generalized Gini mean difference test.

## 2. The Gini Mean Difference Arc-Lengths Test

Comparable to Rao's arc-lengths test is the Gini mean difference of the sample arc-lengths, i.e.

$$G_n = \frac{1}{n(n-1)} \sum_{i=1}^n \sum_{j=1}^n \frac{|nD_i - nD_j|}{2} = \frac{\sum_{i=1}^n \sum_{j=1}^n (nD_i - nD_j)_+}{n(n-1)}$$
(2.1)

which corresponds to taking h(u, v) = |u - v|/2. The statistic  $G_n$ , which compares these sample arc-lengths between themselves, is of the form  $W_n(h)$ and an average over all pairs of absolute pairwise differences of the sample arc-lengths. The Gini mean difference spacings test was first proposed in Jammalamadaka and Goria (2004) for testing goodness-of-fit on the real line. There, under the goodness-of-fit null hypothesis (i.e. linear uniformity on [0, 1]), they derive both the exact and asymptotic distributions, and show that it has good performance based on Monte Carlo powers.

Under the null hypothesis of circular uniformity, the sample arc-lengths between successive observations should be approximately evenly spaced, about  $(2\pi)/n$  apart, and  $G_n$  should be close to zero. Large values of  $G_n$  resulting from unusually large arc-lengths or unusually short arc-lengths between observations, are evidence for directionality, and rejection of the null hypothesis of circular uniformity. Like Rao's test, the Gini mean difference test  $G_n$  is one of the few spacings-type tests for which both the exact and asymptotic distributions are known, under the null hypothesis. Here, we will adapt both the exact and asymptotic null distributions for the Gini mean difference spacings test on the real line to the case of the unit circle with circumference of length  $2\pi$ .

Let  $U_1, U_2, \ldots, U_{n-1}$  be independent Uniform([0, 1]) random variables, and let  $\{X_k\} = \{(2\pi)U_k\}$  define (n-1) independent  $\text{Uniform}([0, 2\pi))$  random variables. We define the *uniform spacings* on the unit interval [0, 1] by the random variables

$$T_k = U_{(k)} - U_{(k-1)}, \text{ for } k = 1, 2, \dots, n$$
 (2.2)

where  $0 \equiv U_{(0)} \leq U_{(1)} \leq U_{(2)} \leq \ldots \leq U_{(n-1)} \leq U_{(n)} \equiv 1$ .

Under the null hypothesis, the sample arc-lengths  $\{D_k\}$  are related to the uniform spacings  $\{T_k\}$  by the relation

$$D_k \simeq X_{(k)} - X_{(k-1)} = (2\pi)[U_{(k)} - U_{(k-1)}] = (2\pi)T_k.$$
(2.3)

Here as elsewhere, we use  $\simeq$  to denote the distributional equivalence of quantities on the left and right hand sides of the symbol. Since

$$\sum_{i=1}^{n} \sum_{j=1}^{n} |T_i - T_j| \simeq 2 \sum_{k=1}^{n-1} U_k$$
(2.4)

then

$$\sum_{i=1}^{n} \sum_{j=1}^{n} |D_i - D_j| \simeq (2\pi) \sum_{i=1}^{n} \sum_{j=1}^{n} |T_i - T_j| \simeq 2 \sum_{k=1}^{n-1} X_k.$$
(2.5)

Thus, we have

$$G_n = \frac{1}{2n(n-1)} \sum_{i=1}^n \sum_{j=1}^n |nD_i - nD_j| \simeq \frac{S_{n-1}}{n-1}$$
(2.6)

where  $S_{n-1} = \sum_{k=1}^{n-1} X_k$  is the sum of (n-1) independent Uniform( $[0, 2\pi)$ ) random variables. The probability distribution of  $S_{n-1}$  is a variation of the classical Irwin-Hall Uniform sum distribution, which was first derived by P.S. Laplace in 1814 (cf. Wilks (1962), Feller (1971, Theorem 1, I.9)). The probability density function of  $S_{n-1}$  has the form

$$f_{S_{n-1}}(s) = \frac{I[0 < s < 2\pi(n-1)]}{(2\pi)^{n-1}(n-2)!} \sum_{k=0}^{n-1} \binom{n-1}{k} (-1)^k (s - 2\pi k)_+^{n-2}$$
(2.7)

and can be derived via the Fourier inversion formula, and Cauchy's integral formula from complex analysis. The cumulative distribution function of  $S_{n-1}$  is

$$F_{S_{n-1}}(s) = \frac{I[0 < s < 2\pi(n-1)]}{(2\pi)^{n-1}(n-1)!} \sum_{k=0}^{n-1} \binom{n-1}{k} (-1)^k (s - 2\pi k)_+^{n-1}.$$
 (2.8)

Under the null hypothesis of circular uniformity, the probability density function of  $G_n$  is

$$f_{G_n}(y) = \frac{(n-1) \cdot I(0 < y < 2\pi)}{(2\pi)^{n-1}(n-2)!} \sum_{k=0}^{n-1} \binom{n-1}{k} (-1)^k \left[ (n-1)y - 2\pi k \right]_+^{n-2}$$
(2.9)

with cumulative distribution function

$$F_{G_n}(y) = \frac{I(0 < y < 2\pi)}{(2\pi)^{n-1}(n-1)!} \sum_{k=0}^{n-1} \binom{n-1}{k} (-1)^k \left[ (n-1)y - 2\pi k \right]_+^{n-1} \quad (2.10)$$

and characteristic function

$$\varphi_{G_n}(t) = \int_{-\infty}^{\infty} e^{ity} \, dF_{G_n}(y) = (n-1)^{n-1} \left(\frac{\exp\left(\frac{2\pi it}{n-1}\right) - 1}{2\pi it}\right)^{n-1}, \ (i = \sqrt{-1}).$$
(2.11)

Under the null hypothesis,  $G_n$  has an asymptotic Normal distribution which is applicable to large sample situations. From the classical Central Limit Theorem, in the limit as  $n \to \infty$ ,

$$\sqrt{n}\left(\frac{1}{n-1}\sum_{k=1}^{n-1}U_k - \frac{1}{2}\right) \xrightarrow{D} N_1\left(0, \frac{1}{12}\right).$$
(2.12)

Since  $G_n \simeq \frac{S_{n-1}}{n-1} = \frac{(2\pi)}{n-1} \sum_{k=1}^{n-1} U_k$ , therefore we have in the limit as  $n \to \infty$ ,

$$\sqrt{n}(G_n - \pi) = \sqrt{n} \left( \frac{\sum_{i=1}^n \sum_{j=1}^n |nD_i - nD_j|}{2n(n-1)} - \pi \right) \xrightarrow{D} N_1\left(0, \frac{\pi^2}{3}\right). \quad (2.13)$$

| n  | $\alpha = 0.01$ | $\alpha = 0.02$ | $\alpha = 0.03$ | $\alpha = 0.04$ | $\alpha = 0.05$ | $\alpha = 0.10$ |

Table 1. Upper Percentiles of the Exact Distribution for the Gini Mean Difference Arc-Lengths Test  $G_n$ .

Let

$$\alpha = \mathbb{P}(G_n > y_\alpha) = 1 - F_{G_n}(y_\alpha) \tag{2.14}$$

be the upper-tail probability corresponding to the critical value  $y_{\alpha}$  of the test statistic  $G_n$ . In Table 1, we give the upper percentiles of the exact distribution function for the statistic  $G_n$  for testing the null hypothesis of circular uniformity. The table gives these critical values, which have been

given in degrees for immediate applicability, for small to moderate sample sizes. If for a given sample size n and significance level  $\alpha$ , the observed value of the test statistic  $G_n$ , say  $y_{obs}$ , is greater than the tabulated critical value  $y_{\alpha}$ , i.e.  $y_{obs} > y_{\alpha}$ , then we reject the null hypothesis of circular uniformity.

Note that, under the null hypothesis, the so-called "p-value" or observed significance level can be calculated by

$$p = \mathbb{P}(G_n > y_{obs}) = 1 - F_{G_n}(y_{obs}).$$
(2.15)

Equivalently, the null hypothesis is rejected, whenever  $p < \alpha$ .

## 3. Some Circular Data Analysis Examples

In this section, we discuss some circular data analysis examples.

**Example (Homing Pigeon Data)**. 13 homing pigeons were released one at a time in the Toggenburg Valley in Switzerland under sub-Alpine conditions. They did not appear to have adjusted quickly to the homing direction, but preferred to fly in the axis of the valley, indicating a somewhat bimodal distribution. The vanishing angles are arranged here in increasing order as follows:

20, 135, 145, 165, 170, 200, 300, 325, 335, 350, 350, 350, 355.

Do these homing pigeons have a preferred direction of flight? (This example can also be found in Jammalamadaka and SenGupta (2001).)

The observed value of Rao's arc-lengths test statistic is  $J_{13} = 161.92$  with a p-value between 0.05 and 0.10 (cf. with the table of upper percentiles of the distribution for  $J_n$  in Rao (1976)). On the basis of Rao's arc-lengths test, there is not enough evidence to reject the hypothesis of circular uniformity at the 5% significance level.

On the other hand, the observed value of the Gini mean difference arclengths test statistic is  $G_{13} = 231.67$  with an observed significance level or p-value of p = 0.043. Therefore, the results of the Gini mean difference arclengths test are significant at the 5% significance level and we can reject the null hypothesis of circular uniformity. On the basis of Gini mean difference arc-lengths test, there is sufficient evidence that the homing pigeons have a preferred direction of flight.

**Example (Hospital Birth Times Data)**. Suppose one wants to know whether or not birth times at a hospital are uniformly distributed throughout the day. The alternative hypothesis is that there is a time (or times) when births are more frequent. Table 2 displays hypothetical data for delivery times collected across several days. This data can be found in both Russell and Levitin (1995) and Levitin and Russell (1997).

| k  | Delivery Time         | $\theta_{(k)}$ | $D_k$ |
|----|-----------------------|----------------|-------|
| 1  | 12:20  am             | 5              | 34    |
| 2  | 12:40  am             | 10             | 5     |
| 3  | 12:40  am             | 10             | 0     |
| 4  | 12:48  am             | 12             | 2     |
| 5  | 1:08  am              | 17             | 5     |
| 6  | 5:40  am              | 85             | 68    |
| 7  | 6:00  am              | 90             | 5     |
| 8  | 6:36  am              | 99             | 9     |
| 9  | 6:40 am               | 100            | 1     |
| 10 | 7:20  am              | 110            | 10    |
| 11 | 10:12  am             | 153            | 43    |
| 12 | 3:32  pm              | 233            | 80    |
| 13 | 3:40  pm              | 235            | 2     |
| 14 | 7:44  pm              | 296            | 61    |
| 15 | $10{:}04~\mathrm{pm}$ | 331            | 35    |

Table 2. Hospital Birth Times Data.

These observed event times are modeled as realizations from a continuous circular distribution. The observations can be converted to angles around a circle in an obvious way, e.g. if we want the angular units in degrees, we use  $1 \text{ hr.} = \frac{360 \text{ deg.}}{24} = 15 \text{ deg. and } 1 \text{ min.} = \frac{360 \text{ deg.}}{24 \text{ hr.}} \cdot \frac{1 \text{ hr.}}{60} = 0.25 \text{ deg.}$  Thus, 12:00 am = 0 deg., 6:00 am = 90 deg., 12:00 pm = 180 deg., 6pm = 270 deg., and 9:15 am = 138.75 deg., etc.

Rao's arc-lengths test statistic gives an observed value of  $J_{15} = 177$  with a p-value between 0.01 and 0.05. At the 5% significance level, this is sufficient evidence to reject the null hypothesis of circular uniformity and conclude that there are times when births are more frequent.

On the other hand, the Gini mean difference arc-lengths test statistic gives an observed value of  $G_{15} = 224.86$  with a p-value of 0.053. The results

from the Gini test are borderline significant, and may possibly indicate there are times when births are more frequent.

## 4. Asymptotic Relative Efficiencies

In this section, we discuss the Pitman asymptotic relative efficiencies (ARE) of both the Gini mean difference test  $G_n$  and Rao's test  $J_n$ , as well as generalized versions of these statistics.

We define the generalized Rao's arc-lengths test

$$J_n(r) = \frac{1}{2n} \sum_{k=1}^n |nD_k - 2\pi|^r, \ r > 0$$
(4.1)

and the generalized Gini mean difference arc-lengths test

$$G_n(r) = \frac{1}{2n(n-1)} \sum_{i=1}^n \sum_{j=1}^n |nD_i - nD_j|^r, \ r > 0.$$
(4.2)

For the special case r = 1, we have  $J_n(1) = J_n$  and  $G_n(1) = G_n$ . Moreover, the special case of  $J_n(2)$  corresponds to both  $G_n(2)$  and the statistic  $\frac{1}{n}\sum_{k=1}^{n}(nD_k)^2$ , which will be called the Greenwood statistic.

In the case of large samples, comparing the Pitman ARE's of two test statistics is a way of making a quantitative comparison of two distinct tests for a statistical hypothesis of interest. Broadly speaking, the Pitman ARE of one sequence of tests against another is defined as the limit of the inverse ratio of sample sizes required for two tests to attain the same power at a sequence of alternatives which converges to the null hypothesis.

In order to study Pitman ARE's, one usually needs to obtain the asymptotic distribution of test statistics under a sequence of close alternatives (also called smooth alternatives), which converges to the null hypothesis. In the circular case, the alternative hypothesis can be specified by a sequence of distribution functions  $\{F_n(x) : n \ge 1\}$  that converges to the Uniform( $[0, 2\pi)$ ) distribution function, which corresponds to the null hypothesis, in the limit as  $n \to \infty$ .

For symmetric spacings tests, the appropriate sequence of close alternatives (cf. with Sethuraman and Rao (1970) and Rao and Sethuraman (1975)) is obtained by letting the distribution function

$$F_n(x) = \frac{x}{2\pi} + \frac{L_n(x)}{n^{1/4}}, \text{ for } 0 \le x < 2\pi$$
(4.3)

where  $L_n(0) = L_n(2\pi) = 0$ . We further assume that  $L_n(x)$  is twice differentiable on the unit interval  $[0, 2\pi)$  and that there exists a function L(x) which is twice continuously-differentiable with  $L(0) = L(2\pi) = 0$  and

$$n^{1/4} \sup_{0 \le x < 2\pi} |L_n(x) - L(x)| = o(1)$$
(4.4)

$$n^{1/4} \sup_{0 \le x < 2\pi} |L'_n(x) - l(x)| = o(1)$$
(4.5)

$$n^{1/4} \sup_{0 \le x < 2\pi} |L_n''(x) - l'(x)| = o(1)$$
(4.6)

where l(x) and l'(x) are respectively the first and second derivatives of L(x). Note that  $L(x) = \int_0^x l(u) \, du$  and  $\int_0^{2\pi} l(u) \, du = 0$  by the fundamental theorem of calculus.

The asymptotic Normal distributions of test statistics, under both the null hypothesis and the sequence of close alternatives, can be adapted to the circular case. However, such an adaptation is not really necessary for finding the Pitman ARE's of test statistics, because the Pitman ARE's in the linear case carry over nicely to the circular case without much painstaking effort. The Pitman ARE's of  $J_n(r)$  and  $G_n(r)$  were obtained in Tung and Jammalamadaka (2010) in the context of goodness-of-fit testing on the real line.

Sethuraman and Rao (1970) have shown that among spacings tests of the form  $V_n(g)$ , the most asymptotically efficient, i.e. the asymptotically locally most powerful test (ALMP) is the Greenwood statistic. Tung and Jammalamadaka (2010) have shown that among spacings tests of the form  $W_n(h)$ , the ALMP test is the Gini mean squared difference test

$$G_n(2) = \frac{1}{2n(n-1)} \sum_{i=1}^n \sum_{j=1}^n |nD_i - nD_j|^2$$
(4.7)

which also has the same efficiency as the Greenwood statistic.

Suppose the Pitman ARE of  $J_n(2)$  and  $G_n(2)$  is taken to be 1. The following Table 3, taken from Tung and Jammalamadaka (2010), lists the

Pitman ARE of  $J_n(r)$  and  $G_n(r)$  with respect to various choices of r > 0. It is seen that the Pitman ARE's of  $J_n(1)$  and  $G_n(1)$  are respectively 0.572654 and 3/4, thus the Gini mean difference test  $G_n(1)$  is more asymptotically efficient than Rao's test  $J_n(1)$ . Moreover, it is also seen that the generalized Gini mean difference test  $G_n(r)$  is more Pitman efficient than the generalized Rao's test  $J_n(r)$ , except for the case r = 2, when both tests  $G_n(2)$  and  $J_n(2)$ correspond to the Greenwood statistic and have a Pitman ARE of 1.

| r   | Generalized Rao | Generalized Gini |
|-----|-----------------|------------------|
| 1   | 0.572654        | 3/4              |
| 3/2 | 0.892135        | 0.946889         |
| 2   | 1               | 1                |
| 5/2 | 0.93921         | 0.96137          |
| 3   | 0.818649        | 0.867857         |
| 4   | 0.550562        | 0.615384         |

Table 3. Pitman Asymptotic Relative Efficiencies for  $J_n(r)$  and  $G_n(r)$ .

### 5. Conclusion

We have introduced a new test of uniformity on the circle based on the Gini mean difference of the sample arc-lengths, and obtained both its exact and asymptotic distributions under the null hypothesis. We have provided a table of upper percentile values for this test, which will be of use to applied scientists employing it for circular data analysis. On the basis of Pitman asymptotic relative efficiency, the generalized Gini mean difference test is more asymptotically efficient than the generalized Rao's test.

Extension of the Gini mean difference to the two-sample problem of testing for identical circular distributions involving "spacing-frequencies" (see e.g. Holst and Rao (1980), Holst and Rao (1981), and Rao and Mardia (1980)) will be investigated elsewhere.
