Abstract

Problem: The mechanisms whereby force operates are poorly understood at the fundamental level. Purpose: This paper proposes a mechanism for how a particle detects the field gradient, and how it moves therein. Approach: A non-local hidden-variable (NLHV) theory is used, specifically the Cordus NLHV theory. Findings: The operation of force is proposed to occur from the interaction between the energisation sequence of particle, with the field gradient, resulting in discrete displacement motions of the particle. Specifically the particle sub-structures sweep through a volume of space during their energisation cycle. This locus is warped by the incoming field, hence preferentially displacing the particle along the gradient. Originality: The novel contribution of this work is providing a candidate mechanism for how a particle detects and moves in a field gradient.

Keywords: field; interaction; fundamental; quantum

1 Introduction

The operation of force is something taken for granted. It is intuitively accepted that a particle moves in the gradient of a field. However given that a particle is also assumed to be a zero-dimensional (0-D) point, it is unclear how such a particle would detect the direction or gradient of the field.

A common, though simplistic, explanation is by analogy to a small sphere (e.g. a marble) on an inclined plane in a gravitational situation: it will naturally roll downhill. However a moment’s consideration will show that this analogy does not extend to a 0-D point. For the marble, the line of action of the centre of mass is offset from the contact point with the surface, so a moment arises to roll the ball downwards. For a 0-D point there cannot be a moment arm, hence the analogy fails. If a particle did have volume, either by a volumetrically dispersed aggregation of other 0-D particles (the quantum mechanics premise), or because fundamental particles had volume (the premise of
hidden variable theories), it is unclear how that volume might help the particle detect the field direction in real situations outside of the analogy. So the slope analogy fails.

The slope analogy represents the field as continuous. Another explanation might be attempted by assuming it is discrete, i.e. mediated by the exchange of gauge bosons. In which case it is easier to understand that there may be more incoming gauge bosons on one side of a test particle than on the other, and that this underlies the field gradient. However what such theories fail to explain is the direction of force. What is the mechanism that causes opposite electrical charges to attract, and similar to repel? How does an incoming gauge boson cause movement of the 0-D test particle?

Hence there is an underlying ontological problem with describing how field force interactions occur at the level of fundamental particles. This paper proposes a mechanism for how a particle detects the field gradient, and how it moves therein.

2 Context
The explanation was developed from a non-local hidden-variable (NLHV) theory, specifically that variant called the Cordus theory. As the name suggests, all NLHV theories propose that fundamental particles have sub-structure, though differing greatly in what they propose for those structures. In the case of the Cordus theory the proposal is for an open string-like structure (hence the name), see Figure 1.
Figure 1: The representation of the electron’s internal and external structures. It is proposed that the particle has three orthogonal discrete forces, energised in turn at each reactive end. Adapted from [1].

According to this interpretation, the particle has two reactive ends a physical distance apart and interconnected by a fibril. The fibril is inert relative to other particles, and the interaction of the particle occurs at the reactive ends. This is via the periodic energisation thereof (at the de Broglie frequency). The reactive ends emit discrete forces into space, in three orthogonal emission directions (r, a, and t in the Figure) [2, 3]. The discrete forces are joined into flux tubes. The space between particles therefore comprises a fabric of discrete forces [4].

The theory describes multiple physical phenomena, see Table 1. This shows there is a degree of robustness to the conjectured sub-structures, though this does not constitute proof.

3 **Approach**
The present paper logically extends the concept of the flux tube. Prior work shows that the Lorentz, relativistic Doppler, and time dilation could be derived from first principles using the Cordus theory [19], but required the flux tube to be stretchable. This imposes a conceptual conundrum. How could discrete forces, which are required in the context of synchronous bonding [2] to be in a binary state of energisation, also be continuous as required in the general relativity context? The existence of this duality implied the potential existence of a deeper mechanics, once that could give either outcome depending on the perspective taken.

The specific situation under examination was how the electro-magneto-gravitational fields operated, i.e. the long ranged interactions (excluding the strong and weak). It is apparent that the strength of energisation at a reactive end will evolve over time. The question to be addressed is what the shape of this energisation function might be.

The approach used abductive reasoning. It started with the high-level behaviour, namely the above duality and the existing premises of the wider Cordus theory. Logical inference was then used to determine the possible deeper mechanics. This yields a plausible explanation, though not a proven one. In the process some additional conceptual propositions are made, which add to the wider theory and are consistent with it. These are lemmas, indicated §.

4 Results

4.1 A proposed general mechanism for force

Consider test particle B, say an electron, in an electrostatic field set up by particle A. Each particle has two reactive ends, and for B these are denoted B₁ and B₂. See Figure 2. The location of interest is reactive end B₁ which receives forces from A, and emits its own discrete forces.
Figure 2: Discrete forces emitted by basal particle A, and intercepted by remote test particle B. Each particle has two reactive ends.

Emission of discrete forces occurs at the energisation frequency of the particle (§1)

It is proposed that discrete forces are emitted from massy particles, and at each cycle of energisation a fresh discrete force is created and emitted. It follows that higher frequency particles, i.e. those that are in more energetic states, emit discrete forces more frequently. The corollary is that the magnitude of the force effect is proposed to be determined by the number of discrete forces received.
Similar-charged particles interact via the transphasic synchronous interaction, while opposite-charged particles interact via the cisphasic interaction (§2)

The theory predicts that bonds between proximal particles arise from synchronisation of their discrete force emissions. This is called the synchronous interaction [2] and has been applied to predict the structure of the atomic nucleus for multiple nuclides [14, 15], and also explains Pauli pair structures [5]. Favourable emission states have already been defined for this theory, see [2], and include assembly of opposite charge discrete forces and complete sets of discrete forces. There are two subtypes to the synchronous interaction, which are transphasic and cisphasic. These are when reactive ends from different particles energise out- and in-phase respectively.

This lemma extends the synchronous principle to ranged particles: it is proposed that the same mechanism applies even if the particles are some distance apart, e.g. in the electrostatic force and ranged forces generally.

If the emission of discrete forces of one particle favours the emissions of the other, then the particles move closer together. The direction of motion is along the gradient in a direction that favours increased compatibility or evades incompatibility (as the case may be).

**Force is caused by coercive displacement of reactive ends (§3)**

Under these assumptions, force at the deeper level is a process of discrete displacements of reactive ends, under the coercive effect of incoming discrete forces.

More specifically, force on test particle B is caused by incoming discrete forces interacting with the emission sequence of B’s discrete forces. This coerces the reactive end to re-energise in a different location. Those incoming discrete forces may be from other particle A or the fabric (many other particles) generally.

The nature of the interference for B is the phase difference between its intended emissions vs. the incoming emissions. This prescription causes the reactive end of B to move its location in space, such that it more nearly synchronises its emissions in or out of phase (cis- or transphasic respectively) with the external discrete forces. The process is one of the reactive end of B being drawn to, or evading, the discrete forces produced by distant particles.
Such a motion is a finite displacement and occurs during the energisation cycle of the particle, hence we refer to it as a coerced discrete displacement. It is the particle’s response to the external discrete force. This has the effect that the reactive end energises at a different location to its natural preference, hence causing the position of the particle as a whole to change, and this effect is perceived as force.

The response depends on the bound state of B. For free particle B the free reactive end may move in response to the external discrete forces. For a partially bonded particle B, one reactive end is co-located with the reactive end of other particles, and hence B is constrained in span and frequency and this limits the available locations into which it can move. For particle B bonded at both reactive ends, there is no ability to move. If there is sufficient reaction force applied to the test particle, then it can be prevented from making this discrete displacement. Instead the body as a whole responds to the external discrete forces. Hence a larger body is subject to the same effect of prescribed displacement, but in an aggregate manner. Thus the effect of prescribed displacement scales from the small to the macroscopic discoherent state. If the external discrete forces are sufficiently compelling, even full bonded particle A may be broken free from its assembly. This is consistent with the effect of ionising radiation.

The displacement is not uniform or fixed, being instead determined by the relative strengths of the native vs. incoming discrete force emissions (hence also type and mass of test particle), and the degree of freedom or constraint on the test particle. The test particle makes a small displacement each time it de-energises, and hence the underlying response to the field is a series of discrete motions. As particles have high frequencies (de Broglie frequency), this process is apparently continuous at the macroscopic scale. Hence the explanation does not undermine classical continuous mechanics, but rather offers a deeper explanation. Likewise the force bosons of quantum mechanics are re-explained as discrete forces. Quantum QM requires different bosons for each interaction, whereas the Cordus theory proposes that different attributes of the discrete forces result in the different interactions.

A field comprises sequential discrete forces (§4)
In this way force at the fundamental level is proposed to be a series of discrete displacements of the reactive end, as opposed to a continuous effect per classical mechanics. The perturbing external discrete force is of finite duration, hence the displacement per energisation cycle is also finite. For a particle B in
a steady field, the next discrete force it encounters causes a displacement consistent with the previous one. Hence the particle in this situation shows a consistent direction of discrete displacements, hence a motion of increasing velocity, i.e. acceleration in response to the force field. Thus the effect of the force appears smooth and continuous at the macroscopic level of examination, even though it is fundamentally discrete. A field is interpreted to comprise discrete forces, the action of which causes a particle to move in a rapid series of finite displacements in space.

**Discrete forces are connected in flux tubes (§5)**

The discrete forces are emitted at each cycle of energisation and propagate out into the universe, being released from the emitting particle. The sequence of discrete forces emitted by any one particle is proposed to be connected in a *flux tube*, this being a curvilinear assembly of discrete forces. The discrete force in the flux tube is a persistent structure even when not energised. This concept was used to derive the Lorentz transformation from a Cordus particle basis [19]. The mixing of these flux tubes in the space between matter creates a fabric [17], the density of which is proposed to affect the speed at which the discrete forces propagate [18].

As a particle moves, so the next discrete force is emitted from a different position of the reactive end. Hence the direction of action of the following discrete force will be slightly different to that before it. Hence the flux tube is required, by this theory, to have bends in it corresponding to the energisation cycles of the reactive end. This is particularly relevant in what follows for the explanation of the magnetic interaction. Furthermore the flux tube is proposed to convey the handedness and structure of the discrete force emission, and this is relevant to gravitation.

**The discrete force interactions are fundamentally unidirectional (§6)**

It is proposed that the displacement effect of a received discrete force, and hence the force interaction, is fundamentally unidirectional: when test particle B receives a discrete force, it reacts to it via the displacement effect. The *emitting* particle A is unaffected, unless it also receives a discrete force from B. This means that the process whereby A emits a discrete force does not commit A to a future interaction dependent on whether or not that discrete force is intercepted by B.

This is an unorthodox premise since force is generally held to be reciprocal in action. Indeed in the type of *situation* in which the Earth is positioned, similar
particles affect each other equally, and hence force the bi-directional nature of force is recovered. Nonetheless in general the theory predicts unidirectional effects: discrete forces from A unidirectionally affect B, and those from B affect A, but there is no fixed reciprocity nor an exchange per se. In the Cordus theory situation refers to the reference frame of general relativity, with the addition of the fabric density [19]. The fabric density is variable with matter distribution and epoch of the universe [18].

**Discrete forces are not consumed in the interactions (§7)**

It is proposed that, in general, discrete forces are not consumed by interactions but continue to propagate outward to affect yet other particles. In specific cases the discrete force may be consumed, such as annihilation of matter-antimatter particles [11], and pair-production [12].

**The capability to make discrete displacement of a reactive end is affected by its energisation state (§8)**

The discrete displacement of a reactive end is affected by its energisation state. A reactive end that is fully energised in one of its emission directions (r,a,t) is momentarily stationary in that direction, or would prefer to be so. At times of incomplete energisation the reactive end is mobile and most susceptible to being displaced by an incoming discrete force.

**The reactive end samples the discrete forces around it (§9)**

A reactive end experiences all the discrete forces passing through that region of space which it occupies in its migrations. The reactive end is transparent in that the external discrete forces intrude into the reactive end temporarily as they propagate. Furthermore the reactive end moves in a cyclic locus as it emits, which increases the volume of space it samples. For an explanation, see Lemma 16.

A particle is not solely affected by the fields (or in this case the discrete forces) passing through its centre (or in this case its two reactive ends). Instead it is affected by discrete forces in the nearby locality of the reactive end. The incoming discrete forces occupy a volume of space during their transit. Consequently the reactive end has the ability to sense what is happening in the volume of space immediately around it, with an interaction between the external environment, discrete forces, and reactive end. This is non-local behaviour.
Sampling of the environment provides the mechanism for the reactive end to determine the field gradient (§10)

At intermediate stages of energisation the reactive end moves a small distance in reaction as it undertakes its own emissions. This result in a small-scale repetitive displacement motion of the reactive end at the de Broglie frequency. This motion is in all three directions of space, which allows the reactive end to sweep through -and sample- a small volume of space. This is proposed as the mechanism whereby it senses the gradient of the external field.

The mechanism whereby the reaction end moves under the influence of an external field arises because the RE spends longer time in those regions of space where the density (or strength) of external discrete forces is more favourable (higher or lower depending on relative attributes of particles A and B). It preferentially energises there. Since energisation also means the RE is stationary, it dwells there longer, hence the mean position of the RE is changed.

Section summary
The above provide a qualitative explanation for how force operates at the level of a fundamental particle.

Next it is necessary to consider how the particle detects and moves in the field gradient.

4.2 Mechanism for force & discrete movement in an imposed field

Above it was stated that force is caused by coercive displacement of reactive ends (§3), that the reactive end samples the discrete forces around it (§9), and that this provides the mechanism for the reactive end to determine the field gradient (§10). However these were conceptual propositions.

Now it is possible to substantiate this with a more specific mechanism and represent it in a quantitative formulation.

Discrete force emissions take the form \( \sin^2(\theta/2) \) (§11)

Previous diagrams have shown the reactive ends as either energised or not, but this is simplistic. The strength of energisation, hence also of the emitted discrete forces, evolves over time. The question is what the shape of this energisation function might be. We are required, for reasons of logical consistency with the Lorentz work [19], to see the reactive ends as producing a
continuous flux tube, without breaks, so abrupt step-like functions are excluded. It is logical to assume it takes a sinusoidal function, and ranges between 1 and 0 over a cycle (discrete forces of massy particles do not change sign, though photons do). We also need to consider the second reactive end $B_2$ and that the energy oscillates between the two – this is an established principle of the theory. This requires that the total energy is conserved at any one moment. A relationship that fits these criteria is $\sin^2(\theta/2)$ where $\theta$ is the phase angle of energisation, and this is marked as lemma.

Thus the potential energy $U$ of a discrete force in a particular direction (say $r$) at reactive ends $B_1$ and $B_2$ is:

\[
U_{B_1} = \sin^2 \frac{\theta_B}{2} \tag{1a}
\]

\[
U_{B_2} = \cos^2 \frac{\theta_B}{2} \tag{1b}
\]

Given also that there are three orthogonal discrete force emissions ($r$, $a$, $t$) and that the energisation sequence of these determines the matter-antimatter species [11], then the potential energy is partitioned into three components offset at thirds of the phase cycle:

\[
U_{B_1}(r) = \sin^2 \frac{\theta_B}{2} \tag{2a}
\]

\[
U_{B_1}(a) = \sin^2 \left( \frac{\theta_B}{2} - 120^\circ \right) \tag{2b}
\]

\[
U_{B_1}(t) = \sin^2 \left( \frac{\theta_B}{2} - 240^\circ \right) \tag{2c}
\]

See Figure 3 for a representation of these three phases. The discrete force emissions do not subtract energy from the particle.
Figure 3: Energisation phases in the three orthogonal emission directions \((r,a,t)\) follow a \(\sin^2(\theta/2)\) relation.

Thus the reactive end is never fully de-energised (except momentarily in one axis), and this is consistent with the expectations from the Lorentz derivation for a stretchable flux tube.

This also means that the energy at the basal generator, i.e. the reactive end \(B_1\) has a circular function, see Figure 4.
Figure 4: Resultant energy at the basal generator $B_1$ due to a matter negative charge. The axes are $(r,a,t)$. The larger black marker indicates the nominal origin $(0,0,0)$, and the smaller black marker indicates the location for $\theta = 0$. The chart is deliberately shown incomplete to indicate the direction of rotation.

Thus the phased emission of discrete forces corresponds to a torsional energisation that is carried out into space by the discrete forces. This provides a more substantive explanation for the original assertion that gravitation is conveyed by the torsion in the flux tube. The remote particle $B$ receives this torsional package of discrete forces, and assuming both $A$ and $B$ are matter particles, finds this conducive to its own emissions and moves closer along the field gradient.

The process of emitting discrete forces causes the reactive end to move cyclically in the $(r,a,t)$ directions (§12)

It is proposed that the sinusoidal potential energy function of the discrete forces corresponds to a movement of the reactive end itself. The nature of the motion is inferred as follows. The discrete forces themselves are a type of potential displacement. Hence the displacement that underpins them is the square root of their potential energy function, hence a $\sin(\theta/2)$ dependency.
However the motion must be cyclical, i.e. the reactive end must return to its original position, and this requires positive and negative components to its motion, hence a $\sin(\theta)$ function. Finally, the motion of the reactive end is inversely related to its energisation, being motionless when fully energised, hence a $\cos(\theta)$ relationship. This is shown for a single axis in Figure 5, and for all three axes in Figure 6. Thus the displacement of the reactive end may be inferred to be a circular locus around the nominal location of the reactive end.

![Graph of locus of reactive end displacement and discrete force potential energy](image)

**Figure 5:** The locus of motion of the reactive end follows a $\cos(\theta)$ dependency for each axis, whereas the potential energy follows $\sin^2(\theta/2)$. 
While the positional locus is circular in the absence of an imposed field, the reactive end expands its excursion when in a field. Assuming a field gradient applies and consider only the $r$ direction. The amount of displacement from the locus is presumed to be determined by two factors. The first is the strength of the field, which for simplicity is assumed to be linear (which is approximately true far from the field origin) with gradient $P_{grad}$ and strength $P_{centre}$ at the nominal centre point of the reactive end. Thus one side of the positional locus experiences the field as slightly stronger than the other. The second factor is the mobility of the reactive end, which is inversely related to its energisation, hence to $\cos^2 \theta / 2$. The result is a non-linear distortion of the positional locus of the form:

$$r_{\text{moved}}(\theta) = r(\theta) + (P_{grad} r(\theta) + P_{centre}) \cos^2 \frac{\theta}{2} \quad (3)$$
An example of a distorted positional locus is shown in Figure 7a. Even with a linear field the new locus is a non-linear distortion of the original circular track, i.e. the reactive end is sensitive to the spatial change in field strength. The progressive accumulation of displacement results in a distorted spiral locus with dwell regions of low progression, see Figure 7b.

Figure 7a: Distorted positional locus for a reactive end under the effect of a linear field in the r direction. The larger round symbols show the centre point of the locus, i.e. the nominal position of the reactive end. Values in the r direction are nominal.
Figure 7b. Cumulative locus of the reactive end. Values are nominal.

The significance is that the mean location of the reactive end changes under the effect of the field. This adjustment occurs in discrete intervals at each frequency cycle while the reactive end is exposed to the field. Thus the following lemma is noted.

The positional locus of a reactive end is distorted by the effect of field gradient (§13)

This proves the principle that a field can – under these assumptions – cause a displacement of the reactive end. It also substantiates the idea that the reactive end is able to sample the field gradient around it, and move accordingly. While the above example is based on an electrostatic interaction, there does not appear to be impediment to generalise the principles to any of the ranged fields.

5 Discussion

Findings
The results offer new perspectives on an old problems. The continuous vs. discrete duality of forces, as evidenced in the general relativity vs. quantum perspectives, can be explained. Both are correct: the emitted field is
continuous but the effect is discrete. This because emitted discrete forces have a sinusoidal strength function. At the receiving particle, the mobility of the reactive end is inversely related to its energisation, so the interaction has dwell periods.

It also answers another duality question that arises within the Cordus theory itself: how can a flux tube be continuous if the forces it contains are discrete [19]? The answer is that the reactive end binary states of energised vs. de-energised are an approximation of a sinusoidal strength relationship for energisation. Furthermore with emissions in three orthogonal directions, there is no point in time when the flux tube is completely de-energised, hence its continuity is preserved. This also conceptually allows for the tube to be stretched, which is important in the Lorentz derivation.

**Limitations and future research opportunities**
The nature of the present work is theory-building, and the focus has been on elucidating a mechanism for force generally. This has been formulated in a discrete force function. However what has not been shown is how that formulation might apply to the three ranged interactions: electrostatic, magnetic, and gravitational (EMG). Possible future research might examine whether the form of those equations might be explainable from first principles. This might also help find a way to unify the ranged interactions. Specifically, gravitation has historically been impossible to reconcile with the particle perspective of QM. Nonetheless the present theory, which is also particle-based albeit a very different construct to QM, strongly suggests the EMG interactions all have a common mechanism for how the particle detects and moves in the field gradient. This potentially provides a new way to look at the problem.

Note that the specific method used, abductive reasoning, provides a plausible rather than proven theory. So there may be other solutions, perhaps different formulations for the discrete force function, that could be acceptable, and others should not necessary fixate on the present formulation.

**6 Conclusions**
Per this theory, the operation of force at the more fundamental level is proposed to occur via the reactive end sweeping through a volume of space during its energisation cycle. This locus is warped by the discrete forces of the incoming field, hence preferentially displacing the reactive end along the gradient.
A more comprehensive description would be the following. Emission of discrete forces occurs at the energisation frequency of the particle (§1). If the emission of discrete forces of one particle favours the emissions of the other, then the particles move closer together. The direction of motion is along the gradient in a direction that favours increased compatibility or evades incompatibility between the discrete forces from the two particles (§2). This is primarily related to transphasic and cisphasic (out- and in-phase) energisation sequences. Force at the deeper level is a process of discrete displacements of reactive ends, under the coercive effect of incoming discrete forces (§3). The reactive end is able to sample the field gradient around it (§9-10), because it moves in a cyclic locus in reaction to its own emission of discrete forces (§12). The positional locus of a reactive end is distorted by the effect of field gradient (§13). The reactive end spends longer time in those regions of space where the density (or strength) of external discrete forces is more favourable, and this changes its mean position in space. This adjustment occurs in discrete intervals at each frequency cycle while the reactive end is exposed to the field.

The underlying mechanism for force is therefore conceptualised as coerced displacement of the reactive end.

The novel contribution of this work is providing a candidate mechanism for how a particle detects and moves in a field gradient.
