Does Geometric Algebra provide a loophole to Bell’s Theorem?

Richard D. Gill

21 October, 2019

Abstract

Geometric Algebra, pioneered by David Hestenes as a universal language for physics, was proposed some years ago as an alternative framework to the quantum mechanics of interacting qubits by Chris Doran, Anthony Lasenby and others. Independently of this, in 2007 Joy Christian published the first of a series of works culminating in a book Christian (2014). He claimed to have refuted Bell’s theorem with a local realistic model of the famous singlet correlations by taking account of the geometry of space, as expressed through Geometric Algebra.

The present paper first explores Geometric Algebra as a tool for quantum information and explains why it did not live up to its early promise. In summary, whereas the mapping between 3D geometry and the mathematics of one qubit is already thoroughly understood, the Doran and Lasenby extension to a system of entangled qubits, though ingenious, does not appear to bring in new geometric insights but on the contrary, only reproduces the usual complex Hilbert space approach in a clumsy way. The problem is that the tensor product of two Clifford algebras is not a Clifford algebra. The dimension is too large, an ad hoc fix is needed. Several are possible.

I also analyse two of Christian’s earliest, shortest, least technical, and most accessible works (Christian 2007, 2011), exposing a conceptual and an algebraic error.

In the meantime, that author has published revisions and ambitious extensions of his theory in RSOS (Royal Society - Open Source), arXiv:1806.02392, and in IEEE Access, arXiv:1405.2355. The new papers have similar defects to the original ones, more complexity, and new surprising elements; RSOS has published an “expression of concern”.

In another new paper, Christian claims he has found a counter-example to Hurwitz’s theorem that the only division algebras are \( \mathbb{R}, \mathbb{C}, \mathbb{H}, \mathbb{O} \); arXiv:1806.02392, Submitted (to a pure mathematics journal). His “counter-example” is the real Clifford Algebra \( \mathbb{C}l(0,3) \) which is not a division algebra at all. At the end of the paper I run through the new elements of the new papers.

1 Introduction

In 2007, Joy Christian surprised the world with his announcement that Bell’s theorem was incorrect, because, according to Christian, Bell had unnecessarily restricted the co-domain of the measurement outcomes to be the traditional real numbers. Christian’s first publication on arXiv spawned a host of rebuttals and these in turn spawned rebuttals of rebuttals by Christian. Moreover, Christian also published many sequels to his first paper, most of which became chapters of his book Christian (2014) second edition; the first edition came out in 2012.
His original paper [Christian (2007)] took the Clifford algebra $\mathcal{C}_{3,0}(\mathbb{R})$ as outcome space. This is “the” basic geometric algebra for the geometry of $\mathbb{R}^3$, but geometric algebra goes far beyond this. Its roots are indeed with Clifford in the nineteenth century but the emphasis on geometry and the discovery of new geometric features is due to the pioneering work of David Hestenes who likes to promote geometric algebra as the language of physics, due to its seamless combination of algebra and geometry. The reader is referred to the standard texts [Doran and Lasenby (2003)] and [Dorst, Fontijne and Mann (2007)] the former focusing on applications in physics, the latter on applications in computer science, especially computer graphics. The Wikipedia pages on geometric algebra, and on Clifford algebra, are two splendid mines of information, but the connections between the two sometimes hard to decode; notations and terminology are not always consistent.

David Hestenes was interested in marrying quantum theory and geometric algebra. A number of authors, foremost among them Doran and Lasenby, explored the possibility of rewriting quantum information theory in the language of geometric algebra. This research programme culminated in the previously mentioned textbook [Doran and Lasenby (2003)] which contains two whole chapters carefully elucidating this approach. However, it did not catch on, for reasons which I will attempt to explain at the end of this paper.

It seems that many of Christian’s critics were not familiar enough with geometric algebra in order to work through Christian’s papers in detail. Thus the criticism of his work was often based on general structural features of the model. One of the few authors who did go to the trouble to work through the mathematical details was Florin Moldoveanu. But this led to new problems: the mathematical details of many of Christian’s papers seem to be different: the target is a moving target. So Christian claimed again and again that the critics had simply misunderstood him; he came up with more and more elaborate versions of his theory, whereby he also claimed to have countered all the objections which had been raised.

It seems to this author that it is better to focus on the shortest and most self-contained presentations by Christian since these are the ones which a newcomer has the best chance of actually “understanding” totally, in the sense of being able to work through the mathematics, from beginning to end. In this way he or she can also get a feeling for whether the accompanying words (the English text) actually reflect the mathematics. Because of unfamiliarity with technical aspects and the sheer volume of knowledge which is encapsulated under the heading “geometric algebra”, readers tend to follow the words, and just trust that the (impressive looking) formulas match the words.

In order to work through the mathematics, some knowledge of the basics of geometric algebra is needed. That is difficult for the novice to come by, and almost everyone is a novice, despite the popularising efforts of David Hestenes and others, and the popularity of geometric algebra as a computational tool in computer graphics. Wikipedia has a page on “Clifford algebra” and another page on “geometric algebra” but it is hard to find out what is the connection between the two. There are different notations around and there is a plethora of different products: geometric product, wedge product, dot product, outer product. The algebraic literature jumps straight into abstract Clifford algebras, without geometry, and wastes little time on that one particular Clifford algebra which happens to have so many connections with the geometry of three dimensional Euclidean space, and with the mathematics of the qubit.

Interestingly, in recent years David Hestenes also has ardently championed mathematical
modelling as the study of stand-alone mathematical realities. I think the real problem with Christian’s works is that the mathematics does not match the words; the mismatch is so great that one cannot actually identify a well-defined mathematical world behind the verbal description and corresponding to the mathematical formulas. Since his model assumptions do not correspond to a well-defined mathematical world, it is not possible to hold an objective discussion about properties of the model. As a mathematical statistician, the present author is particularly aware of the distinction between mathematical model and reality – one has to admit that a mathematical model used in some statistical application, e.g., in psychology or economics, is really “just” a model, in the sense of being a tiny and oversimplified representation of the scientific phenomenon of interest. All models are wrong, but some are useful. In physics however, the distinction between model and reality is not so commonly made. Physicists use mathematics as a language, the language of nature, to describe reality. They do not use it as a tool for creating artificial toy realities. For a mathematician, a mathematical model has its own reality in the world of mathematics.

The present author already published (on arXiv) a mathematical analysis, Gill (2012), of one of Christian’s shortest papers: the so-called “one page paper”, Christian (2011), which moreover contains the substance of the first chapter of Christian’s book. In the present paper he analyses in the same spirit the paper Christian (2007) which was the foundation or starting shot in Christian’s project. The present note will lay bare the same fundamental issues which are present in all these works. In fact, the model is not precisely the same in every publication, but constantly changes. We will find out that Christian’s (2007) model is not complete: the central feature, a definition of local measurement functions, is omitted. However there is little choice in how to fill the gap, and that is done in the 2011 version (though the author does not state explicitly that he is actually adding something to the earlier version of the model).

What is common to both these short versions of Christian’s theory is a basic conceptual error and a simple algebraic (sign) error. I think it is important to identify these with maximal clarity and that is why it is best to focus on the shortest and most self-contained presentations of the theory. One sees that the model is based on a dream which evaporates in the cold light of day. If one only uses mathematics as an intuitive language in which to describe physical insights, if a particular mathematical formalism does not match physical intuition, then the mathematics is at fault: not the intuition. However if there is no stand-alone mathematical model behind the dream... then it remains a dream which cannot be shared with other scientists.

I shall return to both projects: Doran and Lasenby’s project to geometrise quantum information, and Christian’s to disprove Bell; at the end of this paper. First it is necessary to set up some basic theory of geometric algebra. What is the Clifford algebra $\mathbb{Cl}_{3,0}(\mathbb{R})$ and what does it have to do with Euclidean (three-dimensional) geometry? What does it have to do with the quantum information theory of a system of qubits? We will actually start very close to a single qubit by discussing an alternative way of looking at the two-by-two complex matrices. Since each of the four complex entries of such a matrix has a real and an imaginary part, the whole matrix is determined by 8 real numbers. Restricting attention to the addition and subtraction of these matrices, and scalar multiplication (the scalars in question being reals, we are looking at an eight-dimensional real vector space. We will study the interaction between the real vector space structure and the operation of matrix multiplication, together giving us what the pure mathematicians call a real algebra.
2 Geometric Algebra

I will first discuss the real algebra of the two-by-two complex matrices. We can add such matrices and obtain a new one; we can multiply two such matrices and obtain a new one. The zero matrix acts as a zero and the identity matrix acts as a unit. We can multiply a two-by-two complex matrix by a real number. This is what we call \textit{scalar multiplication}. We can therefore take \textit{real linear combinations}. Matrix multiplication is associative so we have a \textit{real unital associative algebra}. Unital just means: with a unit; real means that the scalars in scalar multiplication are reals, and therefore, as a vector space (i.e., restricting attention to addition and scalar multiplication), our algebra is a vector space over the real numbers.

The four complex number entries in a two-by-two complex matrix can be separated into their real and imaginary parts. In this way, each two-by-two complex matrix can be expressed as a \textit{real linear combination} of eight “basis” matrices: the matrices having either $+1$ or $i$ in just one position, and zeros in the other three positions. Obviously, if a real linear combination of those 8 matrices is zero, then all eight coefficients are zero. The vector-space dimension of our space is therefore eight.

I will now specify an alternative vector-space basis of our space. Define the Pauli spin matrices
\[
\sigma_x = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}, \quad \sigma_y = \begin{pmatrix} 0 & -i \\ i & 0 \end{pmatrix}, \quad \sigma_z = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}
\]
and the identity
\[
I = \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix}
\]
and define
\[
1 = I, \quad e_1 = \sigma_x, \quad e_2 = \sigma_y, \quad e_3 = \sigma_z, \quad \beta_1 = i\sigma_x, \quad \beta_2 = i\sigma_y, \quad \beta_3 = i\sigma_z, \quad M = iI.
\]

It is not difficult to check that this eight-tuple is also a vector space basis. Note the following:
\[
e_1^2 = e_2^2 = e_3^2 = 1,
\]
\[
e_1e_2 = -e_2e_1 = -\beta_3, e_2e_3 = -e_3e_2 = -\beta_2, e_3e_1 = -e_1e_3 = -\beta_1,
\]
\[
e_1e_2e_3 = M.
\]
These relations show us that the two-by-two complex matrices, thought of as an algebra over the reals, are isomorphic to $\mathcal{C}\ell_{3,0}(\mathbb{R})$, or if you prefer, form a \textit{representation} of this algebra. By definition, $\mathcal{C}\ell_{3,0}(\mathbb{R})$, is the associative unital algebra over the reals generated from $\mathbb{1}$, $e_1$, $e_2$ and $e_3$, with three of $e_1$, $e_2$ and $e_3$ squaring to $\mathbb{1}$ and none of them squaring to $-\mathbb{1}$, which is the meaning of the “3” and the “0”: three squares are positive, zero are negative. Moreover, the three basis elements $e_1$, $e_2$ and $e_3$ anti-commute. The largest possible algebra over the real numbers which can be created with these rules has vector space dimension $2^{3+0} = 8$ and as a real vector space, a basis can be taken to be $\mathbb{1}$, $e_1$, $e_2$, $e_3$, $e_1e_2 = -\beta_3$, $e_1e_3 = \beta_2$, $e_2e_3 = -\beta_1$, $e_1e_2e_3 = M$. The algebra is associative (like all Clifford algebras), but not commutative.

This description does not quite tell you the “official” definition of Clifford algebra in general, but is sufficient for our purposes. We are interested in just one particular Clifford algebra, $\mathcal{C}\ell_{3,0}(\mathbb{R})$, which is \textit{the} Clifford algebra of three dimensional real geometry. It is called the (or a) \textit{geometric algebra} and the product is called the geometric product, for reasons which will soon become clear.
I wrote $1$ for the identity matrix and will later also write $0$ for the zero matrix, as one step towards actually indentifying these with the scalars $1$ and $0$. However, for the time being, we should remember that we are not (at the outset) talking about numbers, but about elements of a complex matrix algebra over the reals. Complex matrices can be added, multiplied, and should remember that we are not (at the outset) talking about numbers, but about elements towards actually indentifying these with the scalars $1$ and $0$. However, for the time being, we sign can be fixed in many ways: for instance, by taking an odd permutation of $(\beta_1, \beta_2, \beta_3)$. In particular, changing the signs of all three does the job. But also the triple $(\beta_1, \beta_2, \beta_3)$ and, in duality with this, $(\beta_1, \beta_2, \beta_3)$, which is an odd permutation, and changed two signs, an even number. We ended up with $e_1e_2e_1e_3e_2e_3$ in the conventional lexicographic ordering.

Switching some signs or permuting the order does not change the algebra generated by $1, \beta_1, \beta_2, \beta_3$. These four elements do generate a sub-algebra of $\mathcal{C}_{3,0}(\mathbb{R})$ which is isomorphic to the quaternions. The quaternion sub-algebra is called the “even sub-algebra” of our Clifford algebra since it is built from just the products of even numbers of $e_1$, $e_2$ and $e_3$.

Obviously, $M$ commutes with everything, and obviously $M^2 = -1$. Also $Me_1 = \beta_1$, $Me_2 = \beta_2$, $Me_3 = \beta_3$ and, in duality with this, $e_1 = -M\beta_1$, $e_2 = -M\beta_2$, $e_3 = -M\beta_3$. Thus any element of $\mathcal{C}_{3,0}(\mathbb{R})$ can be expressed in the form $p + Mq$ where $p$ and $q$ are quaternions, $M$ commutes with the quaternions, and $M$ is itself another square root of minus one. However one must be careful with parametrisation and be aware of “left-handed” and “right-handed” ways to define and work with the quaternions.

Notice that $(1 - e_i)(1 + e_i) = 0$ (the zero two-by-two matrix). So the algebra $\mathcal{C}_{3,0}(\mathbb{R})$ possesses zero divisors (in fact, very many!), and hence not all of its elements have inverses.

The real reason for calling this algebra a geometric algebra comes from locating real 3D space within it, and also recognising geometric operations and further geometric structures with the algebra. To start with, look at the linear span of $e_1$, $e_2$ and $e_3$. This can be identified with $\mathbb{R}^3$: from now on, real 3D vectors are real linear combinations of $e_1$, $e_2$ and $e_3$. So let us look at two elements $a$, $b$ of $\mathbb{R}^3$, thus simultaneously elements of the linear span of $e_1$, $e_2$ and $e_3$. In the latter incarnation (i.e., as elements of $\mathcal{C}_{3,0}(\mathbb{R})$), we can multiply them; what do we find? The answer is easily seen to be the following:

$$ab = (a \cdot b) \mathbb{1} + M(a \times b).$$

Here, $a \cdot b$ stands for the (ordinary) inner product of two real (three dimensional) vectors, hence a real number, or a scalar; $a \times b$ stands for the (ordinary) cross product of two real
three dimensional vectors, hence a real vector. As such, it is a real linear combination of $e_1$, $e_2$ and $e_3$. Multiplying by $M$ gives us the same real linear combination of $\beta_1$, $\beta_2$, $\beta_3$.

Thus the geometric algebra $\mathbb{C}\ell_{3,0}(\mathbb{R})$ contains as a linear subspace the real vectors of $\mathbb{R}^3$; the geometric product of two such elements encodes both their vector dot product and their vector cross product. The dot product and the cross product of real vectors can both be recovered from the geometric product, since these parts of the geometric product live in parts of the eight dimensional real linear space $\mathbb{C}\ell_{3,0}(\mathbb{R})$ spanned by disjoint sets of basis elements. The real linear subspace generated by $\beta_1$, $\beta_2$, $\beta_3$ is called the set of bivectors, just as the real linear subspace generated by $e_1$, $e_2$, $e_3$ is identified with the set of vectors. The real linear subspace generated by the single element $\mathbb{1}$ is identified with the real numbers or scalars and in particular, we identify the scalar $1$ and the element $\mathbb{1}$, the scalar $0$ and the element $0$. The real linear subspace generated by the single element $M$ is called the set of trivectors, also known as pseudo-scalars.

Bivectors can be thought of as directed planes. Going further still, rotation of vectors can be represented in terms of bivectors and so-called rotors. I will come back to this point later.

So we have seen that $\mathbb{C}\ell_{3,0}(\mathbb{R})$ is a beautiful object, containing within itself the quaternions, the complex numbers, the two-by-two complex matrices, three dimensional real vectors; and its product, sometimes called “geometric product”, contains within it both the inner and outer product of real vectors. Moreover, everything comes in dual pairs: the vectors and the bivectors; the quaternions and the product of the quaternions with $M$, the scalars and the pseudo-scalars. Every element of the algebra can be split into four components: scalar, vector, bivector and pseudo-scalar. The algebra is called graded. The parts we just named constitute the zeroth, first, second and third grades of the algebra. The product of elements of grades $r$ and $s$ belong to the grade $r+s$ modulo 4.

The fact that $\mathbb{C}\ell_{3,0}(\mathbb{R})$ has as a representation the algebra of complex two-by-two matrices over the reals is, on the whole, not much more than a side-note in the literature on geometric algebra. In the theory of Clifford algebra, it is just one tiny piece in the theory of classification of Clifford algebras in general. It seems to this author that this representation should help very much to “anchor” the theory for those coming from quantum theory and quantum foundations. However, it must be pointed out that the standard textbook on geometric algebra for physicists, [Doran and Lasenby (2003)] has two whole chapters on quantum mechanics, the first containing a geometric algebraic representation of the quantum theory of one spin half particle, the second doing the same for two entangled spin half particles. This even contains a carefully worked out analysis of the singlet state, including derivation of the famous EPR-B correlation $-\cos(a \cdot b)$.

The reader is referred to Chapters 8 and 9 of [Doran and Lasenby (2003)], whose end-notes contain many, many further references. An important point to notice is that prior to Christian’s work, there already was a large literature devoted to expressing quantum theory in terms of geometric algebra. Though it seems that this literature did not gain a place in mainstream quantum theory, one of Christian’s aims had already been fulfilled: geometric algebra had already been put forward as a vehicle for re-writing quantum theory with geometry instead of Hilbert space at the forefront. I will later try to explain why, I believe, Doran and Lasenby’s project to geometrise quantum information theory never caught on.
2.1 Remarks on computation

Before continuing, I would like to make some remarks on computation. In order to test formulas, or in order to simulate models, it is convenient to have access to computer languages which can “do” computer algebra.

First of all, the fact that $\mathbb{C}^{\ell,0}(\mathbb{R})$ can be identified with the two-by-two complex matrices means that one can implement geometric algebra as soon as one can “do” complex matrices. One needs to figure out how to get the eight coordinates out of the matrix. There are easy formulas but the result would be clumsy and involve a lot of programming at a low level. The relation with the quaternions is more promising: we can represent any element of $\mathbb{C}^{\ell,0}(\mathbb{R})$ as a pair of quaternions, and the real and the imaginary parts of the two component quaternions immediately give us access to the scalar and bivector, respectively trivector (also called “pseudo scalar”) and vector parts of the element of the algebra. For those who like to programme in the statistical language $\mathbb{R}$ it is good to know that there is an $\mathbb{R}$ package called “onion” which implements both the quaternions and the octonions.

Here a small digression starts. There exists a huge menagerie of somewhat related mathematical objects, and sometimes notations and nomenclature are confused and confusing. For instance, the octonions are another eight dimensional algebra which however is not associative. There are weird and wonderful and deep connections between these various objects and in particular, concerning the sequence 1, 2, 4, 8, which is where a particular construction taking us from the reals to the complex numbers to the quaternions and finally to the octonions stops. But this is not part of our story. Another Clifford algebra $\mathbb{C}^{0,3}(\mathbb{R})$ is also related to pairs of quaternions, but also not part of our story. End of digression.

Nicest of all is to use a computer system for doing real geometric algebra, and for this purpose I highly recommend the programme GAViewer which accompanies the book [Dorst, Fontijne and Mann (2007)] http://www.geometricalgebra.net. It not only does geometric algebra computations, it also visualises them, i.e., connects to the associated geometry. Moreover the book and the programme are a nice starting point for two higher dimensional geometric algebras, of dimension 16 and 32 respectively, which encode more geometric objects (for instance, circles and affine subspaces), and more geometric operations, with the help of the further dimensions of the algebra.

3 Christian’s first model

After several pages of general introduction, [Christian (2007)] gives a very brief specification of his (allegedly) local realist model for the singlet (or EPR-B) correlations, obtained through the device of taking the co-domain of Bell’s measurement functions to be elements of the geometric algebra $\mathbb{C}^{\ell,0}(\mathbb{R})$ rather than the conventional (one dimensional) real line.

Conventionally, a local hidden variables model for the singlet correlations consists of the following ingredients. First of all, there is a hidden variable $\lambda$ which is an element of some arbitrary space over which there is a probability distribution referred to in physicist’s language sometimes as $\rho(\lambda)d\lambda$, sometimes as $d\rho(\lambda)$. This hidden variable is often thought to reside in the two particles sent to the two measurement devices in the two wings of the experiment, and therefore to come from the source; but one can also think of $\lambda$ as an assemblage of classical variables in the source and in both particles and in both measurement devices which together determine the outcomes of measurement at the two locations. Any “local stochastic” hidden
variables model can also be re-written as a deterministic local hidden variables model. This rewriting (thinking of random variables as simply deterministic functions of some lower level random elements) might not correspond to physical intuition but as a mathematical device it is a legitimate and powerful simplifying agent.

Secondly, we have two functions $A(a, \lambda)$ and $B(b, \lambda)$ which take the values $\pm 1$ only, and which denote the measurement outcomes at Alice’s and Bob’s locations, when Alice uses measurement setting $a$ and Bob uses measurement setting $b$. Here, $a$ and $b$ are 3D spatial directions conventionally represented by unit vectors in $\mathbb{R}^3$. The set of unit vectors is of course also known as the unit sphere $S^2$.

Bell’s theorem states that there do not exist functions $A$ and $B$ and a probability distribution $\rho$, on any space of possible $\lambda$ whatever, such that

$$\int A(a, \lambda)B(b, \lambda)d\rho(\lambda) = -a \cdot b$$

for all $a$ and $b$ in $S^2$.

Christian claims to have a counter-example and the first step in his claim is that Bell “unphysically” restricted the co-domain of the functions $A$ and $B$ to be the real line. Now this is a curious line to take: we are supposed to assume that $A$ and $B$ take values in the two-point set $\{-1, +1\}$. In fact, the correlation between $A$ and $B$ in such a context is merely the probability of getting equal (binary) outcomes minus the probability of getting different (binary) outcomes. In other words: Bell’s theorem is about measurements which can only take on two different values, and it is merely by convention that we associate those values with the numbers $-1$ and $+1$. We could just as well have called them “spin up” and “spin down”. In the language of probability theory, we can identify $\lambda$ with the element $\omega$ of an underlying probability space, and we have two families of random variables $A_a$ and $B_b$, taking values in a two point set, without loss of generality the set $\{-1, +1\}$, and Bell’s claim is: it is impossible to have $\text{Prob}(A_a = B_b) - \text{Prob}(A_a \neq B_b) = -a \cdot b$ for all $a$ and $b$.

However, let us bear with Christian, and allow that the functions $A$ and $B$ might just as well be thought of as taking values in a geometric algebra . . . as long as we insist that they each only take on two different values.

Christian used the symbol $n$ to denote an arbitrary unit vector (element of $S^2$) and in formulas (15) and (16) makes the following bold suggestion:

$$A_n = B_n = \mu \cdot n \sim \pm 1 \in S^2$$

where $\mu \cdot n$ has been previously defined to be $\pm M n$ (I use the symbol $M$ instead of Christian’s $I$). Christian talks about the dot here standing for a “projection” referring, presumably, to the duality between vectors and bivectors. Christian sees $\mu$ as his local hidden variable, giving us the story that space itself picks at random a “handedness” for the trivector $M = e_1 e_2 e_3$, thought of as a directed volume element. This story is odd; after all, the “handedness” of $e_1 e_2 e_3$ is merely the expression of the sign of the evenness of the permutation 123. Of course, the multiplication rule of geometric algebra, bringing up the cross product does again involve a handedness convention: but this is nothing to do with physics, it is only to do with mathematical convention, i.e., with book-keeping.

But anyway, within Christian’s “model” as we have it so far, we can just as well define $\lambda$ to be a completely random element of $\{-1, +1\}$, and then define $\mu = \lambda M$. The resulting probability distribution of $\mu$ is the same; we have merely changed some names, without changing the model.
So now we have the model

\[ A(\mathbf{a}, \lambda) = \lambda \mathbf{M} \mathbf{a}, \quad B(\mathbf{b}, \lambda) = \lambda \mathbf{M} \mathbf{b} \]

which says that the two measurement functions have outcomes in the set of pure (unit length) bivectors. Now, those two sets are both isomorphic to \( S^2 \), and that is presumably the meaning intended by Christian when using the congruency symbol \( \cong \): our measurements can be thought of as taking values in \( S^2 \). At the same time, each measurement takes on only one of two different values (given the measurement direction) hence we can also claim congruency with the two point set \( \{ -1, +1 \} = \{ \pm 1 \} \). But of course, these are two different congruencies! And they still need to be sorted out. What is mapped to what, exactly . . .

This is where things go badly wrong. On the one hand, the model is not yet specified, if Christian does not tell us how, exactly, he means to map the set of two possible values \( \pm \mathbf{M} \mathbf{a} \) onto \( \{ \pm 1 \} \) and how he means to map the set of two possible values \( \pm \mathbf{M} \mathbf{b} \) onto \( \{ \pm 1 \} \). On the other hand, Christian proceeds to compute a correlation (in the physicist’s sense: the expectation value of a product) between bivector valued outcomes instead of between \( \{ \pm 1 \} \) valued outcomes. No model, wrong correlation.

Let us take a look at each mis-step separately. Regarding the first (incomplete specification), there are actually only two options (without introducing completely new elements into the story), since Christian already essentially told us that the two values \( \pm 1 \) of (my) \( \lambda \) are equally likely. Without loss of generality, his model (just for these two measurement directions) becomes either

\[ A(\mathbf{a}, \lambda) = B(\mathbf{b}, \lambda) = \lambda = \pm 1 \]

or

\[ -A(\mathbf{a}, \lambda) = B(\mathbf{b}, \lambda) = \lambda = \pm 1 \]

and hence his correlation is either +1 or −1, respectively.

Regarding the second mis-step, Christian proceeds to compute the geometric product \((\mu \cdot \mathbf{a})(\mu \cdot \mathbf{b})\) (later, he averages this over the possible values of \( \mu \)). Now as we have seen this is equal to \((\lambda \mathbf{M} \mathbf{a})(\lambda \mathbf{M} \mathbf{b}) = \lambda^2 \mathbf{M}^2 \mathbf{a} \mathbf{b} = -\mathbf{a} \cdot \mathbf{b} - M(\mathbf{a} \times \mathbf{b})\) and therefore certainly not equal to \(-\mathbf{a} \cdot \mathbf{b} - \lambda \mathbf{M} \mathbf{a} \times \mathbf{b}\).

4 Christian’s second model

It seems clear to me that by 2011, Christian himself has realised that his “model” of 2007 was incomplete: there was no explicit definition of the measurement functions. So now he does come up with a model, and the model is astoundingly simple . . . it is identical to my second model:

\[ A(\mathbf{a}, \lambda) = -B(\mathbf{b}, \lambda) = \lambda = \pm 1. \]

However, he still needs to get the singlet correlation from this, and for that purpose, he daringly redefines correlation, by noting the following: associated with the unit vectors \( \mathbf{a} \) and \( \mathbf{b} \) are the unit bivectors (in my notation) \( \mathbf{M} \mathbf{a} \) and \( \mathbf{M} \mathbf{b} \). As purely imaginary elements of the bivector algebra or quaternions, these are square roots of minus one, and we write

\[ A(\mathbf{a}, \lambda) = (\mathbf{M} \mathbf{a})(-\lambda \mathbf{M} \mathbf{a}) = \lambda \]

\[ B(b, \lambda) = (\lambda M b)(M b) = -\lambda \]

where \( \lambda \) is a “fair coin toss”, i.e., equal to \( \pm 1 \) with equal probabilities \( \frac{1}{2} \).

Now the cunning device of representing these two random variables as products of fixed bivectors and random bivectors allows Christian to propose a generalised Pearson bivector correlation between \( A \) and \( B \) by dividing the mean value of the product, by the non random “scale quantities” \( M a \) and \( M b \). In other words, \( M a \) and \( M b \) are thought of as standard deviations. The Clifford algebra valued measurement outcome \( \pm 1 \) is thought of as having a standard deviation which is a bivectorial root of \(-1\).

Since the geometric product is non commutative, one must be careful about the order of these operations (and whether we divide on the left or the right), but I will follow Christian in taking what seems natural choices: “a” always on the left, “b” on the right.

Unfortunately, since \( AB = -1 \) with probability one, the Christian-Pearson correlation should be \( - (M a)^{-1}(M b)^{-1} = -(M a)(M b) = -a \cdot b - M(a \times b) \), just as before. However, just as in the 2007 paper, Christian succeeds again in 2011 in getting a sign wrong, so as to “erase” the unwanted bivector cross-product term from the “correlation”. In Gill (2012) I have analysed where he went wrong and put forward an explanation of how this mistake could occur (ambiguous notation and inaccurate terminology, driven of course by powerful wishful thinking). It should be noted that he also hides the sign error somewhat deeper in complex computations, looking at the average of a large number of realisations and using the law of large numbers, rather than just computing the expectation “theoretically”.

I will discuss the other versions of Christian’s theory at the end of this paper. He has elaborated more or less the same “theory” with the same repertoire of conceptual and algebraic errors in various papers with increasing levels of complexity. This work shows a remarkable degree of dedication and persistence, and erudition too, as more and more complex mathematical constructions are brought into play. However the flaws in the foundation are unchanged and one of them (as has been said by many before) is unredeemable: Bell’s theorem is about probabilities of different combinations of pairs of binary outcomes. A local hidden variable theory has to explain the correlations between binary outcomes which are predicted by quantum mechanics, following standard, minimal, interpretations: quantum mechanics predicts the probability distribution of measurement outcomes. Experimenters (in this field) count discrete events and estimate probabilities with relative frequencies.

## 5 Geometrizing quantum information theory

I assume that the reader is already familiar with the standard “Bloch sphere” picture of quantum states, quantum operations, and quantum measurements for a single qubit. This means that the first of Doran and Lasenby’s two chapters on quantum information hold few surprises. Quantum states can be represented as points in the Bloch ball, thus as real 3D vectors of length less than or equal to one. Pure states lie on the surface of the ball, mixed states in the interior. Unitary evolutions correspond to rotations of the Bloch sphere and these are represented by right and left multiplication with a unitary matrix and its Hermitian conjugate. In geometric algebra, rotation of a 3D real vector is expressed using an object called a “rotor” and the geometric idea is that we do not rotate around a vector, but in a plane. Oriented planes are represented by bivectors.

One curious point is that Doran and Lasenby also attempt to map the vector (wave function) representation of a pure state into the geometric algebra framework. Since the
density matrix is a completely adequate representation of any state, pure or mixed, this seems to me to be superfluous. Why not agree that a pure state is represented by its density matrix, hence a point on the unit sphere, hence a real vector of unit length? They do achieve their aim by thinking of state vectors as being the result of a 3D rotation from a fixed reference direction, hence pure states are represented by rotors which involve a choice of reference direction.

All in all, one could argue that rephrasing the mathematics of a single qubit in terms of real geometric algebra demystifies the usual approach: no more complex numbers, just real 3D geometry. Doran and Lasenby hint several times in their book and other publications that their approach also has the promise of delivering an unconventional interpretation of quantum mechanics, but they never appear to follow this up.

Having all the mathematical machinery of the complex two-by-two matrices at their disposal, it is essentially a straightforward matter to now also extend the discussion to several (entangled) qubits. Indeed, their book contains a reworking of the computation of the singlet correlations for the special case of a maximally entangled pair of qubits.

The approach is simply to take the (outer) product of as many copies of $\mathcal{C}_3(\mathbb{R})$ as we have qubits. Thus no new geometry is involved and in fact we move out of the realm of Clifford algebras: a product of several Clifford algebras is not a Clifford algebra itself. Certainly it is the case that the outer product of two copies of $\mathcal{C}_3(\mathbb{R})$ contains, as an algebra, everything that we need relative to the usual Hilbert space approach. However it contains more than we need. The problem is that in the Hilbert space approach, the tensor product of the identity with $i$ times the identity is equal to the tensor product of $i$ times the identity with the identity. But taking the outer product of two Clifford algebras defines two distinct elements: $1 \otimes M$ and $M \otimes 1$.

Thus we should form the basic space for a composite system not just by taking a product of spaces for the subsystems but also by adding a further equality $1 \otimes M = M \otimes 1$.

Notice that the two-by-two complex matrices have real dimension eight, while the four-by-four complex matrices have real dimension 32. However, $8 \times 8 = 64$. Thus if we believe the usual Hilbert space story for the mathematics of two qubits, then states, operators, measurements, … can all be represented in a real algebra of dimension 32. Adding an extra equality $1 \otimes M = M \otimes 1$ reduces the dimension of $\mathcal{C}_3(\mathbb{R}) \otimes 2$ from 64 to 32 and now we do have exactly the algebra which we need in order to carry the “usual” Hilbert space based theory.

In fact, Doran and Lasenby, taking their cue from their representation of pure states as rotors, representing a rotation from a reference direction to the direction of the state, construct a different reduction by imposing a different equality. Their point is that geometrically, we need to align the reference directions of the two subsystems. This leads to an algebraically more complicated “base space”, with perhaps better geometric interpretability, than the obvious algebraic reduction, which comes down to identifying the complex root of minus one, $i$, as being “the same” in the two Hilbert spaces of the two subsystems: mathematically that is a natural step to take, but what does it mean physically?

The proof of the pudding should be in the eating. On the one hand, everything one can do with the Clifford algebra approach can also be done in the Hilbert space approach: after fixing the dimension issue, one has two mathematically isomorphic systems, and the choice between the two is merely a matter of “picking a coordinate system”. So far, it seems that the Clifford algebra approach did not pay off in terms of easier computations or geometric insight, when we look at systems of several qubits. On the other hand, the geometric insight
for a single qubit was already available and has become completely familiar. The geometric algebra approach did not lead to new \textit{interpretational} insights in quantum theory. Finally, it does not extend in an easy way to higher-dimensional systems: where is the geometric algebra of the qutrit?

However I hope that this paper will encourage others to take a fresh look for themselves.

6 Further publications

6.1 The International Journal of Physics paper, 2015

\textit{Macroscopic Observability of Spinorial Sign Changes under $2\pi$ Rotations.}

I wrote a paper pointing out various extraordinary errors and entitled \textit{Macroscopic Unobservability of Spinorial Sign Changes}. It was accepted and published in \textit{IJTP},

6.2 The Annals of Physics paper, 2015

\textit{Local Causality in a Friedmann-Robertson-Walker Spacetime.}

This paper mysteriously vanished from the web-site of the once famous journal \textit{AoP} after it had been accepted but before the contents page of the next issue was definitive. On the web page one can read “This article was erroneously included in this issue. We apologize for any inconvenience this may cause.” The author had not been informed.

Quite amazingly, this paper includes a computer simulation, allegedly of the author’s model but actually a simulation of Pearle’s famous detection loophole model of 1970. The author does not himself read or write computer programs, but has some supporters who write software for him. Since it is impossible to implement his own model while still getting the right answer, they are forced to modify Christian’s own definitions or even to simply write code to implement already existing models earlier invented by others, of which there are many. I will elsewhere publish further details about my own re-discovery, correction, and implementation of Pearle’s model.

6.3 The RSOS paper, 2018

\textit{Quantum correlations are weaved by the spinors of the Euclidean primitives.}
https://royalsocietypublishing.org/doi/full/10.1098/rsos.180526
\textit{RSOS (Royal Society - Open Source), arXiv:1806.02392}

The author claims that Bell made an extraordinary error in the proof of his theorem. Namely, it is claimed that the use of expressions involving simultaneously measurement functions evaluated at several different measurement settings cannot possibly have any physical meaning and hence that proofs which depend on the evaluation of such expressions are physically meaningless and hence invalid.
The point, of course, is that, under local realism, the local hidden variable $\lambda$ is supposed to exist, and various functions thereof are also supposed, by the assumption of local realism, to exist. Hence one can mathematically consider any combinations of those functions one likes, and if that leads to observable consequences, for instance, bounds on correlations which can be observed in experiments, then those bounds must be valid, if local realism is true.

Note that when I use the word “exists”, I speak as a mathematician, and I am discussing mathematical models. For me, local realism means the existence of a mathematical model which reproduces the predictions of quantum mechanics (or approximately does so). It is up to physicists and to philosophers to thrash out what they mean when they use words like local, real, or exist.

The paper yet again proposes a local hidden variables model in which the hidden variable $\lambda$ is a fair coin toss, taking the values $\pm 1$. It follows that the pair $A(a,\lambda), B(b,\lambda)$ can only take the values $(−1,−1), (−1,+1), (+1,−1)$ or $(1,+1)$. Their product can only take the values $\pm 1$ and the only probabilities around are $\frac{1}{2}, \frac{1}{2}$. This means that the expectation value of a product $A(a,\lambda)B(b,\lambda)$, whatever the values of the settings $a, b$, can only be $−1, 0$ or $+1$. I learnt this argument from Heine Rasmussen.

The proof that the singlet correlations are produced by this model is more sophisticated than ever; and the paper actually claims to deal with all quantum correlations, not just the EPR-B correlations. The usual errors can be located in the proofs, together with a new one: a limit is computed as $s_1 \to a$ and $s_2 \to b$, while imposing the “physical” constraint $s_1 = −s_2$. The notation is non-standard and not explained, but not surprisingly, this doesn’t make much sense unless $a = −b$. The result is a correlation of $±1$, which is indeed what is desired if $a = −b$, but not otherwise.

There is also a proof of an astonishing pure mathematical result in this paper, which has been separated off and submitted as a separate publication to a pure mathematics journal. I will deal with that at the end of this section. The paper has not yet appeared in print.

6.4 The IEEE Access paper, 2018

*Bell’s Theorem Versus Local Realism in a Quaternionic Model of Physical Space.*

https://ieeexplore.ieee.org/document/8836453

*IEEE Access, arXiv:1405.2355*

This is actually a revised version of the disappearing *IJTP* paper *Local Causality in a Friedmann-Robertson-Walker Spacetime* which I discussed earlier. It combines elements from all previous works.

6.5 The Pure Mathematics paper, 2018

*arXiv:1806.02392*

*Eight-dimensional Octonion-like but Associative Normed Division Algebra.*

In this latest paper, which Christian says is *Submitted* (to a pure mathematics journal), Christian claims he has found a counter-example to Hurwitz’s theorem that the only division algebras are $\mathbb{R}, \mathbb{C}, \mathbb{H}, \mathbb{O}$ of dimensions 1, 2, 4 and 8. His “counter-example” is the real Clifford Algebra $\mathbb{C}l_{0,3}$ which is not a division algebra at all.

He writes “the corresponding algebraic representation space ... is nothing but the eight-dimensional even sub-algebra of the $2^4 = 16$-dimensional Clifford algebra $\mathbb{C}l_{4,0}$”.

13
This space is well known to be isomorphic to $\mathbb{C} \ell_{0,3}$. The wikipedia pages on Clifford Algebras are very clear on this, and as far as I can see, well sourced and highly accurate. One can take as basis for the 8 dimensional real vector space $\mathbb{C} \ell_{0,3}$ the scalar 1, three unit vectors, three unit bivectors, and the pseudo-scalar. Take any unit vector $u$. It satisfies by definition $u^2 = 1$ hence $u^2 - 1 = (u - 1)(u + 1) = 0$. If the space could be given a norm such that the norm of a product is the product of the norms, we would have $\|u - 1\| \|u + 1\| = 0$ hence either $\|u - 1\| = 0$ or $\|u + 1\| = 0$ (or both), implying that $u = 1$ or $u = -1$, neither of which are true.

Recall that a normed division algebra is an algebra that is also a normed vector space and such that the norm of a product is the product of the norms; a division algebra is an algebra such that if a product of two elements equals zero, then at least one of the two elements concerned must be zero. A splendid resource on the Hurwitz theorem and the octonions is John Baez’ celebrated 2002 article in the Bulletin of the American Mathematical Society reproduced on his web pages http://math.ucr.edu/home/baez/octonions/. Full proofs are given but already the key definitions and main theorems are clearly stated in the first couple of pages.

There do exist some exotic objects called “exotic spheres”: differentiable manifolds that are homeomorphic but not diffeomorphic to the standard Euclidean $n$-sphere. That is, a sphere from the point of view of all its topological properties, but carrying a smooth structure that is not the familiar one. They were first discovered by Milnor in 1956 for the 7-sphere, and have been further classified by him and many other researchers. It is unknown if exotic 4-spheres exist. There are no other exotic spheres in dimensions 1 up to 6; from then on, they only exist in some dimensions, and much is still unknown about them.

Christian claims that his model depends on the Hopf fibration, a wonderful way to look at the 3-sphere. He claims that a uniform distribution on $S^3$ relative to the Hopf fibration differs from the usual uniform distribution on $S^3$. But this makes no sense. “Uniform distributions” are defined relative to some symmetries, and the Hopf fibration does not introduce new symmetries to $S^3$ beyond the familiar ones of “flatland”, i.e., of Euclidean geometry.
